- ❒ CLASSIFICATION
- ❒ DIAGNOSING HEADACHES
- ❒ PRIMARY HEADACHES
  - Migraine (ICD-10: G43)
  - Tension-Type Headache (ICD-10: G44.2)
  - Trigeminal Autonomic Cephalalgias (ICD-10: G44.0)
  - Hemicrania Continua
- ❒ SECONDARY HEADACHES
  - Headache Attributed to Nontraumatic Subarachnoid Hemorrhage (ICD-10: G44.812)
  - Headache Attributed to Giant Cell Arteritis (ICD-10: G44.812)
  - Headache Attributed to Idiopathic Intracranial Hypertension (ICD-10: G44.820)
  - Headache Attributed to Intracranial Neoplasm (ICD-10: G44.822)
  - Sleep Apnea Headache (ICD-10: G44.882)

Headaches are the most prevalent neurologic disorder. It is estimated that approximately 50% of the general population have headaches during any given year and more than 90% report a lifetime history of headache. Tension-type headache (TTH) is the most common form of primary headache, with a lifetime prevalence of about 52% compared to the lifetime prevalence of migraine of 18%. Chronic headache, defined as 15 or more headache days a month, affects 1.7–4% of the world's adult population. Despite regional variations, headache disorders are a worldwide problem, affecting people of all ages, races, income levels, and geographic areas. Headaches are relatively rare in children but increase with age. Headache in general, and migraine specifically, increases in frequency during adolescence, particularly in women of childbearing age.

CLASSIFICATION

The International Classification of Headache disorders (ICHD-3; Table 12-1) classifies headaches based on specific inclusion and exclusion criteria, and is a flexible operational tool for both clinical and research application.[1] In this classification there are three domains, namely primary headaches; secondary headaches; and neuropathies, facial pains, and other headache disorders. Nearly 300 different types of headaches and facial pain are described in the ICHD-3. While some types of headaches are significantly more common than others, one must be mindful that the rate of misdiagnosis is probably equivalent to one's knowledge (or lack thereof). Diagnostic challenges are compounded by the fact that many patients experience more than one type of headache, and that some patients are, unfortunately, unable to provide an accurate headache history, which is one of the most important aspect of the diagnostic work-up.

DIAGNOSING HEADACHES

The diagnosis of headache is largely based on clinical symptoms and therefore an accurate history represents a crucial element of the diagnostic process. A comprehensive history

needs time, interest, focus, and establishment of rapport with the patient. When to ask what question to elicit specific information is an art that is acquired by practice and improves with experience. Rather than relying on the patient to report pertinent symptoms, the clinician must possess sufficient knowledge to know what questions to ask in succession and what symptoms to explore.

Many patients experience more than one type of headache. Patients may distinguish various types of headaches according to location, severity, triggering factors, or associated factors. For each type of headache, the following elements need to be determined as part of the complete headache history, starting with the headache of greatest importance to the patient: (1) headache location, (2) onset, (3) precipitating factors, (4) quality, (5) intensity, (6) frequency and duration, (7) triggering factors, (8) aggravating factors, (9) relieving factors, and (10) associated factors. Ascertaining the characteristic pain quality may help distinguish one type of headache from another. For instance, while most TTHs are described as tight "band-like" pain or pressure, migraines tend to be described as "throbbing" or "pounding." While the pain intensity of a migraine is often rated as severe, that of a TTH is often mild or moderate. Associated factors may include photophobia or phonophobia, which is relevant for the diagnosis of migraine, or the presence of autonomic symptoms, which is relevant for the diagnosis of trigeminal autonomic cephalalgias (TACs). It is often helpful for the patient to complete a headache diary (Figure 12-1; numerous versions are available for download as smartphone apps), as an aid to establishing a diagnosis, monitoring the headache symptoms, and/or evaluating the response to treatment.[2]

A critical consideration in evaluating headache is ruling out an underlying structural lesion or systemic disease, such as intracranial tumor, severe infection, aneurysm, uncontrolled hypertension, or stroke (i.e., secondary headaches). The systematic SNNOOP10 is an important and useful screen for secondary headaches (Table 12-2).[3] A neurologic examination with emphasis on the gross function of the cranial nerves is essential when the history is suggestive of a secondary headache. Diagnostic imaging, such as computed tomography (CT) or magnetic resonance imaging (MRI), is useful in screening for intracranial pathology. An MRI and magnetic resonance angiography (MRA) of the brain with contrast is the diagnostic modality of choice in nonemergent cases. In the presence of a normal neurologic examination, the prevalence of vascular and neoplastic findings is low, 6.6% and 1.4%, respectively.[4] In 2020, the American Headache Society recommended against the need for neuroimaging for migraines in the absence of atypical features (Table 12-2).[5]

Headaches are highly comorbid with oral and facial pain. The International Classification of Orofacial Pain emphasizes three types of interactions between headaches and orofacial pain.[6] First, headache patients can experience additional facial pain during headache attacks; second,

Table 12-2 SNNOOP10 red flags to identify secondary headache.

	Sign or Symptom
1	Systemic symptoms including fever
2	Neoplasm in history
3	Neurologic deficit or dysfunction (including decreased consciousness)
4	Onset of headache is sudden or abrupt
5	Older age (after 50 years)
6	Pattern change or recent onset of headache
7	Positional headache
8	Precipitated by sneezing, coughing, or exercise
9	Papilledema
10	Progressive headache in atypical presentations
11	Pregnancy or puerperium
12	Painful eye with autonomic features
13	Post-traumatic onset of headache
14	Pathology of the immune system such as HIV
15	Painkiller overuse or new drug at onset of headache

headaches may be replaced by facial pain of the same quality, intensity, and duration; and third, facial pain resembling primary headaches may present in headache-naïve patients. It is not unusual for headaches to present in the midface or dentoalveolar region, mimicking dental pain. Another important comorbidity is psychopathology, especially depression, anxiety, and somatization. Evidence from Genome-Wide Association Study (GWAS) data suggests significant shared genetic underlying mechanisms for migraine and depression.[7] The psychologic status of the patient may need to be assessed by a clinical psychologist, given the well-demonstrated relationship between chronic head pain, poor sleep, and elevated psychosocial distress. Assessment of disability or limitation of activities, during and after a headache episode, should also be considered, especially for migraineurs. The extent of disability can be gauged using instruments such as a Migraine Disability Assessment (MIDAS) questionnaire and the Headache Impact Test (HIT-6).[8]

PRIMARY HEADACHES

The ICHD-3 classifies headaches into primary and secondary headaches.[1] The primary headaches represent the vast majority of headaches and are defined as headaches without an underlying disease or structural cause. These headaches include migraine, TTH, TAC, and other primary headache disorders (Table 12-1).

Migraine (ICD-10: G43)

Migraine is more than "just a headache." It is a complex but relatively benign neurologic disorder with head pain as one of its clinical manifestations. It is also associated with a broad spectrum of other symptoms caused by the involvement of several brain structures. There are 23 International Classification of Diseases, Tenth Revision (ICD-10) codes for migraine diagnosis, reflecting the complexity of its subtypes.

Epidemiology

The global prevalence of migraine is approximately 14.4% and it is three times more frequent in females than males.[9] In children, abdominal migraine is a subtype of functional abdominal pain affecting about 13.5% of children worldwide. A high incidence of infant colic has been reported in migraineurs compared to controls.[10] In females, there is a sudden increase in prevalence during puberty and a decline following menopause. Considering the high prevalence during the most productive years of a patient's life, there is, consequently, a substantial cost to society due to decreased productivity and increased healthcare utilization. According to the 2016 Global Burden of Disease (GBD) study, migraine is the second most disabling condition in the world (second to low back pain).[11] The consequential impaired functioning and decreased quality of life make migraine a debilitating neurologic disease.[12] It is therefore no surprise that an increased risk of suicidal behavior has been reported in chronic migraineurs.[13] About a third of migraineurs also experience auras, and female migraineurs who experience auras are more susceptible to ischemic stroke.[14]

Pathophysiology

Migraine is a complex neurovascular headache.[15] Its etiopathophysiology is not completely understood. The phenomenon underlying the migraine pain and aura is cortical spreading depression (CSD), which is a self-propagating neuronal and glial depolarization that spreads across the cerebral cortex. This process results in neuronal dysfunction, substantiated by recent evidence of microstructural abnormalities of the trigeminal nerve in migraineurs.[16] The headache also involves recurrent activation of the trigeminocervical complex by neurotransmitters, such as neuropeptides, of which the calcitonin gene-related peptide (CGRP) is known to be a key player, and other inflammatory mediators, which cause neurogenic inflammation and neuronal sensitization.[17] Research on gut–brain interaction suggests

that the gut microbiota profile also plays a role in migraine pathogenesis.[18]

There appears to be a genetic and familial risk, as more than half of all migraineurs report having other family members who suffer from migraine. In addition, specific mutations leading to rare causes of vascular headache have been identified.[15] Hemiplegic migraine, for example, is caused by mutations in genes that encode ion channel and transport proteins. Genetic mutations cause impaired neurotransmission and cortical hyperexcitability, which result in increased susceptibility to CSD and impaired sensory processing. The gene and environment interaction has received much attention in the last decade. This epigenetic link in migraine suggests that DNA methylation of numerous genes is also involved in migraine pathogenesis.[19]

Migraine is a spectrum disorder. In some people, episodic migraine increases in frequency and evolves into chronic migraine, a process known as transformation. The pathophysiologic mechanisms responsible for chronification are not well understood, but likely involve genetic and epigenetic factors, neurogenic inflammation, and central sensitization. In recent years, TTH and migraine have been considered to be part of the same continuous spectrum rather than individual and distinct disease states.

Migraine, especially greater headache pain intensity and frequency, is significantly comorbid with insomnia, depression, anxiety, gastric ulcers, angina, and epilepsy.[20] The comorbidity of migraine and temporomandibular disorders (TMD) is also well established.[21] Individuals suffering from both TMD and migraine also had higher prevalence of bodily pain and systemic diseases.[22] A prospective cohort in the Orofacial Pain: Prospective Evaluation and Risk Assessment (OPPERA) study identified migraine as a risk factor for the development of TMD.[23] Therefore, prompt management of migraine may reduce the risk of developing TMD.

Clinical Features

The migraine headache is a moderate to severe, pulsating, unilateral head pain that is aggravated by routine physical activity (such as walking or climbing stairs). In addition, nausea and/or vomiting, or photophobia and phonophobia, are present. Osmophobia has been reported to increase the diagnostic sensitivity of migraine.[24] The headache begins with gradual onset, reaching a peak in 2–4 hours. The pain typically lasts 4–72 hours untreated or unsuccessfully treated. Migraine may present as isolated facial pain, rendering it an important differential diagnosis for dental pain and TMD.[25] Orofacial migraine is an episodic or chronic pain that presents exclusively in the orofacial region, without head pain, with the characteristics and associated features of migraine as described in the ICHD-3.[6] The three-item ID Migraine screener is a valid and reliable screening instrument for migraine, which is especially useful in primary care and epidemiologic settings.[26]

In migraine with aura, the headache is preceded or accompanied by one or more fully reversible aura symptoms. An aura is a unilateral, stereotyped, sensory, motor, visual, speech, brainstem, or retinal focal neurologic symptom. The aura symptoms usually develop gradually and last minutes. Visual aura is the most common. Sensory aura such as paresthesia follow a cortical somatotopic pattern and may involve the face, lips, and tongue. Rarely, focal motor weakness may occur. Prodromal symptoms such as fatigue, poor concentration, and neck stiffness may begin hours to a few days before a migraine. These symptoms should not be confused with aura symptoms. What was previously misconstrued as migraine triggers, such as eating chocolate and bright light, is now known to be prodromal symptoms warning of the impending migraine. These symptoms announce the arrival of the migraine and precede the head pain. Patients should be taught to recognize these prodromal symptoms so that abortive medications can be administered early in the migraine attack for maximum efficacy. Similarly, postdromal symptoms, such as fatigue or mood change, may last hours or a few days following the migraine.

Migraines occurring at least 15 days per month for more than 3 months fulfill the criteria for chronic migraine, although patients with 8 or more migraine days per month are similarly disabled.[27] Data from the Chronic Migraine Epidemiology and Outcomes (CaMEO) study suggests that the presence of noncephalic pain (pain in the face, neck, back, arms, legs, chest, abdomen, and other locations) may identify episodic migraineurs who are at risk of chronicity.[28] The American Academy of Neurology recommends neuroimaging only for migraine with atypical headache patterns or neurologic signs.[29]

Management

The management of migraine includes patient education, in addition to pharmacologic and nonpharmacologic strategies. The patient needs to be educated about the diagnosis, etiology, trigger avoidance (if applicable), and management strategies. Generally, pharmacotherapy is divided into prophylactic or preventative therapy, and acute or abortive therapy.

Patients experiencing four or more migraine headache days per month, patients whose migraines significantly interfere with daily routine despite acute treatment, and patients in whom acute treatment is contraindicated, has failed, or is overused (defined as use in 10 or more days per month) are candidates for prophylactic therapy.[30] First-line migraine preventatives (Table 12-3) include anticonvulsants (such as topiramate, which is the only US Food and Drug Administration (FDA)-approved oral chronic migraine

Table 12-3 Migraine preventative medications listed in order of most established efficacy.

Drug Class	Examples
Anticonvulsants	Topiramate, valproate sodium, divalproex sodium
Beta-adrenergic blockers	metoprolol, propranolol, timolol
Onabotulinum toxin	Onabotulinum toxin A
Calcitonin gene-related peptide monoclonal antibodies (CGRP MABs)	Erenumab, fremanezumab, galcanezumab
Triptans	Frovatriptan
Antidepressants	Amitriptyline, venlafaxine

Table 12-4 Migraine-abortive medications (listed in order of most established efficacy).

Drug Class	Examples
Nonsteroidal anti-inflammatory drugs (NSAIDs)	Aspirin, ibuprofen, diclofenac, naproxen
Ergot alkaloids	Dihydroergotamine, ergotamine
Triptans (5HT receptor agonists)	Almotriptan, eletriptan, frovatriptan, naratriptan, rizatriptan, sumatriptan, zolmitriptan, lasmiditan
Gepants (calcitonin gene-related peptide [CGRP] receptor antagonists)	Ubrogepant, rimegepant
Opioids	Butorphanol

preventative), β-adrenergic receptor blockers (metoprolol, propranolol, and timolol), frovatriptan, and onabotulinum toxin A. Second-line therapy includes amitriptyline, venlafaxine, atenolol, and nadolol. The oral prophylactics must be taken daily and usually have a 2–6-week period before an effect is observed. Onabotulinum toxin A is FDA approved for the management of chronic migraine and is injected every 3 months via the PREEMPT protocol using a total of 155 units into 31 injection sites.[31] Onabotulinum toxin A acts via blocking the release of pro-inflammatory and excitatory neurotransmitters and reducing the pronociceptive ion channels on the afferent neurons. Monoclonal antibodies (MABs) targeting the CGRP receptor (such as erenumab, fremanezumab, and galcanezumab) have been recently approved by the FDA for the prevention of migraine.[32] CGRP pathway blockers are the first mechanism-specific migraine treatment. The CGRP MABs are injected subcutaneously monthly and are devoid of drug interaction concerns. The most common adverse effects are injection site discomfort, constipation, and hypertension. They are indicated upon failure of at least two oral preventatives or inadequate response to at least two quarterly injections of onabotulinum toxin A.[30] A reasonable goal for preventative therapy is a 50% reduction in migraine headache days, a significant decrease in migraine duration or pain intensity, improved response to acute treatment, reduction in migraine-related disability, or improvement in quality of life.

Episodic migraine can often be managed with abortive therapy alone. While most individual attacks are successfully managed with oral agents, parenteral drugs may be necessary when nausea and/or vomiting accompany the attacks. Abortive agents for migraine (Table 12-4) include the nonsteroidal anti-inflammatory drugs (NSAIDs), ergotamine derivatives, the triptans (5-$HT_{1B/1D/1F}$ agonists), opioids, and the gepants (CGRP receptor antagonists). Ergotamine and its derivatives are nonselective 5-hydroxytryptamine (5-HT_1) receptor agonists, whereas the triptans are selective 5-HT_1 receptor agonists. Triptans are available in oral, nasal, and parenteral formulations, and in combination with NSAIDs. They are contraindicated in ischemic vascular conditions, uncontrolled hypertension, and other significant cardiovascular disease. A novel selective 5-HT_{1F} receptor agonist, lasmiditan, is devoid of vasoconstrictor properties.[33] Lasmiditan acts presynaptically to block the release of pro-nociceptive neurotransmitters, and therefore has a high positive response rate. It is also a more specific agonist, resulting in fewer side effects, most commonly dizziness. Novel CGRP receptor antagonists, the gepants (such as ubrogepant and rimegepant), have also been recently approved by the FDA for the acute treatment of migraine.[34] The gepants do not have a vasoconstrictor effect either. The blockage of the CGRP pathway in the form of both abortive agents and prophylaxis has blurred the line in the concept of acute versus preventative therapy. It is noteworthy that the presence of cutaneous allodynia increases the likelihood of poor response to treatment for all oral abortive agents, urging the need for prompt administration at migraine onset and the use of intranasal and injectable agents (due to faster onset compared with oral agents).[35] It is also noteworthy that frequent use of migraine-abortive medications may cause medication-overuse headaches (defined as the use of abortive medication for 10–15 days per month and that the abortive is causing the increase in headaches).

Nonpharmacologic management plays an important role in the management of migraine. This includes biobehavioral therapies such as relaxation training, biofeedback, cognitive behavioral therapy, mindfulness and meditation, and other forms of complementary and alternative therapies such as acupuncture treatment.[36] These modalities are important for patients in whom pharmacologic management is contraindicated and for those who prefer nonpharmacologic management. In addition, when combined with pharmacotherapy,

they may enhance the clinical therapeutic outcome or permit a reduction in the amount of medications used. Pericranial nerve blocks, including occipital nerve blocks and sphenopalatine ganglion blocks, have been investigated for both migraine abortion and prevention.[37] They are associated with few contraindications, good safety, and are generally well tolerated. Percutaneous implantation of neurostimulators and surgical decompression procedures have also received much attention despite the lack of well-designed clinical trials. Neuromodulation approaches such as single-pulse transcranial magnetic stimulation, noninvasive vagus nerve stimulation, and external trigeminal nerve stimulation have been approved by the FDA for migraine treatment.[38] Last but not least, adequate management of migraine comorbidities is integral to the success of migraine management. Comorbid depression, anxiety, insomnia, and widespread pain (including TMD) should be identified and their management prioritized.

Tension-Type Headache (ICD-10: G44.2)

Epidemiology

TTH affects 26.1% of individuals worldwide.[11] The GBD study estimated that 1.89 billion people worldwide had TTH while a lower number, 1.04 billion, had migraine. Although TTH has a similar, if not higher, socioeconomic impact compared to migraine, much less recent research has been conducted on TTH compared to migraine research. This is possibly because TTH is less disabling. Over 80% of adults experience TTH periodically. Some contrasts between TTH and migraine include that (1) TTH is rarely disabling in its severity (unlike migraine); (2) the female:male ratio for TTH is 5:4, indicating that women are only slightly more likely to be affected than men (in contrast with the preponderance of female migraineurs); and (3) the average age of onset of TTH is higher than that for migraine, namely 25–30 years.

Pathophysiology

Although TTH is common, the pathophysiology remains unclear. Contrary to what its name suggests, electromyography has not revealed an increase in resting muscle tension in TTH. Pericranial muscle tenderness is not a universal finding in TTH, leading to the hypothesis that central mechanisms are likely responsible for the peripheral pain. The overlap between TTH and myofascial pain has also been well described. There were significantly more active trigger points in the head, neck, shoulder, and upper back muscles of patients with chronic TTH (CTTH) compared with controls.[39] In a randomized controlled trial, dry needling significantly reduced the intensity, frequency, and duration of CTTH compared to sham dry needling.[40] Therefore, a peripheral mechanism in the pathogenesis of TTH cannot be excluded either. The generalized lowered pressure pain threshold in myofascial pain may contribute to the central sensitization in TTH. In addition, the overlap between TTH and Headache Attributed to TMD (TMDH) is also noteworthy (see Chapter 10). TMDH is a secondary headache caused by a disorder of the structures in the temporomandibular region. While the need to screen and rule out secondary headaches cannot be overemphasized, the experience of more than one headache type is not uncommon and can complicate the diagnosis.

Genetic twin association studies in monozygotic twins suggest that shared genetic factors likely account for the comorbidity of migraine and TTH. In a longitudinal population-based study, 23.3% of migraineurs evolved into definite TTH 5 years later, while 14.7% of those with TTH evolved into definite migraine.[41] Only 32.3% remained as TTH. The transition from migraine to TTH and vice versa over time is therefore not unusual. TTH and migraine are thus believed to be on the same continuous spectrum rather than distinct entities.

Similar to migraine, TTH is highly associated with sleep disturbances (especially CTTH) and psychiatric comorbidity such as stress, anxiety, and depression.[42,43] A higher prevalence of excessive daytime sleepiness has been reported in CTTH compared with episodic TTH (ETTH) and no headache.[44] The frequency of suicidality was significantly higher in TTH, especially in CTTH, compared with controls.[45]

Clinical Features

The ICHD-3 classifies TTH into four categories, namely infrequent ETTH, frequent ETTH, CTTH, and probable TTH. At least two of the following headache characteristics must be present: bilateral location; pressing or tightening (nonpulsatile) quality; mild to moderate intensity; and not aggravated by routine physical activity. Nausea or vomiting is absent, either photophobia or phonophobia may be present, and the headaches may or may not be associated with pericranial tenderness upon palpation of the frontalis, temporalis, masseter, pterygoid, sternocleidomastoid, splenius, or trapezius muscles. The headache duration is between 30 minutes and 7 days. While infrequent ETTH occurs fewer than 12 days per year (i.e., <1 day per month), frequent ETTH occurs between 12 and 180 days per year (between 1 and 14 days per month for more than 3 months), and CTTH occurs more than 180 days per year (at least 15 days per month for more than 3 months).

Management

Guidelines on the management of TTH have not changed since the European Federation of Neurological Societies Task Force's recommendations in 2010.[46] Similar to migraine, pharmacotherapy for TTH includes the use of abortive and/or

prophylactic medications. Abortive medications include analgesics (such as acetaminophen), NSAIDs (such as ibuprofen, ketoprofen, naproxen, and diclofenac), and their combinations. Prophylactic medications should be considered in frequent ETTH and CTTH, and they include amitriptyline and other antidepressants such as mirtazapine and venlafaxine. Pharmacotherapeutics for migraine, such as triptans and onabotulinum toxin, have not been shown to be effective for TTH. Nonpharmacologic management includes biobehavioral therapies, such as electromyography biofeedback and cognitive behavioral therapy, and other forms of complementary and alternative therapies (such as acupuncture). Comorbidities, such as sleep disorders and psychopathology, should also be identified and managed, along with associated myofascial pain and TMDH.

Trigeminal Autonomic Cephalalgias (ICD-10: G44.0)

TACs are primary headache disorders characterized by unilateral attacks of intense pain associated with ipsilateral autonomic features such as lacrimation, conjunctival injections, nasal congestion, rhinorrhea, and ptosis. This group includes five headaches: cluster headache (CH), paroxysmal hemicrania (PH), short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing (SUNCT), short-lasting unilateral neuralgiform headache attacks with cranial autonomic symptoms (SUNA), and hemicrania continua (HC).[1]

A fundamental characteristic of all the TACs is that the pain is strictly unilateral. The pain is usually localized in the orbital, supraorbital, or temporal areas (V1), but it can sometimes present in the distribution of the maxillary (V2) and mandibular (V3) branches of the trigeminal nerve and described as "facial pain or toothache."[47] Other characteristic clinical features of the TACs include agitation/restlessness (mainly in CH) and the circadian periodicity of the attacks (also CH). To differentiate the type of TACs, it is very important to consider the differences in duration and frequency of the attacks, and the response to indomethacin.[48]

The pathophysiology of TACs is not well understood yet, but at least three domains are involved: the trigeminovascular system, the autonomic system, and the hypothalamus. The trigeminal autonomic reflex, a connection between the trigeminovascular system and the autonomic system, is responsible for the prominent cranial autonomic symptoms.[49] Several brain imaging studies have shown an activation of the posterior hypothalamus (ipsilateral in some TACs and contralateral in others) in all the TACs.[50] The connection between the hypothalamus and the trigeminovascular system is probably mediated by several neurotransmitters such as orexin.

Although TACs are primary headaches, some intracranial pathologies such as pituitary adenomas, aneurysms, arteriovenous malformations, and hemangiomas may mimic TACs in their clinical presentation. The work-up for all the TACs should include a brain MRI with dedicated views of the cavernous sinus and pituitary gland. An MRA of head and neck and pituitary laboratory exam may also be indicated.[51]

Cluster Headache

CH is a primary neurovascular headache disorder with episodic and chronic subtypes. As the name suggests, CH involves a cluster of headaches, usually occurring over a period of several weeks. The episodic form is characterized by at least two cluster phases lasting seven days to one year, separated by a cluster-free interval of at least three months. The chronic form is characterized by the absence of sustained periods of remission, and can transform from the episodic type, in which the clusters occur more than once a year without remission or the cluster-free interval is shorter than three months.

Epidemiology

CH is a rare disorder compared to migraine, with a prevalence in the general population of 0.1%, but it is the most diagnosed TAC. It is more prevalent in males, with a male:female ratio of 3:1. Age at onset is between 20 and 40 years. When occurring with trigeminal neuralgia, it is known as the cluster-tic syndrome.

Clinical Features

CH is among the most painful of all headache disorders, with the pain usually described as severe and boring or piercing. Patients typically pace the room and are unable to lie down. The attacks can last between 15 and 180 minutes, occurring once every other day to eight times per day. The headache is unilateral and localized in the orbital, supraorbital, and/or temporal areas. At least one ipsilateral autonomic symptom (such as conjunctival injection and/or lacrimation, nasal congestion and/or rhinorrhea, eyelid edema, forehead and facial sweating, or miosis and/or ptosis) is present with or without restlessness or agitation. Occasionally an ipsilateral Horner's syndrome is present. These autonomic signs are a stark contrast to migraine. A peculiar characteristic of CH is the circannual and circadian presentation. The attacks tend to come at a specific season of the year and occur at one or more predictable times of the day. These cluster periods or bouts are separated by remission periods lasting months or years.

Management

Management of CH includes use of medication to abort the acute attacks as well as preventative treatment.[52] Abortive

medications include the triptans (especially parenteral, considering the short duration of the attacks, such as subcutaneous sumatriptan, and intranasal zolmitriptan and sumatriptan). One limitation of the triptans is the inability to be used multiple times a day. During an active cluster period, headaches occur repeatedly during the day, necessitating additional acute or preventative medications.[53] Oxygen inhalation at a rate of 10 L/min is also effective at aborting a cluster attack. It can be used multiple times a day with minimal side effects.[54] Recently, galcanezumab (a CGRP MAB) was FDA approved for the treatment of episodic cluster.[55–57] The use of intranasal lidocaine, noninvasive vagus nerve stimulation, neuromodulation, and, for refractory patients, a sphenopalatine ganglion stimulator has also been reported.[38,53,58,59]

Preventative medications are gradually titrated during the cluster cycle. After two weeks (in episodic clusters) and one to two months (in chronic clusters) of headache freedom, preventative medications should be discontinued to determine whether remission has occurred. These include verapamil, lithium, oral corticosteroids, melatonin, and galcanezumab.[48] Greater occipital block with anesthetic and steroids is an adjunctive measure.[60] Hypothalamic deep brain stimulation has shown benefit for refractory clusters.[61]

Paroxysmal Hemicrania

Epidemiology

PH is a rare disorder with an estimated prevalence of 0.5 per 100 or less and with a female:male ratio of approximately 2:1. The age of onset is usually the fourth and fifth decades, although a few childhood-onset cases have been described. The ICHD-3 classifies PH into episodic and chronic forms.[1] The episodic form occurs in periods of up to one year, with pain-free or remission periods of at least three months. The chronic form (CPH) occurs for more than one year or with remission periods lasting less than three months. The latter is more prevalent. Like cluster-tic, CPH-tic has also been described.

Clinical Features

PH usually presents as severe unilateral pain in orbital, supraorbital, and temporal areas. The pain is often described as throbbing, aching, or boring, with an abrupt onset and cessation. Similar to other TACs, pain is associated with ipsilateral cranial autonomic symptoms. Photophobia or phonophobia may also be present, but it is lateralized, in contrast to migraine. Compared to CH, the pain attacks of PH have a higher frequency, occurring at least several times a day, and shorter duration, lasting 2–30 minutes. The circadian rhythmicity observed in CH is absent in PH. The most important diagnostic criterion is the dramatic and absolute response to indomethacin.[62]

Management

Due to the short duration of attacks, PH is managed with prophylactic medications. Indomethacin is titrated in divided doses (usually three times a day), with an initial dose of 75 mg/day and increased up to 225mg/day if needed. If a patient is intolerant to the gastrointestinal side effects of indomethacin, a trial of celecoxib or topiramate is indicated. Greater occipital nerve blocks have reportedly been beneficial.

Short-Lasting Unilateral Neuralgiform Headache Attacks

Short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing (SUNCT) and short-lasting unilateral neuralgiform headache attacks with cranial autonomic symptoms (SUNA) are the two forms of short-lasting neuralgiform headaches. Their phenotypes are very similar and the main difference is, as stated in their names, that SUNCT exhibits both conjunctival injection and lacrimation, while SUNA has either one or neither.

Epidemiology

SUNCT and SUNA are rare primary headache disorders, with a reported prevalence between 1 and 100 in 100,000. SUNCT is more prevalent and may be a subtype of SUNA. The age of onset is usually in the fourth to seventh decades, and they are more common in males.[63]

Clinical Features

The pain is unilateral, moderate, or severe in intensity, often described as burning, stabbing, or electric. The distribution is often in the ophthalmic division of the trigeminal nerve. The attacks can occur as a single stab, a group of stabs, or a saw-tooth pattern. These attacks can be repetitive and frequent, and can last minutes or hours despite short-lasting individual attacks.[64]

A unique feature of SUNCT/SUNA, absent in the other TACs, is that pain can be triggered by innocuous cutaneous stimuli such as touching the face, wind, chewing, or brushing the teeth.[65] This feature, combined with the duration and frequency, can sometimes lead to a misdiagnosis of trigeminal neuralgia or occasionally odontogenic pain. Some important distinguishing features include that trigeminal neuralgia lacks cranial autonomic features, affects the maxillary and mandibular of the trigeminal nerve more often than the ophthalmic division, and has a refractory period.[66,67]

Management

The most effective treatment for SUNCT/SUNA is intravenous lidocaine performed by experienced providers.[66] The use of lamotrigine, topiramate, gabapentin, pregabalin, oxcarbazepine, and duloxetine has been described. Greater occipital nerve blocks and occipital nerve stimulation have also been proposed.

Hemicrania Continua

HC is a persistent, constant, strictly unilateral headache associated with ipsilateral autonomic signs and symptoms and/or with restlessness or agitation. Like PH, it responds dramatically to indomethacin.[68] The unremitting subtype, exhibiting continuous pain for at least one year without remission, is more prevalent.

Epidemiology

HC constitutes about 1% of patients with daily or unilateral headaches. The onset is between the third and fifth decades, and it is more common in females.

Clinical Features

The pain, often described as sharp, throbbing, or stabbing, is located unilaterally in the frontal, temporal, and periorbital areas. It is continuous, with episodes of exacerbation. The episodes of exacerbation are associated with autonomic features (usually lacrimation) and migrainous features such as photophobia, phonophobia, nausea, and/or vomiting. The exacerbation period can be triggered by stress, alcohol, poor sleep, and bright lights. Due to the presence of migrainous features in HC, it may be misdiagnosed as chronic migraine. Important distinctions between chronic migraine and HC include that HC is usually side-locked, rarely remits completely, and always responds to a therapeutic dosage of indomethacin.[69,70]

Management

In HC, indomethacin is used at the same dosage as that used for PH. The use of celecoxib, topiramate, gabapentin, and melatonin has also been described. Melatonin, a pineal hormone with a similar chemical structure to indomethacin, can also be used in combination with indomethacin to reduce the dosage of the latter, thereby reducing dyspepsia.[71]

SECONDARY HEADACHES

As described in the ICHD-3, secondary headaches include all headaches caused by an underlying disorder (Table 12-1), even if the headache characteristics resemble primary headaches.[1] The systematic SNNOOP10 is an important and useful screen for secondary headaches (Table 12-2).[3] Management of the underlying disease or condition is key to headache resolution. A selection of secondary headaches is described here.

Headache Attributed to Nontraumatic Subarachnoid Hemorrhage (ICD-10: G44.810)

Also known as the thunderclap headache, the headache attributed to nontraumatic subarachnoid hemorrhage (SAH) is associated with a high mortality of 40–50%. It is classified under the category of headache attributed to cranial or cervical vascular disorder in the ICHD-3.[1] A ruptured aneurysm is the most common cause of SAH, which accounts for about 1% of patients who present with a headache in the emergency department. The headache may be the only symptom of SAH, creating a diagnostic challenge. Up to 25% of SAHs are misdiagnosed.[72] About 20% of aneurysms leak before they rupture, with some patients reporting a severe headache several days or 1–2 weeks prior. This is known as the sentinel, or warning, headache.

The SAH headache is abrupt in onset, peaking within seconds or minutes, often reaching 7 (out of 10) in intensity within 1 minute of onset (therefore known as "thunderclap"). The Ottawa SAH rule recommends investigation for SAH in the presence of one or more of these symptoms: neck pain or stiffness; age 40 years or greater; witnessed loss of consciousness; headache onset during exertion; thunderclap headache; or limited neck flexion on examination.[73] The sudden or thunderclap onset of the "worst headache of my life" is a medical emergency, and aneurysmal SAH must be excluded with a non-contrast-enhanced CT scan (approximately 90% sensitive for SAH), and a lumbar puncture if the CT scan is negative.[74] The fluid-attenuated inversion recovery (FLAIR) MRI has also demonstrated good sensitivity for SAH.[75] Most vascular disorders underlying SAH (such as a ruptured aneurysm) require immediate neurosurgical intervention such as endovascular coiling or surgical clipping. Many patients continue to experience headaches even years after the hemorrhage.[76]

Headache Attributed to Giant Cell Arteritis (ICD-10: G44.812)

Giant cell (previously known as temporal) arteritis (GCA) is an idiopathic large vessel vasculitis preferentially affecting the external carotid artery and the aorta. In the ICHD-3, it is classified under the category of headache attributed to cranial or cervical vascular disorder.[1] GCA is an important differential for sudden-onset and persistent headache in

patients above 60 years of age. The incidence of GCA is 77 per 100,000 individuals and women account for 65% of cases. GCA is associated with a higher risk of ischemic stroke and dementia, and can be comorbid with polymyalgia rheumatica.

The manifestations of GCA include sudden-onset headache and sudden permanent loss of vision. Serologic markers include an elevated erythrocyte sedimentation rate (60–100 mm/h), C-reactive protein, and platelet count.[77] A temporal artery ultrasound (particularly a color-coded duplex sonography) and/or biopsy confirms the diagnosis of GCA.[78] Since vision loss in the second eye may follow within one week of vision loss in one eye (due to anterior ischemic optic neuropathy), prompt administration of intravenous glucocorticoids (or 60–100 mg of oral prednisolone for up to 3 days, followed by a 12–18-month taper) is essential.[79] Tocilizumab, an MAB blocker of IL-6, is approved for the treatment of GCA and has shown sustained disease remission.[80]

Headache Attributed to Idiopathic Intracranial Hypertension (ICD-10: G44.820)

Idiopathic intracranial hypertension (IIH) is classified under the category of headache attributed to nonvascular intracranial disorder in the ICHD-3 and was formerly known as pseudotumor cerebri.[1] IIH is a rare disorder characterized by raised intracranial pressure (greater than 250 mm cerebrospinal fluid [CSF]) of unknown cause.[81] Current theories suggest that there may be increased secretion or decreased absorption of CSF, and/or venous sinus stenosis causing obstruction of the cerebral venous outflow.[82] Associated spontaneous CSF leak has been reported.[83] IIH is more prevalent in young, obese women, although in prepubertal patients there is no association with gender or obesity. The diagnosis of IIH is based on neuroimaging and lumbar puncture.[84]

The headache attributed to IIH presents as a profoundly disabling new headache or a preexisting headache that is significantly worsening in frequency and/or intensity. The accompanying visual impairment, such as blurred vision, due to papilledema (i.e., swelling of the optic disc because of the elevated intracranial pressure) may potentially result in permanent visual loss. Severe increases in intracranial pressure may also result in unilateral or bilateral sixth nerve palsies. Psychiatric comorbidity is highly prevalent and associated with poorer outcome, along with increased risk of death from suicide and overdose.[85–87] While therapeutic lumbar puncture can provide partial and temporary relief, post–lumbar puncture headaches can be an unfortunate sequela.[88] The management also includes weight loss, and the use of acetazolamide and diuretics. Surgical interventions include optic nerve sheath fenestration, CSF diversion with ventriculoperitoneal or lumboperitoneal shunts, and venous sinus stenting.[89] Relapse or recurrence following treatment is not unusual.

Headache Attributed to Intracranial Neoplasm (ICD-10: G44.822)

Headache attributed to intracranial neoplasm is one of numerous nonvascular intracranial disorders. Based on the ICHD-3 diagnostic criteria, the demonstration of a space-occupying intracranial neoplasm and the evidence of causation must be demonstrated.[1] Although approximately 30% of patients with brain tumors report headaches, headache is the isolated presenting symptom in less than 0.2%.[90] Other accompanying symptoms, such as neurologic deficits and seizures, are usually reported.

The clinical features of headache attributed to intracranial neoplasm are varied and there is no pathognomonic symptom. The presentation may sometimes be very similar to a migraine, but the key feature suggestive of intracranial neoplasm relates to the headache progression or deterioration. Tumors should therefore be suspected in progressively severe new "migraine" headaches that are solely unilateral. Vomiting preceding headaches by weeks is highly characteristic of tumors of the posterior cranial fossa.[91]

Sleep Apnea Headache (ICD-10: G44.882)

Obstructive sleep apnea (OSA) is a sleep-related breathing disorder characterized by recurrent episodes of partial or complete obstruction of the upper airway during sleep. An Apnea-Hypopnea Index (AHI) of five or more episodes per hour of sleep (where the AHI is the division of the number of apneic events by the total sleep time) indicates the presence of sleep apnea. The consequences of OSA include sleep fragmentation (due to microarousals that occur in an attempt to reestablish upper airway patency), hypoxia, and hypercapnia. Although OSA affects more men than women, the sleep apnea headache affects more women than men. Moreover, in women, self-reported morning headaches are predictive of moderate to severe OSA.[92]

The sleep apnea headache is classified under headache attributed to disorder of homeostasis in the ICHD-3.[1] It is a (usually) bilateral headache present upon awakening that lasts less than four hours. It is described as a "pressing" headache, not accompanied by nausea, photophobia, or phonophobia. The ICHD-3 diagnostic criteria require a causal relation with a diagnosis of OSA to be established, confirmation with an overnight polysomnography, and resolution of the headache with the management of the OSA. The pathophysiology of the sleep apnea headache is

unknown. An important differential for frequent morning headaches is sleep bruxism.[93] This is complicated by the fact that one-third of OSA patients have concomitant sleep bruxism.[94] It is nevertheless noteworthy that maxillary oral appliances for bruxism (i.e., "night guards") may increase the severity of OSA in some patients.[95]

Diseases of the Respiratory Tract

Michael Glick, DMD

Given the fact that the oral cavity is contiguous with the trachea and lower airway, it is biologically plausible that conditions within the oral cavity might influence lung function. Respiratory infections are commonly encountered among dental patients. Commonalities between chemotherapeutic options and the anatomic proximity with the oral cavity lead to much interplay between oral and respiratory infections. Recent studies have reported on oral bacteria as causative pathogens in respiratory diseases and conditions associated with significant morbidity and mortality. Furthermore, some respiratory illnesses, such as asthma, may have an effect on orofacial morphology or even on the dentition. This chapter discusses the more common respiratory illnesses and explores the relationship between these conditions and oral health.

UPPER AIRWAY DISEASES

There are several major oral health concerns for patients with upper respiratory infections. These concerns are about infectious matters; for example, the possible transmission of pathogens from patients to health care workers and reinfection with causative pathogens through fomites such as toothbrushes and removable oral acrylic appliances. Furthermore, antibiotic resistance may develop because of the use of similar types of medications for upper respiratory infections and odontogenic infections. Lastly, oral mucosal changes, such as dryness due to decongestants and mouth breathing, and increased susceptibility to oral candidiasis in patients using long-term glucocorticoid inhalers, may be noticed.

Burket's Oral Medicine, Thirteenth Edition. Edited by Michael Glick, Martin S. Greenberg, Peter B. Lockhart, and Stephen J. Challacombe.

Viral Upper Respiratory Infections

The most common cause of acute respiratory illness is viral infection, which occurs more commonly in children than in adults. Rhinoviruses account for the majority of upper respiratory infections in adults.[1] These are ribonucleic acid (RNA) viruses, which preferentially infect the respiratory tree. At least 100 antigenically distinct subtypes have been isolated. Rhinoviruses are most commonly transmitted by close person-to-person contact and by respiratory droplets. Shedding can occur from nasopharyngeal secretions for up to 3 weeks, but 7 days or less is more typical. In addition to rhinoviruses, several other viruses, including coronavirus, influenza virus, parainfluenza virus, adenovirus, enterovirus, coxsackievirus, and respiratory syncytial virus (RSV), have also been implicated as causative agents. Infection by these viruses occurs more commonly during the winter months in temperate climates.

Pathophysiology

Viral particles can lodge in either the upper or lower respiratory tract. The particles invade the respiratory epithelium, and viral replication ensues shortly thereafter. The typical incubation period for rhinovirus is 2 days, with a symptom duration of 7 to 14 days.[2] During this time, active and specific immune responses are triggered, and mechanisms for viral clearance are enhanced. The period of communicability tends to correlate with the duration of clinical symptoms.

Clinical and Laboratory Findings

Signs and symptoms of upper respiratory tract infections are somewhat variable and are dependent on the sites of inoculation.[3] Common symptoms include rhinorrhea, nasal congestion, and oropharyngeal irritation. Nasal secretions can be serous or purulent. Other symptoms that may be present include cough, fever, malaise, fatigue, headache, and myalgia.[2] A complete blood count (CBC) with differential may demonstrate an increase in mononuclear cells, lymphocytes, and monocytes ("right shift"). Laboratory tests are typically not required in the diagnosis of upper respiratory infections. Viruses can be isolated by culture or determined by rapid diagnostic assays. However, these tests are rarely clinically warranted.

Diagnosis

A diagnosis is made on the basis of medical history as well as confirmatory physical findings. Diagnoses that should be excluded include acute bacterial rhinosinusitis, allergic rhinitis, and group A streptococcal pharyngitis.

Management

The treatment of upper respiratory infections is symptomatic as most are self-limited. Analgesics can be used for sore throat and myalgias. Antipyretics can be used in febrile patients, and anticholinergic agents may be helpful in reducing rhinorrhea. Oral or topical decongestants, such as phenylephrine and pseudoephedrine, may be effective in terms of decreasing subjective nasal congestion.[4] Adequate hydration is also important in homeostasis, especially during febrile illnesses.

Antimicrobial agents have no role in the treatment of acute viral upper respiratory infections. Presumptive treatment with antibiotics to prevent bacterial superinfection is not recommended.[2] Any excessive use of antibiotics can result in the development of drug-resistant bacteria.[3]

Antiviral compounds have not been found to provide significant benefit for viral upper respiratory infections.[5]

Prognosis

As most patients recover in 5 to 10 days, the prognosis is excellent. However, upper respiratory infections can put patients at risk for exacerbations of asthma, acute bacterial sinusitis, and otitis media; this is especially so in predisposed patients, such as children and patients with an incompetent immune system.

Oral Health Considerations

The most common oral manifestation of upper respiratory viral infections is the presence of small round erythematous macular lesions on the soft palate. These lesions may be caused directly by the viral infection, or they may represent a response of lymphoid tissue. Individuals with excessive lingual tonsillar tissue also experience enlargement of these foci of lymphoid tissue, particularly at the lateral borders at the base of the tongue.

Treatment of upper respiratory infections with decongestants may cause decreased salivary flow, and patients may experience oral dryness (see Chapter 9 "Salivary Gland Diseases" for a discussion of the treatment of oral dryness).

Although there has been discussion in regards to a relationship between dentofacial morphology, malocclusion, and nasal obstruction, there is currently no clear causal relationship.[6]

Allergic Rhinitis and Conjunctivitis and Nonallergic Rhinitis

Allergic rhinitis is a chronic recurrent inflammatory disorder of the nasal mucosa. Similarly, allergic conjunctivitis is an inflammatory disorder involving the conjunctiva. When both conditions occur, the term *allergic rhinoconjunctivitis* is used. The basis of the inflammation is an allergic hypersensitivity (type I) to environmental triggers. Allergic rhinoconjunctivitis can be seasonal or perennial. Typical seasonal triggers include grass, tree, and weed pollens. Common perennial triggers include dust mites, cockroach, animal dander, and mold spores.

Allergic rhinitis is one of the most prevalent chronic medical conditions in the United States (US). It affects up to 58 million people in the US.[7] Allergic rhinitis is associated with a significant economic burden with a total of more than $11.2 billion (US) in direct costs due to this condition in 2005.[8] It is estimated that allergic rhinitis accounts for 3.5 million lost work days and 2 million missed school days each year.[9]

When nasal congestion, postnasal drainage and rhinorrhea are present perennially and, in the absence of significant sneezing or itching, this may be indicative of an entity called nonallergic rhinitis (NAR). NAR typically presents at a later age. The most common triggers for NAR include smoke, strong odors or fragrances, and changes in temperature or barometric pressure. When NAR occurs in conjunction with allergic rhinitis, this is termed mixed rhinitis and is the most common form of rhinitis in adults.[10]

Pathophysiology

Patients with allergic rhinoconjunctivitis have a genetically predetermined susceptibility to allergic hypersensitivity reactions, known as atopy. Prior to the allergic response, an initial phase of sensitization is required. This sensitization phase is dependent on exposure to a specific allergen and on recognition of the allergen by the immune system. The end result of the sensitization phase is the production of specific immunoglobulin E (IgE) antibody and the binding of this specific IgE to the surface of tissue mast cells and blood basophils. Upon re-exposure to the allergen, an interaction between surface IgE and the allergen takes place, which results in IgE crosslinking. The crosslinking of surface IgE triggers degranulation of the mast cell and basophils causing the release of preformed mediators. This is the early-phase allergic reaction. Histamine is the primary preformed mediator released by mast cells, and it contributes to the clinical symptoms of sneezing, pruritus, and rhinorrhea. Mast cells also release cytokines that permit amplification and feedback of the allergic response. These cytokines cause an influx of other inflammatory cells, including eosinophils, resulting in the late-phase allergic reaction. Eosinophils produce many proinflammatory mediators that contribute to chronic allergic inflammation and to the symptom of nasal congestion.

NAR includes two main subtypes. Vasomotor rhinitis is sometimes erroneously used synonymously with NAR. It is thought that neural or glandular pathways are involved in causing symptoms of congestion and rhinorrhea in response to nonspecific environmental irritants such as temperature changes (e.g., cold or dry air) or pollutants. Another subtype of NAR termed gustatory rhinitis involves significant rhinorrhea within a few hours after eating (hot and spicy food are the most common triggers) and is thought to be due to stimulation of the vagus nerve.[11]

Clinical and Laboratory Findings

The symptoms of allergic rhinoconjunctivitis can vary from patient to patient and depend on the specific allergens to which the patient is sensitized. Conjunctival symptoms may include pruritus, lacrimation, crusting, and burning. Nasal symptoms may include sneezing, pruritus, clear rhinorrhea, and nasal congestion. Other symptoms can occur, such as postnasal drainage with throat irritation, pruritus of the palate and ear canals, and fatigue.

The clinical signs of allergic rhinoconjunctivitis include injection of the conjunctiva with or without cobblestoning; prominent infraorbital creases/folds (Dennie–Morgan lines), swelling, and darkening ("allergic shiners"); a transverse nasal crease; and frequent upward rubbing of the tip of the nose (the allergic "salute"). Direct examination of the nasal mucosa reveals significant edema and a pale blue coloration of the turbinates. A copious clear rhinorrhea is often present. Nasal polyps may also be visible. Postnasal drainage or oropharyngeal cobblestoning might be identified upon examination of the oropharynx. A high-arched palate, protrusion of the tongue, and overbite may be seen.

Laboratory investigations are usually kept to a minimum. Patients with allergic rhinitis might have elevated levels of serum IgE and an elevated total eosinophil count. These findings are not, however, sensitive or specific indicators of atopy. Microscopic examination of nasal secretions often demonstrates significant numbers of eosinophils. Blood tests, such as the traditional radioallergosorbent test (RAST), is a method of testing for specific allergic sensitivities that is based on circulating levels of specific IgE. Specific IgE levels are determined by using serum samples and are quantified by using radioactive markers. Although bloodwork is somewhat less reliable than skin testing (see below), it is a useful test in certain situations, such as pregnancy or severe chronic skin disorders, including atopic dermatitis.

Classification

There is no universal classification system for allergic rhinoconjunctivitis. Many authors make the distinction between perennial and seasonal illness, with the former being caused mainly by indoor allergens (e.g., house dust mites, cockroaches, pets) and the latter being triggered primarily by outdoor allergens (e.g., trees, grasses, weeds). Perennial allergic rhinitis sufferers might benefit more from specific environmental control measures than would seasonal allergic rhinitis sufferers.

Diagnosis

The diagnosis of allergic rhinoconjunctivitis is usually apparent, based on history and physical examination. Patients present with a history suggestive of allergic sensitivity, recurrent symptoms with specific exposures, or predictable exacerbations during certain times of the year.

Symptoms that have recurred for 2 or more years during the same season are very suggestive of seasonal allergic disease. Alternatively, the history might indicate a pattern of worsening symptoms while the patient is at home, with improvement while the patient is at work or on vacation; this pattern is highly suggestive of perennial allergic disease with indoor triggers. The presence of the characteristic physical findings described above would confirm the presence of allergic rhinoconjunctivitis.

The preferred method of testing for allergic sensitivities is skin testing, which is performed with epicutaneous (prick/scratch) tests and this can be followed by intradermal testing if needed. Prick skin testing is the type most widely used. With prick testing, a small amount of purified allergen is inoculated through the epidermis only (i.e., epicutaneously) with a pricking device. Positive (histamine) and negative (saline) controls are used for comparison (Figures 13-1A and 13-1B). Reactions are measured at 15 minutes, and positive reactions (wheal and flare reactions) indicate prior allergen sensitization. Tests that yield negative results may be repeated intradermally to increase the sensitivity of the testing. All tests with positive results need to be interpreted carefully in the context of the patient's history and physical findings.

NAR is a diagnosis of exclusion. Therefore, other etiologies of rhinitis such as allergic, pharmacologic, infectious, and structural, and so on, must be excluded.[10]

Management

Three general treatment modalities are used in the therapy of allergic rhinoconjunctivitis: allergen avoidance, pharmacotherapy (medication), and immunotherapy (i.e., allergy injections). The best treatment is avoidance of the offending allergen. This requires the accurate identification of the allergens implicated and a thorough knowledge of effective interventions that can minimize or eliminate the exposure. Complete avoidance is rarely possible.

Figure 13-1A Skin prick allergy testing about to be applied to the forearm of patient to a panel of allergens.

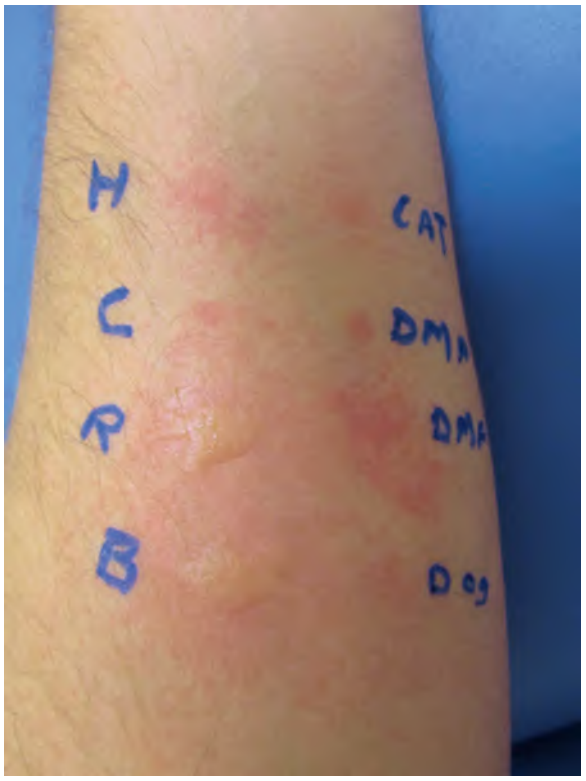

Figure 13-1B Positive sensitivities to multiple allergens from previous panel placed. Note the large wheals (bubble) and flare (redness) to Ragweed and Birch tree. Note: H=histamine, C=Control, R=Ragweed, B=Birch, DM=Dust mite.

Pharmacotherapy is often recommended for patients with incomplete responses to allergen avoidance and for patients who are unable to avoid allergen exposures. Many treatment options are available. For patients with prominent sneezing, pruritus, or rhinorrhea, antihistamines are an excellent treatment option. Second-generation antihistamines such as cetirizine, loratadine, and fexofenadine are now widely available. These medications deliver excellent antihistaminic activity with few side effects.[12] Oral decongestants can be added to oral antihistamines to relieve nasal congestion and obstruction. Combination medications are available in once-daily and twice-daily dosage forms for ease of administration. Leukotriene receptor antagonists may have additional benefit as well. Some studies have demonstrated that therapy with a leukotriene receptor antagonist plus antihistamine may have a greater effect than either agent administered alone.[12,13] For patients with daily nasal symptoms or severe symptoms that are not relieved with antihistamine-decongestants, topical anti-inflammatory agents for the nasal mucosa are available. These medications include corticosteroid, antihistamine, and cromolyn sodium nasal sprays.

The benefits of topical corticosteroids include relief of the total symptom complex and once daily dosing.

Immunotherapy is an effective means of treatment for patients with allergic rhinoconjunctivitis. Numerous studies have shown the efficacy of long-term allergen immunotherapy in inducing prolonged clinical and immunologic tolerance.[14] Immunotherapy is available for a variety of airborne allergens, including grass, tree, and weed pollens; dust mites; animal dander; and mold spores. Formulations include subcutaneous injections, sublingual drops, and sublingual tablets. Excellent candidates for immunotherapy include those patients who are unable to avoid exposures, patients with suboptimal responses to pharmacotherapy, patients who prefer to avoid the long-term use of medications, and women who are contemplating pregnancy.

First-line treatment of NAR is either an intranasal glucocorticoid and/or an intranasal antihistamine such as azelastine. There are no head-to-head studies comparing these two treatment options. Combination therapy is often used if monotherapy is not sufficient. For patients with gustatory rhinitis or significant rhinorrhea, ipratropium nasal spray may be helpful. Adjunctive therapies include nasal saline sprays and nasal irrigations, oral antihistamines, and short-term oral or nasal decongestants. Antileukotriene and intranasal chromone efficacy are less well established in NAR.[15]

Prognosis

Although allergic rhinoconjunctivitis is not a life-threatening disorder, it does have a significant impact on the patient's quality of life. With proper allergy care, most patients can lead normal lives, with an excellent quality of life.

Oral Health Considerations

The use of decongestants and first-generation antihistamines may be associated with oral dryness. There may also be an increased incidence of oral candidiasis in long-term users of topical corticosteroid-containing sprays.

It has been reported that dental personal are at risk for allergic respiratory hypersensitivity from exposure to dental materials such as methacrylates and natural rubber latex.[16] These allergenic materials, however, have been eased out of the dental workplace due to the widespread understanding of their allergic/irritant potential.

Otitis Media

Otitis media is inflammation of the middle ear space and tissues. It is the most common illness occurring in children who are 8 years of age or younger. Approximately 70% of children experience at least one episode of otitis media by age 3 years; of these, approximately one third experience three or more episodes in this same time interval.[17]

Otitis media can be subdivided into acute otitis media, recurrent otitis media, otitis media with effusion, and chronic suppurative otitis media. The underlying problem in all types of otitis media is dysfunction of the Eustachian tube. A poorly functioning Eustachian tube does not ventilate the middle ear space sufficiently. This lack of proper ventilation results in pressure changes in the middle ear and subsequent fluid accumulation. The fluid frequently becomes infected, resulting in acute otitis media. The most common infectious causes are *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, and viruses. In chronic infections, *Staphylococcus aureus* and anaerobic organisms may be causative pathogens while in young infants Gram-negative bacilli may be isolated.[18]

Pathophysiology

There are several factors that influence the pathogenesis of otitis media. Nasopharyngeal colonization with large numbers of bacteria such as *S. pneumoniae*, *H. influenzae*, or *M. catarrhalis* and pathogenic viruses can increase the risk of otitis media. The likelihood of aspiration of these nasopharyngeal pathogens can be increased by nasal congestion or obstruction, negative pressure in the middle ear space, acute viral upper respiratory infections, and exposure to tobacco smoke.[19] For infants, breastfeeding can decrease the risk of otitis media, whereas impaired immune responsiveness can increase this risk.

Under normal circumstances, the Eustachian tube acts to ventilate the tympanomastoid air cell system during the act of swallowing. Any process that impairs normal Eustachian tube function can lead to negative pressure in the middle-ear space. Transient impairments of Eustachian tube function are seen in conditions that cause nasopharyngeal mucosal edema and obstruction of the Eustachian tube orifice, such as allergic rhinitis and viral upper respiratory infections. Chronic Eustachian tube obstruction can be seen with several conditions, including cleft palate and nasopharyngeal masses, such as enlarged adenoids. Aspiration of nasopharyngeal pathogens can then occur due to negative pressure in the middle ear space, with subsequent infection by these pathogens. This leads to the clinical manifestations of otitis media.

Clinical And Laboratory Findings

The most common symptoms in acute otitis media are fever and otalgia. Other symptoms include irritability, anorexia, and vomiting. Parents may note their child pulling or tugging at one or both ears. Symptoms of a viral upper respiratory infection might also be present, preceding the development of otitis media. On physical examination, the tympanic membrane may appear erythematous and bulging, suggesting inflammation of the middle ear. Other otoscopic

findings include a loss of landmarks and decreased mobility of the tympanic membrane as seen by pneumatic otoscopy.[18]

In otitis media with effusion, patients often complain of "clogged" ears and "popping." Otoscopic examination reveals serous middle-ear fluid, and air-fluid levels may be present. The mobility of the tympanic membrane is usually diminished, and mild to moderate conductive hearing loss may be demonstrated. In chronic suppurative otitis media, otorrhea is present and can be visualized either from a tympanic membrane perforation or from surgically placed tympanostomy tubes.

Investigations that can aid in the diagnosis or management of otitis media include tympanometry and myringotomy with aspiration. Tympanometry is a technique that measures the compliance of the tympanic membrane by using an electroacoustic impedance bridge. Decreased compliance of the tympanic membrane indicates a middle-ear effusion. Myringotomy with aspiration can be useful in situations when culture of the middle ear fluid is needed, such as with immunocompromised hosts or with patients who have persistent effusions despite medical management.

Classification

Acute otitis media is defined as middle-ear inflammation with an infectious etiology and a rapid onset of signs and symptoms. Otitis media with effusion is defined as a middle ear effusion (often asymptomatic) that can be either residual (3 to 16 weeks following acute otitis media) or persistent (lasting more than 16 weeks). Recurrent otitis media is defined as three or more new episodes of acute otitis media in 6 months' time or four or more new episodes in a 12-month period. Chronic suppurative otitis media is defined as persistent otorrhea lasting longer than 6 weeks.

Diagnosis

The diagnosis of otitis media is made on the basis of the history and physical examination. The most useful tool for diagnosing otitis media is pneumatic otoscopy, which allows the clinician not only to visualize the tympanic membrane but also to assess its mobility. As stated above, an immobile tympanic membrane probably represents the presence of middle ear fluid, and (in the context of a confirmatory medical history) the diagnosis of otitis media is made in such a case.

Management

Recent practice guidelines in the management of otitis media without significant signs and symptoms, have suggested that observation with close follow-up is justified.[20] There is evidence that suggests that antibiotics may be more beneficial in certain children, specifically those aged less than 2 years with bilateral acute otitis media and in those with both acute otitis media and otorrhea.[21,22] If antibiotics are indicated, initial antibiotic therapy is directed toward the most common middle-ear pathogens. Common choices include amoxicillin, azithromycin, and trimethoprim-sulfamethoxazole. In recalcitrant cases, treatment is directed toward β-lactamase-producing organisms and antibiotic-resistant strains of *S. pneumoniae*. Common choices for this situation include high-dose amoxicillin, amoxicillin-clavulanate, second- or third-generation cephalosporins, and clindamycin. The duration of therapy varies from 3 to 14 days.[20]

Multiple surgical modalities currently are used for the management of otitis media, including myringotomy with or without tympanostomy tube insertion, tympanocentesis, and adenoidectomy. Insertion of tympanostomy tubes is indicated when a patient experiences more than six acute otitis media episodes during a 6-month period or has recurrent otitis media in addition to otitis media with effusion or persistent bilateral effusions for longer than 3 months. A trial of antibiotic prophylaxis is commonly carried out prior to surgical consultation.[20]

Antihistamines and decongestants are ineffective for otitis media with effusion and are not recommended for treatment.[23] The management of chronic suppurative otitis media often includes parenteral antibiotics to cover infection by *Pseudomonas* species and anaerobic bacteria.

Prognosis

The prognosis for acute otitis media is excellent. Studies show that over 80% of children in the United States who were treated symptomatically for acute otitis media without antibiotics had complete resolution of otitis without suppurative complications.[24] However, complications can occur, more commonly in patients younger than 1 year of age. The most common complication is conductive hearing loss related to persistent effusions. Serious complications, including mastoiditis, cholesteatoma, labyrinthitis, extradural or subdural abscesses, meningitis, brain abscess, and lateral sinus thrombosis, are uncommon.[25]

Oral Health Considerations

Many children with recurrent otitis media are treated frequently (and sometimes for extensive periods) with various antibiotics. Included in the antibiotic armamentarium are medications that are also used for odontogenic infections. Oral health care providers need to be aware of what type of antibiotics the patient has taken within the previous 4 to 6 months, to avoid giving the patient an antibiotic to which resistance has already developed. It has been demonstrated that antibiotic regimens used for the treatment of otitis media promote the emergence of antibiotic-resistant bacteria.[26] Furthermore, the extended use of antibiotics may result in the development of oral candidiasis.

Sinusitis

Sinusitis is defined as an inflammation of the epithelial lining of the paranasal sinuses. The inflammation of these tissues causes mucosal edema and an increase in mucosal secretions. The most common trigger is an acute upper respiratory infection, although other causes, such as exacerbations of allergic rhinitis, dental infections or manipulations, and direct trauma can be implicated. If blockage of sinus drainage occurs, retained secretions can promote bacterial growth and subsequent acute bacterial sinusitis.

Acute sinusitis is a very common disorder, affecting about 31 million Americans per year.[27] Sinusitis accounts for about $5.8 billion (US) in costs with about 73 million days of restricted activity per year.[28]

Pathophysiology

The paranasal sinuses are air-filled cavities that are lined with pseudostratified columnar respiratory epithelium. The epithelium is ciliated, which facilitates the clearance of mucosal secretions. The frontal, maxillary, and ethmoid sinuses drain into an area known as the ostiomeatal complex. Rhythmic ciliary movement and the clearance of secretions can be impaired by several factors, including viral upper respiratory infections, allergic inflammation, and exposure to tobacco smoke and other irritants. In addition, foreign bodies (accidental or surgical) or a severely deviated nasal septum can cause obstruction. If blockage of the sinus ostia or obstruction of the ostiomeatal complex occurs, stasis of sinus secretions will allow pooling in the sinus cavities, which facilitates bacterial growth.

The most common organisms found in acute bacterial sinusitis are *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*. Organisms that are commonly associated with chronic sinusitis are *Staphylococcus aureus* and anaerobic bacteria such as *Bacteroides* spp and *Fusobacterium* spp. Sinusitis due to a fungal infection rarely occurs, usually in immunocompromised patients and in patients who are unresponsive to antibiotics.[29]

Clinical and Laboratory Findings

The symptoms of acute sinusitis include facial pain, tenderness, and headache localized to the affected region. Sinusitis affecting the sphenoid sinuses or posterior ethmoid sinuses can cause headache or pain in the occipital region. Other symptoms that are commonly described include purulent nasal discharge, fever, malaise, and postnasal drainage with fetid breath. Occasionally, there may be toothache or pain with mastication. Patients with chronic sinusitis often present with other symptoms that are often vague and poorly localized. Chronic rhinorrhea, postnasal drainage, nasal congestion, sore throat, facial "fullness," and anosmia are common complaints.

Physical examination reveals sinus tenderness and purulent nasal drainage. On occasion, erythema and swelling of the overlying skin may be evident. The nasal mucosa can appear edematous and erythematous, and nasal polyps might also be visible.

In routine cases of suspected acute bacterial sinusitis, imaging studies are not required. When there are more persistent symptoms as in chronic sinusitis or an incomplete response to initial management, imaging studies may become appropriate. Plain-film radiography is not helpful for establishing ostiomeatal complex disease. Computed tomography (CT) is the study of choice for documenting chronic sinusitis with underlying disease of the ostiomeatal complex and is superior to magnetic resonance imaging (MRI) for the identification of bony abnormalities. CT can also accurately assess polyps, reactive osteitis, mucosal thickening, and fungal sinusitis.[29]

Classification

Sinusitis is classified as either acute, subacute, or chronic, based on the duration of the inflammation and underlying infection. Acute sinusitis is defined as inflammation of less than 4 weeks, subacute as 4 to 8 weeks, and chronic as either longer than 8 to 12 weeks in duration.[30]

Diagnosis

The diagnosis of acute sinusitis is made on the basis of history and physical examination. As previously noted, radiologic evaluations may be helpful in certain situations. Patients with recurrent disease need to be evaluated for underlying factors that can predispose patients to sinusitis. Allergy evaluation for allergic rhinitis is often helpful. Chronic sinusitis may be the presentation of an underlying systemic disease, such as granulomatosis with polyangiitis (formerly known as Wegener's) or eosinophilic granulomatosis with polyangiitis (formerly Churg–Strauss). Other predisposing factors, such as tobacco smoke exposure, immunodeficiency, cystic fibrosis, primary ciliary dyskinesia, and septal deviation, should be considered.[29,30]

CT usually aids the diagnosis of chronic sinusitis. Evaluation of the ostiomeatal complex is crucial in the management of these patients. In addition, rhinoscopy may be helpful for direct visualization of sinus ostia.

Management

Initial medical treatment consists of antibiotics to cover the suspected pathogens, along with topical or oral decongestants to facilitate sinus drainage. First-line antibiotics such as amoxicillin are often effective, although second-generation cephalosporins, azithromycin, and amoxicillin-clavulanate can be helpful in resistant cases. Comprehensive treatment of bacterial sinusitis may also include adequate hydration,

sinus rinses, steam inhalation, and pharmacologic measures intended to treat underlying disease, such as rhinitis, and to restore ostial patency. Nasal glucocorticoids are thought to be potentially effective adjuncts to antibiotic therapy, but available objective data have not unequivocally demonstrated effectiveness.[31] Acute frontal or sphenoid sinusitis can be serious because of the potential for intracranial complications. Intravenous antibiotics are indicated, and surgical intervention is considered, based on the condition's response to medical management.[29]

The management of chronic sinusitis involves antibiotics of a broader spectrum, and a prolonged treatment course may be required. Topical corticosteroids or short courses of oral corticosteroids may help reduce the swelling and/or obstruction of the ostiomeatal complex.[29] Avoidance of exacerbating factors such as allergens or tobacco smoke should be emphasized. Patients with histories suggestive of allergy should undergo a thorough allergy evaluation. Dupilumab is currently approved for the treatment of refractory chronic rhinosinusitis with nasal polyps in adults. Several of the other biologic agents currently approved for the treatment of moderate-to-severe persistent asthma are actively being studied as treatment options as well (see section Asthma).[32]

Patients who have chronic sinusitis with evidence of disease of the ostiomeatal complex who fail medical management often require surgical intervention. Functional endoscopic sinus surgery (FESS) involves the removal of the ostiomeatal obstruction through an intranasal approach. This procedure can be performed with either local or general anesthesia and without an external incision. The recovery time from this procedure is short, and morbidity is generally low.

Prognosis

Patients treated for acute sinusitis usually recover without sequelae. Children with sinusitis, particularly ethmoid and maxillary sinusitis, are at risk for periorbital or orbital cellulitis. Periorbital cellulitis is most often treated on an outpatient basis with broad-spectrum antibiotics and rarely leads to complications. Orbital cellulitis, on the other hand, requires hospital admission with broad-spectrum intravenous antibiotics. Further treatment is tailored on a case-by-case basis and may entail surgical or endoscopic drainage of the infection.[33]

Frontal sinusitis can extend through the anterior wall and present as Pott's puffy tumor. Sinusitis can also spread intracranially and result in abscess or meningitis. These complications, although uncommon, are more likely to occur in male adolescent patients.

Patients with chronic sinusitis are more likely to require a prolonged recovery period, with a resultant decrease in quality of life. Chronic medication use can lead to side effects or other complications, such as rhinitis medicamentosa from prolonged use of topical decongestants. Surgical intervention and underlying-factor assessment will often reverse the chronic process, leading to an improvement in quality of life.

Oral Health Considerations

Patients with sinus infections who present with a complaint of a toothache are commonly encountered in a dental office. The oral health care professional evaluating the patient must be able to differentiate between an odontogenic infection and sinus pain. On history, sinus infections usually present with pain involving more than one tooth in the same maxillary quadrant, whereas a toothache usually involves only a single tooth. Ruling out odontogenic infections by a dental examination and appropriate periapical radiography strengthens a diagnosis. Additional testing,[34] including pulp testing of teeth with large restorations as well as limited field cone beam CT of potential sources of infection may rule in an odontogenic origin of both sinus-localized pain as well as maxillary sinusitis of endodontic origin.[34,35]

Chronic sinus infections are often accompanied by mouth breathing. This condition is associated with oral dryness and (in long-time sufferers) increased susceptibility to oral conditions such as gingivitis.[36]

As with other conditions for which the prolonged use of antibiotics is prescribed, the potential development of bacterial resistance needs to be considered. Switching to a different class of antibiotics to treat an odontogenic infection is preferable to increasing the dosage of an antibiotic that the patient has recently taken for another condition.

The use of decongestants may be associated with oral dryness, which may need to be addressed.

Laryngitis and Laryngotracheobronchitis

The upper airway is the site of infection and inflammation during the course of a common cold, but respiratory viruses can affect any portion of the respiratory tree. Laryngitis is defined as an inflammation of the larynx, usually because of a viral infection. Laryngotracheobronchitis (also termed viral croup) involves inflammation of the larynx, trachea, and large bronchi. Although these illnesses have distinct presenting features, both result from a similar infectious process and the reactive inflammation that follows. Laryngitis can present at any age, although it is more common in the adult population.[37] In contrast, laryngotracheobronchitis is an illness seen primarily in young children and has a peak incidence in the second and third years of life. These infections are most common during the fall and

winter months, when respiratory viruses are more prevalent.

The viruses most commonly implicated in laryngitis are parainfluenza virus, coxsackieviruses, adenoviruses, and herpes simplex virus. The viruses most commonly associated with laryngotracheobronchitis are parainfluenza virus, RSV, influenza virus, and adenovirus.[38]

Acute laryngitis can also result from excessive or unusual use of the vocal cords, gastroesophageal reflux, or irritation due to tobacco smoking.

Pathophysiology

The underlying infectious process is quite similar to that seen in viral infections of the upper respiratory tract (see above). After infection of the respiratory epithelium occurs, an inflammatory response consisting of mononuclear cells and polymorphonuclear leukocytes is mounted. As a result, vascular congestion and edema develop. Denudation of areas of respiratory epithelium can result. In addition to edema, spasm of laryngeal muscles can occur. Because the inflammatory process is triggered by a viral infection, the disease processes are usually self-limited.

Clinical and Laboratory Findings

Patients with laryngitis usually have an antecedent viral upper respiratory infection. Complaints of fever and sore throat are common. The most common manifestation of laryngitis is hoarseness, with weak or faint speech.[37] Cough is somewhat variable in presentation and is more likely when the lower respiratory tract is involved.

Children presenting with viral croup commonly have an antecedent upper respiratory tract infection, which may include fever. Shortly thereafter, a barking cough and intermittent stridor develop. Stridor at rest, retractions, and cyanosis can occur in children with severe inflammation. Neck radiography will demonstrate subglottic narrowing (a finding termed "steeple sign") on an anteroposterior view.

Classification

There is no universal classification system for these illnesses. The anatomic site most affected describes these diseases.

Diagnosis

The diagnosis of laryngitis is based on the suggestive history. There are no specific findings on physical examination or laboratory tests, although the presence of hoarseness is suggestive. The differential diagnosis includes other causes of laryngeal edema, including obstruction of venous or lymphatic drainage from masses or other lesions, decreased plasma oncotic pressure from protein loss or malnutrition, increased capillary permeability, myxedema of hypothyroidism, and hereditary angioedema. Carcinoma of the larynx can also present with hoarseness.

The diagnosis of laryngotracheobronchitis is usually apparent and is based on a suggestive history. Radiologic evaluation may or may not aid physicians in the diagnosis. Only 50% of patients with laryngotracheobronchitis show the classic steeple sign on plain neck radiography (Figure 13-2).[38] With children, it is important to rule out other causes of stridor, including foreign-body aspiration, acute bacterial epiglottitis, and retropharyngeal abscess.[39]

Management

Most cases of laryngitis are mild and self-limited, so only supportive care need be prescribed. The use of oral corticosteroids in severe or prolonged cases can be considered, although their routine use is controversial.[39]

Figure 13-2 Anteroposterior radiograph of the neck show narrowing of the upper trachea that is most evident on the anteroposterior view (black arrows). This type of narrowing is typically present in croup and is known as the steeple sign on the anteroposterior radiograph given its similarity to a church steeple.

The most important aspect in the management of laryngotracheobronchitis is airway maintenance. The standard therapy includes mist therapy, corticosteroids, and racemic epinephrine. Any child with evidence of respiratory distress should be considered a candidate for steroid treatment. Less frequently, hospitalization and intubation or tracheotomy are necessary.[38]

Prognosis

As with viral upper respiratory infections, most cases of laryngitis and laryngotracheobronchitis are self-limited and require minimal medical intervention. Recovery within a few days to a week is expected. In some cases, laryngotracheobronchitis can recur, although the factors influencing this are not well understood.

Pharyngitis and Tonsillitis

Inflammation of the tonsils and pharynx is almost always associated with infection, either viral or bacterial. The vast majority of cases are caused by viral infections. These infections can be associated with fever, rhinorrhea, and cough. The major viral etiologies include rhinovirus, coronavirus, adenovirus, Epstein-Barr, para-influenza, herpes simplex virus (HSV), and influenza.[40]

The most common bacterial cause of acute tonsillopharyngitis is group A β-hemolytic *Streptococcus* (GABHS) infection, specifically *Streptococcus pyogenes* infection. Proper diagnosis and treatment of this infection are extremely important in order to prevent disease sequelae, namely, acute rheumatic fever and glomerulonephritis. Less common bacterial causes include *Corynebacterium diphtheriae*, *Neisseria gonorrhoeae*, *Chlamydia*, and *Mycoplasma pneumoniae*.

Chronic mouth breathing, chronic postnasal drainage, and inflammation due to irritant exposure can also cause pharyngitis and tonsillitis.

Pathophysiology

Streptococcal infections are spread through direct contact with respiratory secretions. Transmission is often facilitated in areas where close contact occurs, such as schools and daycare centers. The incubation period is 2 to 5 days.

Clinical and Laboratory Findings

Sore throat is the predominant symptom. Associated clinical findings are based on the infectious etiology. Patients with Epstein-Barr virus infections develop infectious mononucleosis, a disease characterized by exudative tonsillopharyngitis, lymphadenopathy, fever, and fatigue. Physical examination can reveal hepatosplenomegaly. Common laboratory findings include leukocytosis, with more than 20% atypical lymphocytes on blood smear. Blood chemistries may reveal elevated liver enzymes.

Infection with coxsackievirus can cause several distinct illnesses, each associated with tonsillopharyngitis. Herpangina is a disease that is characterized by small ulcers that are 2 to 3 mm in size and located on the anterior tonsillar pillars and possibly the uvula and soft palate. Hand-foot-and-mouth disease is characterized by ulcers on the tongue and oral mucosa, in association with vesicles found on the palms and/or soles. Small yellow-white nodules on the anterior tonsillar pillars characterize lymphonodular pharyngitis; these nodules do not ulcerate.

Pharyngoconjunctival fever is a disorder characterized by exudative tonsillopharyngitis, conjunctivitis, and fever. Infection is due to adenovirus.

Measles is a disease with a prodromal phase that is characterized by symptoms of upper respiratory infection, tonsillopharyngitis, and small white lesions with erythematous bases on the buccal mucosa and inner aspect of the lower lip (Koplik's spots). These lesions are pathognomonic of early measles infection.

Streptococcal pharyngitis is characterized by exudative tonsillitis and fever. Physical examination often reveals a beefy red uvula, cervical adenitis, and oral petechiae. Laboratory evaluation should include testing for group A *Streptococcus*.[41]

Classification

Pharyngotonsillitis is classified on the basis of etiology and clinical presentation (see above).

Diagnosis

Diagnosis is based on a history of sore throat and is established by appropriate physical findings and results of testing. A rapid antigen detection test is available for diagnosing streptococcal pharyngitis. The test has a high specificity (95+%) and slightly lower sensitivity (80–90%).[41] The importance of confirmatory cultures is still controversial, with some studies concluding that culture confirmation of negative rapid antigen detection tests may not be necessary in all circumstances.[42]

Antistreptococcal antibody titers reflect past and not present immunologic events and are of no value in the diagnosis of acute GABHS pharyngitis. They are valuable for confirmation of prior GABHS infections in patients suspected of having acute rheumatic fever or post-streptococcal acute glomerulonephritis.

Management

The viral causes of tonsillopharyngitis are treated symptomatically. Gargle solutions, analgesics, and antipyretics are often helpful. The course is self-limited.

Acute streptococcal pharyngitis is treated with oral penicillin V, cephalosporins, macrolides, clindamycin, or an intramuscular injection of benzathine penicillin G. Failure rates for penicillin vary from 6 to 23%, so an additional antibiotic course may be necessary.[41] GABHS carriers appear unlikely to spread the organism to close contacts and are at a low risk of developing complications. Antimicrobial therapy is generally not indicated for the majority of GABHS carriers.[43]

Prognosis

The prognosis for viral tonsillopharyngitis is very good as the infections are self-limited. Late sequelae from group A streptococcal tonsillitis can be avoided by prompt diagnosis and treatment.[43] Other complications due to streptococcal tonsillitis are uncommon but include cervical adenitis, peritonsillar abscesses, otitis media, cellulitis, and septicemia.

Oral Health Considerations

The association between GABHS infection and the development of severe complications, such as rheumatic fever and its associated heart condition, is well known. Although failure to successfully treat GABHS infections was more common in the pre-penicillin era, there are some concerns today regarding reinfection in cases in which penicillin is unable to eradicate the organism. One study found a significant association between the persistence of GABHS on toothbrushes and removable orthodontic appliances and the recovery of GABHS in the oropharynx of symptomatic patients after 10 days of treatment with penicillin.[44] Interestingly, when toothbrushes were rinsed with sterile water, organisms could not be cultured beyond 3 days, whereas nonrinsed toothbrushes harbored GABHS for up to 15 days. Thus, patients with GABHS infections should be instructed to thoroughly clean their toothbrushes and removable acrylic appliances daily. It is also advisable to change to a new toothbrush after the acute stage of any oropharyngeal infection.

LOWER AIRWAY DISEASES

The association between oral health and respiratory diseases has received renewed attention. Several articles have suggested that dental plaque may be a reservoir for respiratory pathogens involved in pneumonia and chronic obstructive pulmonary disease (COPD).[45,46,47,48] Although this may not be a critical problem for ambulatory healthy individuals, deteriorating oral health may be a major factor for both morbidity and mortality among institutionalized elderly persons, as well as for patients in critical care units.

Acute Bronchitis

Acute bronchitis is an acute respiratory infection involving the large airways (trachea and bronchi) that is manifested predominantly by cough with or without phlegm production that lasts up to 3 weeks. In patients who are otherwise healthy and without underlying pulmonary disease, bronchitis is commonly caused by a viral infection.[49] The viruses most commonly implicated are influenza, parainfluenza, and RSV. Viruses that are predominantly associated with upper respiratory tract infections, including coronavirus, rhinovirus, and adenovirus, have also been implicated as causes of acute bronchitis.[50] Acute bronchitis due to bacterial infection is less common. Atypical bacteria including *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and *Bordetella pertussis* are often important causes of bronchitis.[51] *Staphylococcus* and Gram-negative bacteria are common causes of bronchitis among hospitalized individuals.

Pathophysiology

The pathophysiology of acute bronchitis is similar to that of other respiratory tract infections. Following infection of the mucosal cells, congestion of the respiratory mucosa develops. Inflammation causes an increase in secretory activity, resulting in increased sputum production. Polymorphonuclear leukocytes infiltrate the bronchial walls and lumen. Desquamation of the ciliated epithelium may occur, and spasm of bronchial smooth muscle is common.

Clinical and Laboratory Findings

Acute viral bronchitis usually presents with sudden onset of cough, with or without sputum expectoration and without evidence of pneumonia, the common cold, acute asthma, or an acute exacerbation of chronic bronchitis.[50] Chest discomfort may occur; this usually worsens with persistent coughing bouts.[52] Other symptoms, such as dyspnea and respiratory distress, are variably present. Physical examination may reveal wheezing. The presentation may closely resemble an acute asthma exacerbation. Symptoms gradually resolve over a period of 1 to 2 weeks. Patients with underlying chronic lung disease might also experience respiratory compromise, with a significant impairment in pulmonary function.

The presentation of acute bacterial bronchitis is very similar to that of bacterial pneumonia (see below). Symptoms may include fever, dyspnea, productive cough with purulent sputum, and chest pain. Bacterial bronchitis can be differentiated from pneumonia by the lack of significant findings on chest radiography.

Classification

Although there is no universal classification scheme, acute bronchitis can be differentiated on the basis of etiology. Viral

bronchitis presents differently from bacterial bronchitis, as described above.

Diagnosis

Diagnosis of acute bronchitis is based on a suggestive history and a physical examination. Neither blood cell counts nor sputum analyses are particularly diagnostic in otherwise healthy patients. Routine testing for viruses is generally not obtained for bronchitis.[53] Chest radiography may be helpful in distinguishing bacterial bronchitis from pneumonia. Patients with recurrent bouts of acute bronchitis should be evaluated for possible asthma. This evaluation should include pulmonary function testing.

Patients with persistent symptoms in the course of presumed viral bronchitis should be evaluated to determine possible underlying etiologies. Sputum cultures might prove useful in these circumstances but are not performed routinely.[52]

Management

Viral bronchitis can be managed with supportive care only as most individuals who are otherwise healthy recover without specific treatment. If significant airway obstruction or hyperreactivity is present, inhaled bronchodilators, such as albuterol, may be useful. Cough suppressants, such as codeine, can also be considered for patients whose coughing interferes with sleep.

The treatment of bacterial bronchitis may include amoxicillin, amoxicillin-clavulanate, macrolides, or cephalosporins. For suspected or confirmed pertussis infection, treatment with a macrolide or trimethoprim-sulfamethoxazole is appropriate to decrease disease transmission. Although commonly used, inhaled β_2-agonist bronchodilators and mucokinetic agents, like expectorants, are not recommended for routine use in patients with acute bronchitis.[50]

Prognosis

Acute bronchitis carries an excellent prognosis for patients who are without underlying pulmonary disease, and recovery without sequelae is the norm. However, for patients with chronic lung disease and respiratory compromise, bronchitis can be quite serious and may often lead to hospitalization and respiratory failure. In other high-risk individuals, such as those with human immunodeficiency virus (HIV) infection or other immunodeficiencies, acute bronchitis may lead to the development of bronchiectasis.

Oral Health Considerations

Resistance to antibiotics may develop rapidly and last for 10 to 14 days.[52] Thus, patients who are taking amoxicillin for acute bronchitis should be prescribed another type of antibiotic (such as clindamycin or a cephalosporin) when an antibiotic is needed to treat an odontogenic infection.

Pneumonia

Pneumonia is defined pathologically as an infection and a subsequent inflammation involving the lung parenchyma. Both viruses and bacteria are causes, and the presentation is dependent on the causative organism. Pneumonias can be broadly classified as either nosocomial or community-acquired. Nosocomial infections are infections that are acquired in a hospital or health care facility and often affect debilitated or chronically ill individuals. Community-acquired infections can affect all persons but are more commonly seen in otherwise healthy individuals. In the US, there were 52,000 deaths from community-acquired pneumonia in 2007 with 4.2 million ambulatory care visits for this condition in 2006.[54]

Formerly, bacterial pneumonia was categorized into several subtypes; community-acquired pneumonia, aspiration pneumonia, hospital-acquired (nosocomial) pneumonia, ventilator associated pneumonia, and nursing home associated pneumonia. In all cases, connections have been made with oral health status. However, in 2005 a new category was created called health care-associated pneumonia or HCAP.[55] Health care-associated pneumonia was defined as pneumonia occurring in a diverse group of patients, including those undergoing home-infusion therapy or wound care, chronic dialysis, recently hospitalized patients, or nursing home residents. Patients in these settings are often at high risk for pneumonia caused by multidrug resistant organisms such as methicillin-resistant *Staphylococcus aureus* or resistant Gram-negative bacilli. Thus, treatment guidelines for HCAP include broad-spectrum antibiotic therapy.

The most common bacterial cause of community-acquired pneumonia is *S. pneumoniae*, followed by *H. influenzae*. The organisms responsible for HCAP include aerobic Gram-negative bacilli, such as *P. aeruginosa*, *Escherichia coli*, *Klebsiella pneumoniae*, and *Acinetobacter* species. Infections due to Gram-positive cocci, such as *S. aureus*, particularly methicillin-resistant *S. aureus* (MRSA), have been rapidly emerging in the United States as well.[56] A related condition is aspiration pneumonia, which is typically caused by anaerobic organisms most often originating from the gingival crevice.[57] Aspiration pneumonia often occurs in patients with dysphagia, depressed consciousness, or others at risk for aspiration of oral contents into the lung, including alcoholics. Aspiration pneumonia occurs both in the community and in institutional settings.

Atypical organisms commonly associated with pneumonia include *M. pneumoniae*, *Legionella*, and *Chlamydia*.[58] The atypical organisms may cause a pneumonia that differs in clinical presentation from that caused by the aforementioned bacteria (see below). Pneumonia can be caused by viruses, such as influenza, parainfluenza, adenovirus, and RSV, as well as fungi such as *Candida*, *Histoplasma*, *Cryptococcus*, and *Aspergillus*. Pneumonia may also be caused by other organisms including *Pneumocystis jiroveci (carinii)*, seen in immunocompromised hosts, *Nocardia*, and *Mycobacterium tuberculosis*. Infection with these organisms can often be differentiated by chest radiography.

Pathophysiology

The pathophysiology of pneumonia is dependent on the causative infectious organism. In bacterial pneumonia caused by *S. pneumoniae*, for example, the bacteria first enter the alveolar spaces after inhalation. Once inside the alveoli, the bacteria rapidly multiply, and extensive edema develops. The bacteria cause a vigorous inflammatory response, which includes an influx of polymorphonuclear leukocytes. In addition, capillary leakage is pronounced. As the inflammatory process continues, the polymorphonuclear leukocytes are replaced by macrophages. Subsequent deposition of fibrin ensues as the infection is controlled, and the inflammatory response resolves.[58]

Other infections of the lung (i.e., viral, atypical, etc.) are interstitial processes. The organisms are first inhaled into the alveolar spaces. The organisms then infect the type I pneumocytes directly. As these pneumocytes lose their structural integrity and necrosis ensues, alveolar edema begins. Type II pneumocytes proliferate and line the alveoli, and an exudative cellular debris accumulates. An interstitial inflammatory response is mounted, primarily by mononuclear leukocytes. This process can occasionally progress to interstitial fibrosis, although resolution is the norm.

Clinical and Laboratory Findings

Pneumonia due to community-acquired bacterial infection typically presents acutely, with a rapid onset of symptoms. A prodrome similar to that seen with acute infections of the upper respiratory tract is unusual. Common symptoms include fever, pleuritic chest pain, and coughing that produces purulent sputum.[52] Chills and rigors are also common. Pneumonia due to *H. influenzae*, which is seen more commonly in patients with COPD or alcoholism, presents with fever, cough, and malaise. Chest pain and rigors are less common.

Nosocomial pneumonia with *Staphylococcus* secondary to aspiration presents with fever, dyspnea, cough, and purulent sputum. In cases acquired hematogenously, signs and symptoms related to the underlying endovascular infection predominate. Otherwise, respiratory tract symptoms are mild or absent despite radiographic evidence of multiple pulmonary infiltrates. The classic clinical features of nonbacteremic *Enterobacteriaceae* or *Pseudomonas* pneumonia are abrupt onset of dyspnea, fever, chills, and cough in an older patient who is either hospitalized or chronically ill.[59]

Physical examination demonstrates crackles (rales) in the affected lung fields. Decreased breath sounds and dullness to percussion might also be noted. Signs of respiratory distress may be present in severely affected individuals, including retractions, use of accessory muscles, and cyanosis.

With atypical pneumonia, symptoms usually develop over 3 to 4 days and initially consist of low-grade fevers, malaise, a nonproductive cough, and headache. Often systemic complaints are more prominent than the respiratory complaints. Sputum production, if present, is usually minimal. Findings on physical examination of the chest are usually unremarkable, with only scattered rhonchi. Infection due to *Mycoplasma* is common among younger patients. Pneumonias due to viral causes have a similar presentation but can have a more rapid onset.

Infection with *Legionella* spp (Legionnaires' disease) begins with a prodrome consisting of fever and malaise and progresses rapidly to an acute phase of high fever, rigors, pleuritic chest pain, gastrointestinal complaints, and confusion. The cough is typically nonproductive and is only variably present. Elevated liver enzymes and proteinuria indicate renal and hepatic involvement. Hypoxia can also develop and progress rapidly. Legionnaires' disease was first described at an American Legion convention in Philadelphia in 1976. The causative organisms have a predilection for moist areas such as air-conditioning ducts and cooling towers. The infection tends to occur more commonly among middle-aged men with a history of tobacco smoking.

Classification

Pneumonia is initially classified on clinical presentation as either viral, bacterial, or atypical. Different classifications based on radiologic or pathologic manifestations are less commonly used.

Diagnosis

When a patient with probable pneumonia is being evaluated, the possible causative organism will be suggested by: (1) the clinical presentation and course of the illness; (2) the degree of immunocompetency of the patient; (3) the presence or absence of underlying lung disease; and (4) the place of acquisition (hospital or community). Ultimately, the goal

is rapid diagnosis to establish an etiology so that appropriate antimicrobial therapy can be initiated. With community-acquired pneumonia, the diagnosis should be based on a clinical history and physical examination findings. Chest radiography, laboratory studies, and blood cultures may be considered.[60]

In nosocomial infection, the presence of pneumonia is defined by new lung infiltrate on radiography plus clinical evidence that the infiltrate is of an infectious origin. The presence of a new or progressive radiographic infiltrate plus at least two of three clinical features (fever greater than 38 °C, leukocytosis or leukopenia, and purulent secretions) represents the most accurate combination of criteria for starting empiric antibiotic therapy.[56] For diagnosis of ventilator associated pneumonia, quantitative microbiological cultures from bronchoalveolar lavage (BAL) samples are often employed, with pathogenic bacteria $\geq 10^4$cfu/mL of BAL indicative of an infection.[61]

Sputum analysis is the traditional tool used for diagnosis and management. Spontaneously coughed or induced sputum is analyzed by Gram stain and allows for the identification of a select group of pathogens and thus a more directed antibiotic therapy. For example, Gram-positive cocci in pairs (diplococci) are suggestive of pneumococcal infection. Gram-positive cocci in grape-like clusters suggest infection with *S. aureus*. Gram-negative pleomorphic rods are typical of *H. influenzae*, whereas *Klebsiella* is identified by its short, plump Gram-negative rod appearance. Numerous polymorphonuclear leukocytes are also often seen. This method, however, is limited since very often sputum contains bacteria of the normal flora that may be confused with pathogens.

Quantitative cultures for hospital-acquired infections can be performed on endotracheal aspirates or samples collected either bronchoscopically or nonbronchoscopically. These techniques may aid in diagnosis and management as well. Routine culture can identify *S. pneumoniae*, *H. influenzae*, *S. aureus*, and Gram-negative rods. Specialized culturing techniques are needed to identify *Legionella*, *Mycobacterium*, *Nocardia*, *Mycoplasma*, and fungi. Tissue cultures are used to identify viruses and *Chlamydia*. In patients with nosocomial pneumonia, a lower respiratory tract culture should be collected before antibiotic therapy, but collection of cultures should not delay the initiation of therapy in critically ill patients.[56]

Chest radiography can be a valuable tool in the evaluation of the patient with pneumonia. The radiologic presentation is dependent on the infectious etiology and the underlying medical condition of the patient. A pattern of lobar consolidation and air bronchograms is seen most commonly in cases of pneumococcal pneumonia (Figure 13-3). The lower lobes and right middle lobe are most commonly involved. A pattern of patchy nonhomogeneous infiltrates, pleural effusion, and cavitary lesions is common with staphylococcal pneumonia. *Klebsiella* pneumonia typically involves multiple lobes and can also be associated with effusion and cavitation. Viral or atypical organisms usually present with an interstitial infiltrative pattern or patchy segmental infiltrates. Organisms such as *Nocardia*, *Mycobacterium*, and fungi often cause nodular or cavitary lesions, which are demonstrable on chest radiography. Rapid accumulation of pleural fluid or empyema is seen most often with bacterial infection.

The presence of cold agglutinins is suggestive of *Mycoplasma* infection. Cold agglutinins are antibodies (produced in response to *Mycoplasma* infection) that agglutinate red blood cells upon cold exposure. Titers reach maximal levels in 3 to 4 weeks but can be detected 1 week after the onset of disease. These antibodies can be found in 60–70% of patients with *Mycoplasma* pneumonia but are not specific to this disease.

Legionella pneumonia can be diagnosed by a urine antigen assay and by culture of the organism, using specialized media, or by direct fluorescent antibody staining of sputum.

Management

Empiric treatment is started immediately upon diagnosis of pneumonia. Treatment options for outpatients with community-acquired pneumonia include β-lactams (e.g., amoxicillin-clavulanate), macrolides, and doxycycline. Patients who have received antimicrobial therapy within the previous 3 months are at increased risk for infection with antimicrobial-resistant *S. pneumoniae* and may require starting with a fluoroquinolone or a combination of antibiotics (e.g., β-lactam and macrolide).[62]

In the case of nosocomial pneumonia, patients with low risk of infection by an antibiotic-resistant organism should

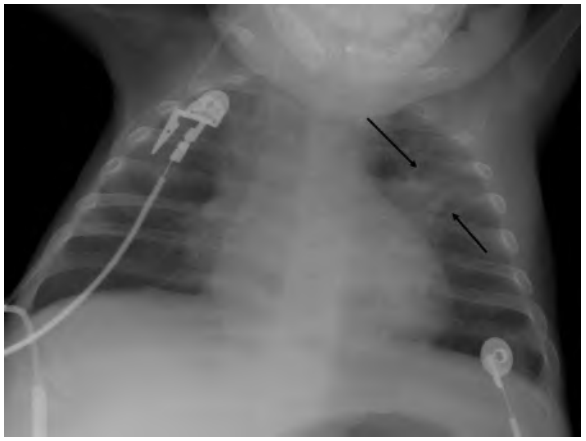

Figure 13-3 Anteroposterior radiograph of the chest in an infant shows an infiltrate in the left upper lobe (black arrows). Blood cultures obtained on this infant were positive for *Pneumoccous*.

be treated with empiric therapy, such as a third-generation cephalosporin or fluoroquinolone. However, more aggressive broad-spectrum therapy (such as an antipseudomonal cephalosporin, carbapenem, or fluoroquinolone, along with linezolid or vancomycin for MRSA), is required for high-risk patients, such as those with a prolonged duration of hospitalization (5 days or more), admission from a health care-related facility, or recent prolonged antibiotic therapy.[56]

Nonspecific treatment for patients with pneumonia includes aggressive hydration to aid in sputum clearance. Chest physiotherapy is advocated by many clinicians, although evidence of efficacy is lacking. If hypoxia is present, supplemental oxygen is given.[62]

A pneumococcal vaccine is available for active immunization against pneumococcal disease. The vaccine is effective for preventing disease from of the most common pneumococcal serotypes. It is effective for adults and for children older than 2 years of age and is recommended for all individuals over the age of 65 years and selected high-risk patients with certain medical conditions.[62] A conjugate pneumococcal vaccine has been part of the US childhood immunization schedule since 2000 and has led to a sustained reduction in hospitalizations for childhood pneumonia.[63]

Prognosis

Mortality due to community-acquired pneumonia is low. The risk of mortality is higher for older patients, patients with underlying pulmonary disease, patients with immunodeficiency (e.g., asplenia), and patients with positive blood cultures. Most deaths occur within 5 days of the onset of disease.

Mortality due to staphylococcal pneumonia is high, and patients who do recover often have residual pulmonary abnormalities. Mortality due to atypical pneumonia is low, with the exception of *Legionella* pneumonia, which has a 15% mortality rate if left untreated.

Oral Health Considerations

The aspiration of salivary secretions containing oral bacteria into the lower respiratory tract can cause aspiration pneumonia. Numerous periodontally associated oral anaerobes and facultative species have been isolated from infected pulmonary fluids.[64] Although most reports suggest increased susceptibility to the development of nosocomial pneumonia from periodontal pathogens, other oral bacteria (such as *Streptococcus viridans*) have been implicated in community-acquired pneumonia.[53]

The connection of oral health to pneumonia involves aspiration of a pathogen from a proximal site; for example, the oral-pharyngeal cavity, into the lower airway. The teeth or dentures have nonshedding surfaces upon which oral biofilms, that is, dental plaque, form, which are susceptible to colonization by respiratory pathogens. Indeed, intensive care subjects were found to harbor greater levels of dental plaque than nonhospitalized control patients, and bacterial pathogens known to cause pneumonia were found to be prevalent in the dental plaque from the intensive care subjects.[46] In some cases, up to 100% of the aerobic flora was found to be *S. aureus*, *P, aeruginosa*, or several enteric species. In contrast, the control dental patients were only rarely colonized by respiratory pathogens. Poor oral hygiene therefore may predispose high-risk patients to oral colonization by respiratory pathogens and therefore increase the risk for lung infection. In addition, the host response to oral biofilms results in inflammation of the periodontal tissues.[65] Thus, inflammatory products from the gingival tissues as well as pathogenic bacteria shed from oral biofilms into the secretions can be aspirated into the lower airway to promote lung infection.[64]

Elderly individuals residing in nursing homes also have an increased prevalence of poor oral health, including increased plaque retention.[66] Studies have evaluated the occurrence of pneumonia in cohorts of elderly individuals who were receiving and not receiving oral care. In one such study, the relative risk of developing pneumonia increased 67% in the group without access to oral health interventions compared with individuals who had access to oral care.[67] These data support the benefit of increased awareness and increased oral health interventions in hospitalized and institutionalized individuals. More intervention studies are needed to assess the impact of oral pathogens on the incidence of pneumonia, but, at present, there is ample evidence that poor oral health status is a risk indicator for the development of pneumonia.

These and other studies support the notion that institutionalized subjects, especially those in hospital intensive care and nursing home settings, have a greater risk for dental plaque colonization by respiratory pathogens than do community-dwelling subjects. This suggests that oral intervention to reduce or control dental plaque may serve as a simple, cost-effective method to reduce pathogen colonization in high-risk populations. Several systematic reviews of the literature have examined the evidence for oral interventions to reduce the risk of pneumonia in hospital and nursing home patients. The weight of the evidence supports the notion that interventions that improve oral hygiene significantly reduce the incidence of pulmonary infection; however, mortality seems unaffected.[68,69,70]

Interventions tested to date include topical disinfections using chlorhexidine[71] and supervised mechanical plaque control augmented with topical agents.[72] Taken together, the available evidence suggests that there is a relationship

between poor oral hygiene and bacterial pneumonia in special care populations, including those in hospital and nursing home settings. Interventions designed to improve oral hygiene may reduce the risk of pneumonia in these populations. This raises the question "what is the present status of oral hygiene practice in hospitals and nursing homes?" A recent paper described clinical practice guidelines for oral hygiene in critically ill patients based upon a systematic literature review followed by prospective consideration of the evidence at a consensus development conference.[73] From this, several recommendations were offered to guide clinicians in the care of vulnerable patients. These recommendations were that provision of effective oral care is an important strategy in reducing nosocomial pneumonia. The remaining recommendation can be found in the selected reading (Liu et al. and Gomes-Filho et al.).

Other measures for consideration for intubated patients may include removal of all dental appliances upon admissions to the critical care unit, periodic repositioning the tube, or deflation of the cuff. Removing hard deposits (e.g., tartar/calculus) from the teeth should be considered, if possible, prior to admission (for example in the case of elective surgery). Placement the patient's head to the side or place in semi-fowlers (semi-reclined body position) will also minimize inadvertent aspiration.

Bronchiolitis

Bronchiolitis is a disease that affects children under the age of 2 years; it is most common among infants aged 2 to 12 months. It is characterized by infection of the lower respiratory tract, with the bronchioles being most affected. The inflammatory response can be caused by various pathogens, including RSV, human metapneumovirus, parainfluenza virus, influenza virus, adenovirus, and *M. pneumoniae*.[74,75]

Pathophysiology

Infection of the bronchioles leads to a marked inflammatory response with a prominent mononuclear cell infiltrate. This inflammatory response results in edema and necrosis of epithelial cells lining small airways, mucosal thickening and mucus hypersecretion, plugging, and bronchospasm.[74] Bronchiolar spasm is an occasional feature. Due to these changes, the lumina of the bronchioles are critically narrowed, leading to areas of micro-atelectasis and emphysema. Respiratory compromise is common, with decreased blood oxygen saturation, hypercarbia, respiratory acidosis, and, in severe cases, respiratory failure.

Clinical and Laboratory Findings

Infants first develop signs and symptoms of an infection of the upper respiratory tract, with low-grade fever, profuse clear rhinorrhea, and cough. Signs of infection in the lower respiratory tract soon follow, including tachypnea, retractions, wheezing, nasal flaring, and, on occasion, cyanosis. Crackles can be audible, and thoracic hyper-resonance can be noted on percussion. Associated findings can include conjunctivitis, otitis media, and pharyngitis. Pulse oximetry can be used to determine oxygen saturation levels.

Chest radiography may show peribronchial cuffing, flattening of the diaphragms, hyperinflation, increased lung markings or areas of atelectasis.

Laboratory studies reveal a mild leukocytosis with a prominence of polymorphonuclear leukocytes ("left shift").

Classification

Bronchiolitis can be classified by the causative agent, as is the case with acute bronchitis.

Diagnosis

The diagnosis is clinical, based on the history and physical examination. Laboratory and radiologic studies for diagnosis are not generally required. The etiology can be determined (and the diagnosis confirmed) by performing a nasopharyngeal culture for RSV and other respiratory viruses. Rapid viral diagnostic assays are also available.

The differential diagnosis includes many other causes of wheezing and respiratory distress in this age group, such as asthma, congenital heart disease, and cystic fibrosis.

Management

Clinical treatment of these infants is generally limited to supportive care. Infants may be placed in cool-mist oxygen tents, where continuous oxygen administration can be given. Due to an increase in insensible water losses, hydration must be ensured. Aerosolized bronchodilators should not be used routinely in the management of bronchiolitis, although a carefully monitored trial may be attempted if there is a documented positive clinical response. Corticosteroid medications are generally not indicated.[76]

Antiviral therapy with ribavirin is rarely used, although it may be considered for use in highly selected situations involving documented RSV bronchiolitis with severe disease or in those who are at risk for severe disease (e.g., immunocompromised and/or hemodynamically significant cardiopulmonary disease).[74] Ribavirin was traditionally administered by aerosolization but now there are intravenous and oral formulations.[77]

Mechanical ventilation is required in the infant with respiratory failure. Very young infants (less than 1 month of age) are at risk for apnea due to RSV infection, so close observation is required.

An intramuscular monoclonal antibody to the RSV F protein, palivizumab, is effective in preventing severe RSV

disease in high-risk infants when given before and during the RSV season. This prophylaxis is currently recommended only for high-risk patient populations, such as those with chronic lung disease, a history of prematurity, or congenital heart disease.[78]

Prognosis

Although mortality due to bronchiolitis is not uncommon, most patients recover without sequelae. Epidemiologic studies with a several-year follow-up of index and control children show a higher incidence of wheezing and asthma in children with a history of bronchiolitis, unexplained by family history or other atopic syndromes. It is unclear whether bronchiolitis incites an immune response that manifests as asthma later or whether those infants have an inherent predilection for asthma that is merely unmasked by their episode of RSV.[78]

Asthma

Asthma is a chronic inflammatory disorder of the airways. It is characterized by recurrent and often reversible airflow limitation due to an underlying inflammatory process. The etiology of asthma is unknown, but allergic sensitivity is seen in most patients with asthma.[5] There is a significant hereditary contribution, but no single gene or combination of genes has yet been identified as causative. Multiple risk factors for the development of asthma have been identified, including family history of asthma, atopy, respiratory infections, inhaled pollutants in indoor and outdoor air and in the workplace, allergens, food sensitivities, and other exposures, such as tobacco smoke.[79]

In the US, asthma affects about 19 million adults and over 6 million children.[80] In addition, asthma represents a significant economic and social burden with about $56 billion (US) spent on medical costs, lost school/work days, and early deaths.[81] It accounted for 3400 deaths in the US in 2010. Overall, trends do not appear to be declining despite advances in our understanding of asthma and newer pharmacologic modalities.

Pathophysiology

The clinical features of asthma are due to the underlying chronic inflammatory process. Although the etiology is not known, certain histopathologic features provide insights into the chronic process. Infiltration of the airway by inflammatory cells such as activated lymphocytes and eosinophils, denudation of the epithelium, deposition of collagen in the sub-basement membrane area, and mast cell degranulation are often features of mild or moderate persistent asthma. Other features seen, include mucus hypersecretion, smooth muscle hypertrophy, and angiogenesis.[82]

Airway inflammation contributes significantly to many of the hallmark features of asthma, including airflow obstruction, bronchial hyper-responsiveness, and the initiation of the injury-repair process (remodeling) found in some patients. Bronchial smooth muscle spasm is instrumental in the excessive airway reactivity. Resident airway cells, including mast cells, alveolar macrophages, and airway epithelium, as well as migrating inflammatory cells, secrete a variety of mediators that directly contract the bronchial smooth muscle. These same mediators, such as histamine, cysteinyl leukotrienes, and bradykinin, increase capillary membrane permeability to cause mucosal edema of the airways.[83]

Atopy is the strongest risk factor associated with the development of asthma. Persistent exposure to relevant allergens in a sensitized individual can lead to chronic allergic inflammation of the airways. Although atopy is seen more commonly in childhood-onset asthma, it can also play an important role in asthma in adults.

Clinical and Laboratory Findings

The hallmark clinical features of asthma are recurrent reversible airflow limitation and airway hyper-responsiveness. These factors lead to the development of the signs and symptoms of asthma, which include intermittent wheezing, coughing, dyspnea, and chest tightness. Symptoms of asthma tend to worsen at night and in the early morning hours. In addition, well-defined triggers may precipitate asthma symptoms. These triggers include allergens, gastroesophageal reflux, exercise, cold air, respiratory irritants, nonsteroidal anti-inflammatory drugs, emotional extremes, and infections, particularly viral infections. Symptoms can progress slowly over time, or they may develop abruptly.[2,84,85,86]

Historical points that suggest the diagnosis of asthma include chronic coughing with nocturnal awakenings, dyspnea or chest tightness with exertion, recurrent "croup" or "bronchitis" associated with infections of the upper respiratory tract, and wheezing that occurs on a seasonal basis. Physical examination of patients with mild disease often shows no abnormalities. However, common findings in patients with more severe disease include an increased anteroposterior chest diameter, a prolonged expiratory phase, wheezing, and diminished breath sounds. Digital clubbing is rarely seen. Concurrent allergic disease such as allergic rhinitis may be present. During acute exacerbations, patients may show signs of respiratory distress, with tachypnea, intercostal retractions, nasal flaring, and cyanosis.

Pulmonary function testing or spirometry is recommended in the initial assessment of most patients with suspected asthma. These tools can often be useful to monitor the course of asthma and a patient's response to therapy. The technique involves a maximal forced expiration following a maximal inspiration (see Figure 13-4). The key measurements are the forced vital capacity (FVC), which is the amount of air expired during the forced expiration, and the forced

expiratory volume in 1 second (FEV_1), which is the volume of air expired during the first second of expiration; FEV_1 is a measure of the rate at which air can be exhaled. Given the FEV_1 and the FEV_1/FVC ratio, an objective determination of airflow limitation is possible. Reversibility can be demonstrated after administration of a short-acting bronchodilator, such as albuterol, and repeating spirometry to demonstrate significant improvement in the FEV_1. In patients with normal baseline spirometry values, a demonstration of bronchial hyper-responsiveness is useful. This is performed by bronchoprovocation, using nonspecific triggers such as histamine or methacholine. When delivered by aerosol, these agents allow the determination of bronchial hyper-reactivity by triggering a decrease in the FEV_1 immediately following inhalation. Subsequent measurements of peak expiratory flow rate (PEFR) at home may also be helpful to assess symptoms, to alert to worsening of airflow obstruction, and to monitor therapeutic responses.[87] The PEFR is easy to determine, and durable metering devices are available at little cost. Newer diagnostic tests, like exhaled nitric oxide levels (FE_{NO}), are becoming useful in detecting eosinophilic airway inflammation.[88]

Allergen skin testing is another valuable tool. This testing allows the accurate identification of allergic triggers, which can translate into more specific therapies, such as allergen avoidance and immunotherapy (see section Allergic rhinitis and conjunctivitis, above). Chest radiography may be useful, especially as a means of excluding other diseases from the diagnosis.

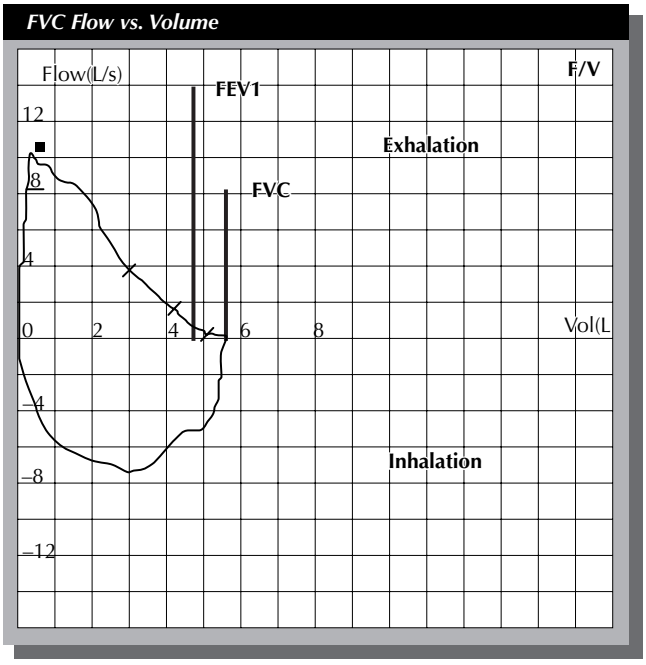

Figure 13-4 Spirometric Flow–Volume curve demonstrating FEV_1 and FVC along with exhalation and inhalation phases.

Classification

Asthma is classified according to its severity taking into consideration impairment and risk. Although there is no universal classification scheme, the guidelines set forth by the National Asthma Education and Prevention Program (NAEPP) in 2007, updated in December 2020, and the Global Initiative for Asthma (GINA), updated in 2019, are widely used in the United States.[82,89,90] Asthma patients are classified as having intermittent, mild-persistent, moderate-persistent, or severe-persistent disease. The categories are defined by both subjective (historical) and objective (spirometric) points. Follow up visits determine asthma is control thus classification can change over time. Asthma may also be classified by the underlying trigger (e.g., exercise-induced asthma and occupational asthma).

Diagnosis

The diagnosis of asthma is made on the basis of a suggestive history, confirmatory physical findings, and the demonstration of reversible airflow limitation. This can be documented during hospitalizations, by outpatient use of spirometry or PEFR determinations, or by clinical assessment after therapeutic trials.

The differential diagnosis of asthma includes other causes of chronic coughing and wheezing. The diseases that are usually considered are chronic rhinitis or sinusitis, cystic fibrosis, gastroesophageal reflux disease, airway narrowing due to compression (i.e., masses), and COPD (chronic bronchitis). Factors favoring the diagnosis of asthma include intermittent symptoms with asymptomatic periods, complete or nearly complete reversibility with bronchodilators, the absence of digital clubbing, and a history of atopy.

Management

The goals of asthma management include the patient having little or no chronic symptoms, few or no exacerbations requiring oral steroids, no hospitalizations, and minimal or no activity limitation. This is to be achieved using the least amount of medication. Ideal control would include no need for short-acting bronchodilators, normal PEFRs, no PEFR variability, and no adverse effects from controller medications. All patients with asthma, regardless of its severity, should have an asthma control plan to aid in understanding the underlying process and treatment options and to effectively treat asthma exacerbations. Regular monitoring of asthma is important; spirometry, PEFR measurement, FE_{NO} levels, and validated questionnaires may be useful tools for this purpose. Avoidance control measures are regularly emphasized, focusing on allergen and irritant triggers. Treatment for concomitant diseases that may exacerbate asthma (such as allergic rhinitis, gastroesophageal reflux disease, and chronic sinusitis) should be instituted.[91]

Pharmacotherapy of asthma is based on the severity of disease. The NAEPP guidelines provide a stepwise approach (steps 1-6) for increasing and decreasing medications based on a patient's asthma severity, and its 2020 Asthma Guideline Update provides new evidence-based recommendations (Figure 13-5).[82]

Patients with **mild-intermittent asthma** usually require a short-acting β2-agonist (SABA) on an as-needed basis (Step 1). These medications (such as albuterol) are preferably administered by inhalation. In addition to relaxing airway smooth muscle, β-agonists enhance mucociliary clearance and decrease vascular permeability.[91]

Patients with **mild-persistent asthma** usually require routine therapy for control of underlying airway (Step 2). The original NAEPP guidelines recommend a daily, low-dose inhaled corticosteroid (ICS) with as-needed (SABA). The NAEPP's 2020 Asthma Guideline Update provides another option: as-needed concomitant ICS and SABA treatment.[82] Inhaled corticosteroids are the most widely used and most effective asthma anti-inflammatory agents.[91] Inhaled corticosteroids are the most potent and consistently effective long-term control medication for asthma.[77] Patients with mild to moderate persistent asthma treated with inhaled steroids have improved symptom scores, decreased exacerbations, less β_2-agonist use, fewer oral steroid courses and fewer hospitalizations.[91] Inhaled corticosteroids have an excellent safety profile at conventional doses, although high-dose therapy can put patients at risk for corticosteroid side

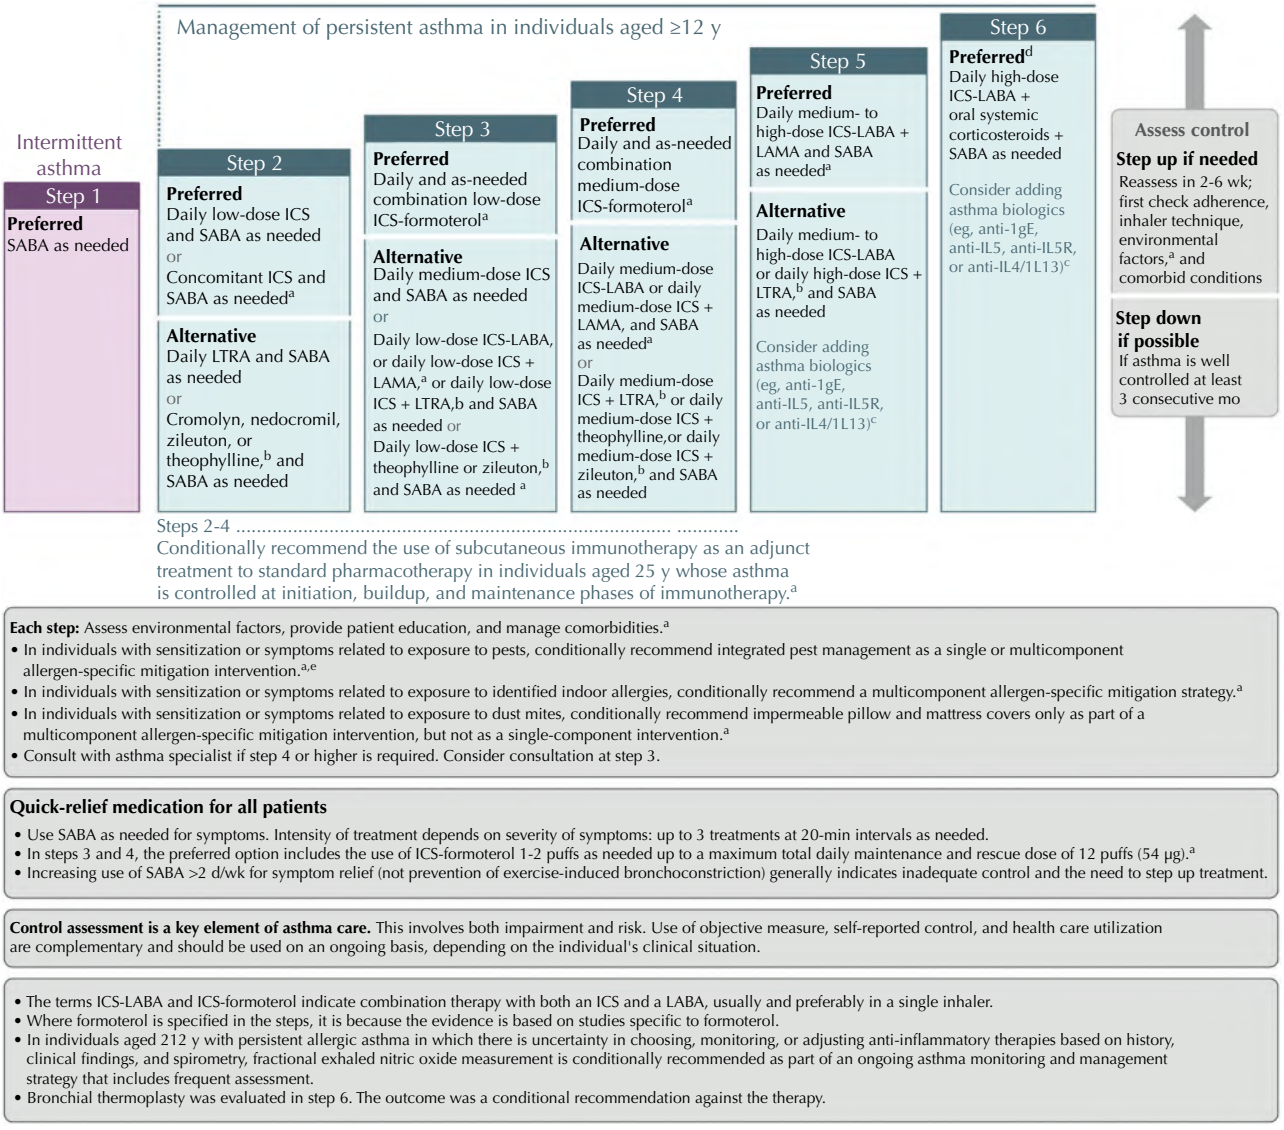

Figure 13-5 Stepwise approach for treating asthma in adults and children ⩾ 12 years. *Source:* From National Heart, Lung and Blood Institute; National Institutes of Health; U.S. Department of Health and Human.

effects. These medications have been used for decades in both children and adults without significant long-term side effects in most patients. Although there is the potential for a decreased growth-velocity effect, evidence suggests that the use of inhaled corticosteroids at recommended doses does not have long-term, clinically significant, or irreversible effects.[82] Alternative medications include the nonsteroidal anti-inflammatory agents nedocromil and cromolyn, leukotriene receptor antagonists (LTRAs), or sustained-release theophylline.

Patients with **moderate-persistent asthma** (Steps 3 or 4) and **severe-persistent asthma** (Steps 5 or 6) require more intensive therapy. Long-acting bronchodilators such as salmeterol and formoterol have been shown to have an additive effect when used with inhaled corticosteroids and are useful additions to inhaled corticosteroid therapy.[92] For steps 3 and 4, the NAEPP's 2020 Asthma Guideline Update now prefers a single maintenance and reliever treatment (SMART), i.e., daily as well as as-needed combination low-dose ICS-formoterol for adults and children ≥ 12 years. Formoterol was the LABA studied in SMART, hence the recommendation is specific to formoterol therapy. Formoterol also has a fast onset of action, and its dose range permits more than twice daily use. The older NAEPP recommendation of using a daily medium-dose ICS with as-needed SABA remains an alternative for step 3.[82]

Tiotropium, an inhaled long-acting muscarinic antagonist (LAMA) that has been widely used in chronic obstructive pulmonary disease (COPD), has been approved as maintenance treatment for asthma. Patients who have persistent symptoms and frequent exacerbations despite ICS/LABA combination therapy may benefit from a LAMA.[90,93] Step 5 in the NAEPP's 2020 Asthma Guideline Update now prefers adding on a LAMA as a controller in patients whose asthma is not sufficiently controlled by a medium- to high-dose ICS/LABA. Step 6 remains unchanged. The use of SMART was not addressed for steps 5 and 6 in this update.[82]

A minority of patients might require long-term corticosteroids; these patients are difficult to manage, but adequate symptom control while minimizing the dose is of paramount importance.[91]

Patients who continue to have uncontrolled asthma despite high dose ICS/LABA therapy or are oral glucocorticoid dependent may be candidates for a biologic agent (Table 13-1). Currently, there are five biologic agents that are FDA-approved for uncontrolled moderate- and/or severe-persistent asthma. Omalizumab, a subcutaneous recombinant humanized monoclonal anti-IgE antibody indicated for

Table 13-1 Biologic agents approved for the treatment of moderate to severe persistent asthma.

Biologic Agent	Target	FDA Approved Age	Labs Required	Route	Dose & Interval	Adverse Effects	Also Approved For
omalizumab (Xolair ©)	IgE	6+ years	IgE 30-700 IU/mL Sensitivity to perennial allergen	SC	Based on weight and IgE level (maximum dose: 375mg every 2 weeks)	Local site reaction Anaphylaxis	CIU
mepolizumab (Nucala ©)	IL-5	6+ years	AEC ≥ 150	SC	100mg every 4 weeks (40mg every 4 weeks for ages 6-11 years)	Local site reaction Herpes Zoster	EGPA
benralizumab (Fasenra ©)	IL-5 Rα	12+ years	AEC ≥ 300	SC	30mg every 4 weeks for the first 3 doses; then every 8 weeks	Headache, fever Local site reaction	
reslizumab (Cinqair ©)	IL-5	18+	AEC ≥ 400	IV	3mg/kg every 4 weeks	Anaphylaxis 0.3% (Black Box warning) Transient increase in CPK	
dupilumab (Dupixent ©)	IL-4Rα	12+ years	None in studies	SC	2 doses: 200mg or 300mg every 2 weeks	Transient eosinophilia Local site reaction Keratitis Conjunctivitis	Atopic dermatitis CRSwNP

AEC: absolute eosinophil count; CIU: chronic idiopathic urticaria; CPK: creatine phosphokinase; CRSwNP: chronic rhinosinusitis with nasal polyps; EGPA: eosinophilic granulomatosis with polyangiitis; IgE: total serum immunoglobulin E; IL-4Rα: interleukin-4 receptor alpha; IL-5: interleukin-5; IL-5Rα: interleukin-5 receptor alpha; IV: intravenous infusion; mg/kg: milligram per kilogram; SC: subcutaneous injection

perennial atopic patients with moderate to severe asthma in patients age 6 and above, has been shown to improve asthma symptom scores, decrease exacerbations, and decrease inhaled corticosteroid doses.[94] Interleukin (IL)-5 mediates eosinophilic inflammation in the airways. There are three monoclonal antibodies that target the IL-5 pathway that have been approved as add-on, maintenance treatment in patients with severe-persistent asthma with an eosinophilic phenotype. Mepolizumab, is a subcutaneous formulation approved in patients aged 6 or older with peripheral eosinophil count of 150/microliter or greater and is administered every 4 weeks. Reslizumab, an IV formulation dosed based on weight, is approved for patients aged 18 and up with a peripheral eosinophil count of 400/microliter or greater. Benralizumab is a monoclonal antibody directed against the IL-5 receptor alpha subunit that decreases IL-5 signaling and also depletes eosinophils through enhanced antibody-dependent cell-mediated cytotoxicity. It has been approved as add-on maintenance therapy in patients aged 12 and up with severe eosinophilic asthma with a peripheral eosinophil count ≥ 300 cells/microliter. These biologics that target the eosinophilic pathway of asthma have all show improved quality of life and a reduction in exacerbation rates.[95,96] Lastly, dupilumab is a humanized monoclonal antibody that targets the alpha subunit of the IL-4 receptor. By binding to this subunit, dupilumab inhibits the activity of cytokines IL-4 and IL-13, integral players in asthma and allergy pathophysiology. Dupilumab is administered subcutaneously and is indicated for the treatment of moderate- to severe-persistent asthma in patients aged 12 and up. Dupilumab has been shown to decrease oral glucocorticoid, reduce exacerbations, and improve lung function.[97]

Other therapies that are also currently under investigation include an antithymic stromal lymphopoietin (TSLP) biologic agent called tezepelumab, a novel glucocorticoid receptor agonist, and a prostaglandin D2 receptor antagonist called fevipiprant.[98,99,100]

Bronchial thermoplasty involves administering thermal energy during bronchoscopy to decrease smooth muscle mass. It has been shown to decrease exacerbations, emergency room visits, and days missed from school/work in patients with severe-persistent asthma.[101] Patients with allergic triggers may benefit from allergen immunotherapy. Many studies have now documented improvement from following a 3- to 5-year course of specific immunotherapy.[102] This is an excellent means of minimizing medications while maintaining control for many patients.

Prognosis

Although asthma is not a curable disease, it is a controllable disease. Asthma education programs are extremely important in making early diagnosis and interventions possible. Despite an increase in our knowledge of the underlying pathophysiology, asthma mortality rates have not declined. With early diagnosis and a comprehensive management plan, patients with asthma can experience a normal life expectancy with good quality of life.

Oral Health Considerations

The main concern when treating any medically complex patient is to avoid exacerbation of the underlying condition. Several protocols suggesting appropriate procedures for dental treatment of asthmatic patients have been put forth.[103,104,87,105] However, few studies assessing the respiratory response of patients to dental care have been performed. One study indicated that although 15% of asthmatic pediatric patients will have a clinically significant decrease in lung function, no clinical parameter or historical data pertaining to asthma can predict this phenomenon.[106]

However, numerous dental products and materials, including toothpaste, fissure sealants, tooth enamel dust, and methylmethacrylate, have been associated with the exacerbation of asthma, whereas other items (such as fluoride trays and cotton rolls) have been suggested as being so associated.[105,106,107,108,109,110,111]

There is still no consensus regarding the association between asthma and dentofacial morphology.[112,113] Although nasal respiratory obstruction resulting in mouth breathing has been implicated in the development of a long and tapered facial form, an increased lower facial height, and a narrow maxillary arch, this relationship has never been substantiated with unequivocal evidence.

Oral manifestations include candidiasis, decreased salivary flow, increased calculus, increased gingivitis, increased periodontal disease, and possible increased incidence of caries.[114,115,116] It is possible that prolonged use of β_2-agonists may cause reduced salivary flow, with a resulting increase in cariogenic bacteria and caries and an increased incidence of candidiasis.[117,118]

Dental treatment for asthmatic patients needs to address the oral manifestations of this condition, as well as its potential underlying systemic complications. Elective dental procedures should be avoided in all but those whose asthma is well controlled. The type and frequency of asthmatic attacks, as well as the type of medications used by the patient, indicate the severity of the disease.

The following are considerations and recommendations for administering dental care to patients who have asthma:

1) Caries risk assessment and fluoride supplements as warranted should be instituted for all asthmatic patients, particular those taking β_2-agonists.
2) The patient should be instructed to rinse his or her mouth with water after using inhalers.

3) Oral hygiene should be reinforced to reduce the incidence of gingivitis and periodontitis.
4) Antifungal medications should be administered as needed, particularly in patients who are taking inhaled corticosteroids.
5) Evaluate potential risks in patients taking long-term systemic corticosteroids associated with major surgical procedures (see Chapter 20 "Transplantation Medicine").
6) Use stress-reducing techniques. Conscious sedation should be performed with agents that are not associated with bronchoconstriction, such as hydroxyzine. Barbiturates and narcotics should be avoided due to their potential to cause bronchospasm and reduce respiratory functions. Nitrous oxide can be used for all but patients with severe asthma as it may irritate the airways.[103]
7) Avoid dental materials that may precipitate an attack. Acrylic appliances should be cured prior to insertion. Dental materials without methylmethacrylate should be considered.
8) Schedule these patients' appointments for late morning or later in the day to minimize the risk of an asthmatic attack.[119]
9) Have oxygen and bronchodilators available in case of an exacerbation of asthma.
10) There are no contraindications to the use of local anesthetics containing epinephrine, but preservatives such as sodium metabisulfite may contribute to asthma exacerbation in susceptible patients.[120] Nevertheless, interactions between epinephrine and R_2-agonists may result in a synergistic effect, producing increased blood pressure and arrhythmias.
11) Judicious use of rubber dams will prevent reduced breathing capability.
12) Care should be used in the positioning of suction tips as they may elicit a cough reflex.
13) About 7–14% of adult asthmatic patients have an allergy to aspirin and other nonsteroidal anti-inflammatory agents.[121] A careful history concerning the use of these types of drugs needs to be elicited. Although the use of acetaminophen has been proposed as an alternative to the use of aspirin, recent data suggest caution because these types of drugs have also been associated with more severe asthma.[122]
14) Drug interactions with theophylline are common. Macrolide antibiotics may increase the level of theophylline, whereas phenobarbitals may reduce the level. Furthermore, drugs such as tetracycline have been associated with more accentuated side effects when given together with theophylline.
15) During an acute asthmatic attack, discontinue the dental procedure, remove all intraoral devices, place the patient in a comfortable position, make sure the airway is opened, and administer a β_2-agonist and oxygen. If no improvement is noted, administer epinephrine subcutaneously (1:1000 concentration, 0.01 mg/kg of body weight, up to a maximum of 0.3 mg) and alert emergency medical assistance.

Chronic Obstructive Pulmonary Disease (COPD)

COPD is a disease state characterized by airflow limitation. The airflow is usually both progressive and associated with an abnormal inflammatory response of the lungs to noxious particles or gases.[123] COPD includes emphysema, an anatomically defined condition characterized by destruction and enlargement of the lung alveoli; chronic bronchitis, a clinically defined condition with chronic cough and phlegm; and small airways disease, a condition in which small bronchioles are narrowed. COPD is present only if chronic airflow obstruction occurs; chronic bronchitis without chronic airflow obstruction is not included within COPD.

The prevalence and burden of COPD are projected to increase in the coming decades due to continued exposures to risk factors and the aging population. The diagnosis should be considered in any patient with symptoms of cough, sputum production or dyspnea, and/or a history of exposure to risk factors for the disease.[123]

Risk factors for the disease can include environmental exposures and host factors, such as a rare hereditary deficiency in the enzyme α_1-antitrypsin. This enzyme is responsible for inhibiting the activity of trypsin and other proteases in the serum and tissues. The characteristic panlobular emphysematous changes that are seen in α_1-antitrypsin deficiency are related to the loss of alveolar walls. More commonly, risk factors for the disease include environmental exposure to tobacco smoke, heavy exposure to occupational dusts and chemicals (vapors, irritants, fumes), and indoor/outdoor pollution.[123]

The clinical course of patients with COPD is quite varied. Most patients display some degree of progressive dyspnea, exercise intolerance, and fatigue. In addition, patients are susceptible to frequent exacerbations, usually caused by infections of the upper or lower respiratory tract. Most patients with COPD have little respiratory reserve. Therefore, any process that causes airway inflammation can lead to clinical deterioration.

Pathophysiology

Three processes are thought to be important in the pathogenesis of COPD: chronic inflammation throughout the airways, parenchyma, and pulmonary vasculature; oxidative stress; and an imbalance of proteases and antiproteases in the lung. These pathologic changes lead to the physiologic changes characteristic of the disease, including mucus hypersecretion, ciliary dysfunction, airflow limitation,

pulmonary hyperinflation, gas exchange abnormalities, pulmonary hypertension, and cor pulmonale.[123]

Expiratory airflow limitation is the primary physiologic change in COPD. Airflow limitation results from fixed airway obstruction mainly. Patients with COPD may also have airway hyperresponsiveness overlapping with asthma.[124] Mucous hypersecretion and ciliary dysfunction lead to chronic cough and sputum production. In advanced COPD, peripheral airway obstruction, parenchymal destruction, and pulmonary vascular abnormalities reduce the lung's capacity for gas exchange, leading to hypoxemia and hypercapnia.[123]

Many toxins in tobacco smoke can cause a vigorous inflammatory response. In humans, chronic exposure to tobacco smoke results in an increase in the number of goblet cells because of hyperplasia and metaplasia. Acrolein, for example, causes both impairment of both ciliary and macrophage activities, as well as increases mucin hypersecretion.[125] Nitrogen dioxide causes direct toxic damage to the respiratory epithelium. Hydrogen cyanide is responsible for the functional impairment of enzymes that are required for respiratory metabolism. Carbon monoxide causes a decrease in the oxygen-carrying capacity of red blood cells by associating with hemoglobin to form carboxyhemoglobin. Lastly, polycyclic hydrocarbons have been implicated as carcinogens.

Hypoxemia is the result of the ventilation-perfusion mismatch that accompanies airway obstruction and emphysema. Portions of the lung that are not aerated due to obstruction cannot oxygenate the blood. This causes a decrease in overall oxygen concentrations. In addition, emphysema causes a decreased diffusion capacity because of a loss of air-space capillary units. Hypercarbia also develops and is often progressive and asymptomatic. Pulmonary hypertension can result from chronic hypoxia due to vasoconstriction of pulmonary vessels.

Patients with emphysema alone have less ventilation-perfusion mismatching early in the course of the disease; this is due to the loss of both air space and supplying blood vessels. Severe hypoxia, pulmonary hypertension, and cor pulmonale are generally not seen until late in the disease process. Emphysema manifests as loss of the elastic recoil of the lungs, making the lungs more compliant. The work of breathing is therefore not significantly increased. However, the decrease in recoil allows the easy collapse of the peripheral airways, leading to further airway obstruction and airflow limitation.[126]

Clinical and Laboratory Findings

Patients with COPD have symptoms of dyspnea, cough, and sputum production. An increase in the production of purulent sputum is a sign of exacerbation due to respiratory infection. Physical findings include diffuse wheezing, possibly associated with signs of respiratory distress, including the use of accessory muscles of respiration (retractions) and tachypnea.[124] Liver enlargement due to congestion, ascites, and peripheral edema can develop as the disease progresses to pulmonary hypertension and cor pulmonale. This leads to the characteristic clinical patient presentation termed the *blue bloater*.

Patients with emphysema present primarily with dyspnea. Patients can be adequately oxygenated in the early stages of the disease and thus can have fewer signs of hypoxia; the term *pink puffer* has been used to describe these patients. Physical findings include an increase in chest wall size. Wheezing is present to varying degrees.

Chest radiography may show evidence of an increase in lung compliance, with flattened diaphragms, hyper-expansion, and an increase in anteroposterior diameter (Figure 13-6). Spirometry will show evidence of airflow limitation. A post bronchodilator FEV_1/FVC ratio of < 0.7 confirms the presence of airflow limitation that is not fully reversible.[127] Complete pulmonary function studies will also indicate an increase in residual volume and total lung capacity.[124] Pulmonary diffusion capacity will be decreased due to a loss of gas-exchanging units.

Classification

COPD is now classified into five stages: at risk, mild, moderate, severe, and very severe. The at-risk stage is defined by normal spirometry, but patients have chronic symptoms of cough and sputum production. Mild, moderate, and severe COPD have evidence of increasing airway obstruction on spirometry in each progressive stage. Finally, very severe COPD is defined by severe airway obstruction with chronic respiratory failure. Patients with severe COPD are at more risk for other systemic diseases including cardiovascular disease, osteoporosis, lung cancer, and depression.[128]

Diagnosis

The diagnosis is suggested by the history and physical findings. Patients often have cough, dyspnea, and sputum production and/or a history of exposure to risk factors. Alternative diagnoses, such as asthma, CF, and congestive heart failure, should be considered. Complete pulmonary function tests are a valuable means of assessing airflow limitation and any reversibility. For patients with more severe disease, assessment of oxygen status with pulse oximetry is a valuable office procedure. A determination of arterial blood gases is important for patients who are clinically deteriorating and for the management of hospitalized patients.[124] Chest radiography can be helpful to exclude alternative diagnoses but is rarely diagnostic in COPD.

Management

There are no curative treatments for chronic bronchitis and emphysema. Smoking cessation is the single most important intervention to stop the progression of COPD. Reduction of

Figure 13-6 Axial computed tomography image of the upper chest demonstrates decreased attenuation of the lung tissue bilaterally, especially on the right (white arrows) where there is evidence of centrilobular emphysema.

exposures to occupational dusts and chemicals and indoor/outdoor pollution can also decrease the progression of disease.[123] Influenza and pneumococcal vaccines are recommended.

Management focuses on reducing symptoms and exacerbations. The most recent Global Initiative for Obstructive Disease guidelines gives management recommendations after patients have been assessed combining symptom scores, airflow limitations, and exacerbations (Figure 13-7). Maintenance therapy includes trials of inhaled bronchodilators such as β-agonists and ipratropium bromide. Long-acting bronchodilators, such as formoterol or salmeterol, may be added as well as mucolytics. Theophylline products have also been used with some efficacy as well as phosphodiesterase-4 inhibitors. Long-term monotherapy with oral or inhaled corticosteroids is not recommended as inhaled steroids with long acting β-agonists are more effective.[123]

Chest physiotherapy has not been proven to be of value in the management of COPD.

The long-term administration of oxygen therapy to patients with chronic respiratory failure increases survival. Additionally, during exacerbations, oxygen therapy is often required. Caution must be used when administering oxygen to patients with COPD as their ventilatory drive will often be diminished. This is the result of chronic retention of carbon dioxide and subsequent insensitivity to hypercarbia. As a result, patients with COPD are sensitive to increases in oxygen tension, which provides the major stimulus for respiratory drive. Oxygen therapy during sleep can also be a useful means of limiting hypoxemia and subsequent pulmonary hypertension. An option for some patients involves lung-volume reduction which removes severely emphysematous tissue from the both upper lobes allowing the remaining tissue to expand and function more effectively.[128]

Antibiotics are often used during exacerbations of COPD. The presence of purulent sputum during an exacerbation generally requires treatment with 7 to 10 days of an oral antibiotic chosen based on local bacterial resistant patterns. The primary pathogens in COPD exacerbations include *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*.

Prognosis

The prognosis is poor for patients who are frequently symptomatic due to COPD. The need for hospital admission for an exacerbation, especially if intensive care is required, is an ominous prognostic sign in COPD as about half of such patients admitted to the intensive care unit do not survive a year after admission.[129]

Oral Health Considerations

The association, if any, between oral disease and lung disease was analyzed by the National Health and Nutrition Examination Survey I (NHANES I).[130] Of 23,808 individuals, 386 reported a suspected respiratory condition (as assessed by a physician) categorized as a confirmed chronic respiratory disease (chronic bronchitis or emphysema) or acute respiratory disease (influenza, pneumonia, acute bronchitis), or not to have a respiratory disease.

Significant differences were noted between subjects having no disease and those having a chronic respiratory disease confirmed by a physician. Individuals with a confirmed chronic respiratory disease had a significantly greater oral hygiene index than subjects without a respiratory disease. Logistic regression analysis was performed to simultaneously control for multiple variables, including gender, age, race, oral hygiene index (OHI), and smoking status. The results of this analysis suggest that for patients having the highest OHI values, the odds ratio for chronic respiratory disease was 4.5.

Another study of elderly subjects (aged 70 to 79) found that, after controlling for smoking status, age, race, and gender, there was a significant association between periodontal health and airway obstruction in former smokers,[131] and an additional study suggested that cigarette smoking may be a cofactor in the relationship between periodontal disease and COPD.[132] A recent systematic review and meta-analysis further confirmed an association between periodontitis and COPD;[133] however, further longitudinal epidemiologic studies and clinical trials are necessary to determine the role of oral health status in COPD.

These results were supported by a subsequent study that measured associations between poor oral health and chronic lung disease, and this study was able to carefully control for a number of potentially confounding variables. Data from NHANES III, which documented the general health and nutritional status of randomly selected United States subjects from 1988 to 1994, were analyzed.[130] This cross-sectional, retrospective study of the NHANES III database included a study population of 13,792 subjects

COMMONLY USED MAINTENANCE MEDICATIONS IN COPD*

Generic Drug Name	Inhaler Type	DELIVERY OPTIONS: *Nebulizer*	*Oral*	*Injection*	Duration Of Action
BETA$_2$-AGONISTS					
SHORT-ACTING (SABA)					
Fenoterol	MDI	√	pill, syrup		4-6 hours
Levalbuterol	MDI	√			6-8 hours
Salbutamol (albuterol)	MDI & DPI	√	pill, syrup, extended release tablet	√	4-6 hours 12 hours (ext. release)
Terbutaline	DPI		pill	√	4-6 hours
LONG-ACTING (LABA)					
Arformoterol		√			12 hours
Formoterol	DPI	√			12 hours
Indacaterol	DPI				24 hours
Olodaterol	SMI				24 hours
Salmeterol	MDI & DPI				12 hours
ANTICHOLINERGICS					
SHORT-ACTING (SAMA)					
Ipratropium bromide	MDI	√			6-8 hours
Oxitropium bromide	MDI				7-9 hours
LONG-ACTING (LAMA)					
Aclidinium bromide	DPI, MDI				12 hours
Glycopyrronium bromide	DPI		solution	√	12-24 hours
Tiotropium	DPI, SMI, MDI				24 hours
Umeclidinium	DPI				24 hours
Glycopyrrolate		√			12 hours
Revefenacin		√			24 hours
COMBINATION SHORT-ACTING BETA$_2$-AGONIST PLUS ANTICHOLINERGIC IN ONE DEVICE (SABA/SAMA)					
Fenoterol/ipratropium	SMI	√			6-8 hours
Salbutamol/ipratropium	SMI, MDI	√			6-8 hours
COMBINATION LONG-ACTING BETA$_2$-AGONIST PLUS ANTICHOLINERGIC IN ONE DEVICE (LABA/LAMA)					
Formoterol/aclidinium	DPI				12 hours
Formoterol/glycopyrronium	MDI				12 hours
Indacaterol/glycopyrronium	DPI				12-24 hours
Vilanterol/umeclidinium	DPI				24 hours
Olodaterol/tiotropium	SMI				24 hours
METHYLXANTHINES					
Aminophylline			solution	√	Variable, up to 24 hours
Theophylline (SR)			pill	√	Variable, up to 24 hours
COMBINATION OF LONG-ACTING BETA$_2$-AGONIST PLUS CORTICOSTEROID IN ONE DEVICE (LABA/ICS)					
Formoterol/beclometasone	MDI, DPI				12 hours
Formoterol/budesonide	MDI, DPI				12 hours
Formoterol/mometasone	MDI				12 hours
Salmeterol/fluticasone propionate	MDI, DPI				12 hours
Vilanterol/fluticasone furoate	DPI				24 hours
TRIPLE COMBINATION IN ONE DEVICE (LABA/LAMA/ICS)					
Fluticasone/umeclidinium/vilanterol	DPI				24 hours
Beclometasone/formoterol/glycopyrronium	MDI				12 hours
Budesonide/formoterol/glycopyrrolate	MDI				12 hours
PHOSPHODIESTERASE-4 INHIBITORS					
Roflumilast			pill		24 hours
MUCOLYTIC AGENTS					
Erdosteine			pill		12 hours
Carbocysteine†			pill		
N-acetylcysteine†			pill		

**Not all formulations are available in all countries. In some countries other formulations and dosages may be available. † Dosing regimens are under discussion. MDI = metered dose inhaler; DPI = dry powder inhaler; SMI = soft mist inhaler. Note that glycopyrrolate & glycopyrronium are the same compound.*

Figure 13-7 Therapeutic options for patients with COPD based on assessment. *Source:* Based on the Global Initiative for Obstruction Lung Disease (GOLD); Global Strategy for the Diagnosis Management, and Prevention of Chronic Obstructive Pulmonary Disease (2021 report). https://goldcopd.org/wp-content/uploads/2020/11/GOLD-REPORT-2021-v1.1-25Nov20_WMV.pdf.

20 years of age and older having at least six natural teeth. A history of bronchitis and/or emphysema was recorded from the medical questionnaire. Lung function was estimated by calculation of the ratio of forced expiratory volume after 1 sec (FEV_1)/forced vital capacity (FVC). Oral health status was deduced from the Decayed Missing Filled System (DMFS/T) index, gingival bleeding, gingival recession, gingival pocket depth, and periodontal attachment level. Subjects with COPD had, on average, more periodontal attachment loss (CAL 1.48 ± 1.35- mean ± SD) than those without COPD (mean CAL 1.17 ± 1.09). The risk for COPD appeared to be significantly elevated when mean attachment loss (MAL) was found to be severe (mean attachment loss; MAL ≥ 2.0 mm) compared with periodontal health (< 2.0 mm MAL: odds ratio 1.35, 95% CI: 1.07–1.71). Furthermore, the odds ratio was 1.45 (95% CI: 1.02– 2.05) for those who had ≥ 3.0 mm MAL. A trend was also noted in that lung function appeared to diminish as the amount of attachment loss increased. No such trend was apparent when gingival bleeding was considered.

Another study examined the relation between airway obstruction and periodontal disease in a cohort of 860 community dwelling elders enrolled in the Health, Aging, and Body Composition Study (Health ABC).[134] Results showed that, after stratification by smoking status and adjustment for age, race, gender, center, and number of pack-years, those with normal pulmonary function had significantly better gingival index (P .036) and loss of attachment (P .0003) scores than those with airway obstruction. Thus, a significant association between periodontal disease and airway obstruction was noted, especially in former smokers.

A recent meta-analysis explored the relationship between periodontal disease and COPD.[135] Fourteen observational studies including 3,988 COPD patients were included in the analysis. A significant association between PD and COPD was identified.[136] There is thus great need for randomized controlled trails to determine if periodontal interventions prevent the initiation and/or progression of COPD.

Apart from the periodontal pathogens mentioned above, *Streptococci* have been shown to be the causative pathogen of exacerbation in 4% of individuals with COPD.[137] One prospective study suggested that oral colonization with respiratory pathogens in patients residing in a chronic care facility was significantly associated with COPD.[138] The relationship between oral pathogens and exacerbations of COPD clearly deserves serious consideration. It is essential that elderly individuals (particularly institutionalized patients) receive adequate oral hygiene in order to minimize respiratory complications.

Drug interactions with theophylline may arise (see above), and an evaluation of medications by the oral health care provider including intermittent antibiotic use is appropriate.

As mentioned above, increased oxygen tension may diminish respiratory function in patients with COPD. Extreme caution must be exercised when administering supplemental oxygen in emergencies.

Cystic Fibrosis (CF)

CF is a multisystem genetic disorder that is characterized chiefly by chronic airway obstruction and infection and by exocrine pancreatic insufficiency, with its effects on gastrointestinal function, nutrition, growth, and maturation.[139]

The disorder is caused by numerous mutations in the gene that encodes the cystic fibrosis transmembrane conductance regulator (CFTR) that helps regulate ion flux at epithelial surfaces. The disease is characterized by hyperviscous secretions in multiple organ systems. Thickened secretions affect the pancreas and intestinal tract, causing malabsorption and intestinal obstruction. In the lungs, viscid mucous causes airway obstruction, infection, and bronchiectasis. Pulmonary complications are the major factors affecting life expectancy in patients with CF. This section focuses on the pulmonary manifestations of CF.

CF is an autosomal recessive trait resulting from mutations at a single gene locus on the long arm of chromosome 7. The incidence of CF among Caucasians is approximately 1 in 3200 births; the incidence is lower among those of other races.[140]

Pathophysiology

The primary defect in the *CFTR* gene results in a defective chloride transport system in exocrine glands. As a result, mucous production occurs without sufficient water transport into the lumen. The resultant mucus is dry, thick, and tenacious and leads to inspissation in the affected glands and organs. In the airways, the viscid secretions impair mucociliary clearance and promote airway obstruction and bacterial colonization. Most airway injury in CF is believed to be mediated by neutrophil products, including proteases and oxidants, liberated by the abundance of neutrophils in the CF airway at almost all ages.[141] Bacterial superinfection is common and can lead to respiratory compromise.

Clinical and Laboratory Findings

Patients with CF may present in infancy with extrapulmonary manifestations such as meconium ileus or failure to thrive. Pulmonary manifestations include cough, recurrent infections of the lower respiratory tract, refractory lung infiltrates, and bronchospasm. Tachypnea and crackles can be found on physical examination. As the disease progresses, digital clubbing and bronchiectasis (Figure 13-8) may become apparent. Most of the nonpulmonary pathology in CF occurs in the gastrointestinal tract and related organs.

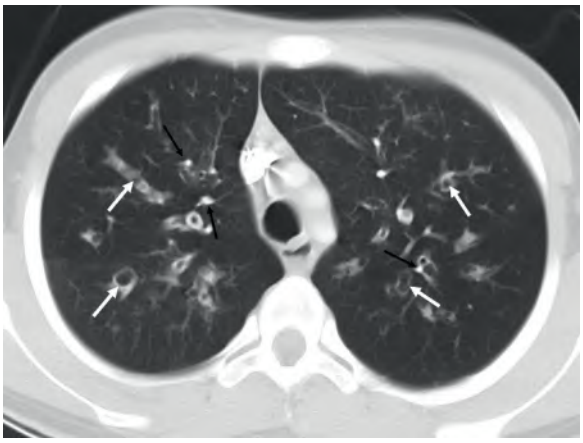

Figure 13-8 Axial computed tomography scan shows thickening of the bronchial walls in the upper lobes and bronchiectasis (dilation of the bronchi) bilaterally (white arrows). The bronchi should be approximately the same size as its associated pulmonary artery (black arrows).

Spirometry and pulmonary function testing are useful tools for documenting and monitoring airflow limitation. Airway obstruction tends to worsen with disease progression, although some patients with CF have mild pulmonary disease. CT analysis of the remarkable lung structural changes may be another potential outcome measure to monitor disease progression.

Classification

There is no universally accepted classification system for CF.

Diagnosis

The diagnosis of CF is based on the presence of pulmonary or extrapulmonary symptoms, as described above. A sweat test can be performed to confirm the diagnosis. The procedure involves the collection of sweat after stimulation with pilocarpine. Samples containing > 60 mEq/L chloride are considered positive. Patients with indeterminate values (40 to 60 mEq/L) can be further assessed by using deoxyribonucleic acid (DNA) mutation analysis. Characteristic nasal epithelial bioelectric abnormalities can also serve as laboratory evidence of CFTR dysfunction and be used to diagnose CF when phenotypic clinical features are present.[139] Due to the importance of early diagnosis, all states have now implemented newborn screening for CF.

Management

Treatment of CF includes antibiotics, bronchodilators, anti-inflammatory agents, chest physiotherapy with postural drainage, and mucolytic agents. In addition to oral and parenteral antibiotics, inhaled antibiotics such as tobramycin are used to help minimize systemic effects.[142] Long-term macrolide antibiotics have been used to effectively treat diffuse panbronchiolitis as well.[139] The use of anti-inflammatory agents in young patients with mild disease may help slow the decline of lung function.[143] Recombinant enzyme deoxyribonuclease therapy has also been shown to offer benefit to some patients with purulent airway secretions.[144] Finally, proper nutrition and exercise are essential. Approximately 90% of patients with CF require mealtime pancreatic enzymes,[129] and vitamin and caloric supplementation is essential as well. Exercise is generally considered beneficial for patients with CF and should be encouraged, except for those with the most severe lung disease and hypoxemia.[145]

Prognosis

Although the mortality rate is high, the most recent statistics from the Cystic Fibrosis Foundation indicate that 50% of patients can now be expected to survive beyond the age of 37 years.[139] The severity of lung disease often determines long-term survival. Lung transplantation has become an accepted treatment for respiratory failure secondary to CF.[146] New treatment modalities that are being investigated to help prolong survival include pharmacologic interventions targeted to improving CFTR functioning (potentiators) and trafficking (correctors).[147]

Oral Health Considerations

It has been suggested that patients with CF may have the same type of dentofacial morphology as other mouth-breathing patients.[148] However, larger prospective studies are needed to confirm this.

Several studies have reported that the number of decayed, missing, and filled teeth and plaque, calculus, and gingival bleeding of CF patients is lower than that of non-CF control subjects, but additional studies cite increased risk.[149] These contradictions may be due age related differences in populations studied[150] and more antibiotic use by CF patients.

It has also been reported that the same bacterial clone of *P. aeruginosa*, an important bacterial pathogen for CF patients, can be found in subgingival plaque and saliva, serving as a reservoir of colonization.[151] This suggests that oral hygiene strategies may help reduce the level of these pathogens in the mouth and thus reduce potential lung infection.

As with other patients with chronic lower respiratory infections, improved oral hygiene including toothbrush hygiene[152] may minimize exacerbation of the underlying condition.

Of note, patients with cystic fibrosis may ultimately receive a lung transplant, so precautions appropriate for post-transplant patients should be followed (Chapter 20 "Transplantation Medicine")

Pulmonary Embolism

Pulmonary embolism (PE) is a result of an exogenous or endogenous material traveling to the lung and causing blockage of a pulmonary arterial vessel. The embolus may

originate anywhere, but it is usually due to a thrombosis in the lower extremities.[153] Other substances, such as septic emboli, venous gas, fat emboli, and intravascular foreign bodies are potential causes of pulmonary emboli.[154] Risk factors for PE include prolonged immobilization (such as in a postoperative state), lower extremity trauma, a history of deep venous thromboses, and the use of estrogen-containing oral contraceptives (especially in association with tobacco smoking).[155] The most common reversible risk factor for PE is obesity, an increasing problem in the US.[156]

Pathophysiology

PE causes occlusion of pulmonary arterial vessels, which results in a ventilation-perfusion mismatch. Massive PE causes right-sided heart failure and is rapidly progressive. Local bronchoconstriction may occur due to factors released by platelets and mast cells at the sites of occlusion. Pulmonary hypertension due to vessel occlusion and arterial vasospasm is a common finding.

Clinical And Laboratory Findings

Patients usually present with dyspnea. Other features that are variably present include chest pain, fever, diaphoresis, cough, hemoptysis, and syncope. Physical findings can include evidence of a lower extremity deep venous thrombosis, tachypnea, crackles or rub on lung auscultation, and heart murmur.

Hypoxemia is common in acute PE. Measurements of arterial blood gases are helpful as patients may demonstrate a decrease in partial pressure of arterial oxygen (PaO_2) and partial pressure of arterial carbon dioxide ($PaCO_2$), with an increase in hydrogen ion concentration (pH). However, normal arterial blood gases do not rule out the possibility of PE.

Diagnosis

The diagnosis is made on the basis of history and physical findings. The diagnostic utility of plasma measurements of circulating D-dimer (a specific derivative of crosslinked fibrin) has been found to have a high negative predictive value of 99.5%.[157] However, in patients with a high clinical probability of a PE, a D-dimer test should not be used since the negative predictive value of this test is low.[158]

Chest radiography is often not helpful but may reveal suggestive signs such as elevated hemidiaphragm, pleural effusions, and pulmonary artery dilatation. Troponin levels may be elevated, the echocardiogram may be abnormal with increased right ventricular volume, and electrocardiography may help establish or exclude alternative diagnoses, such as acute myocardial infarction.

Although the ventilation-perfusion scan has historically been the most common diagnostic test used when PE is suspected, spiral (helical) CT scanning has replaced it at many centers. The use of pulmonary angiography has declined and is typically reserved for cases in which catheter based treatment would be an option.[158]

Management

Heparin, both unfractionated and low molecular weight, remains the mainstay of therapy. For most patients with PE, systemic thrombolytic therapy (such as streptokinase, urokinase, and tissue-type plasminogen activator) is not required unless the patient is hemodynamically unstable. Pulmonary embolectomy may be indicated in select patients who are unable to receive thrombolytic therapy or whose critical status does not allow sufficient time to infuse thrombolytic therapy.[159] Oxygen is administered as necessary, and the need for intubation and mechanical ventilation in massive PE is considered. Patients with recurrent disease may be candidates for vena caval interruption by placement of an inferior vena cava filter.

Prognosis

Although many patients with PE die before medical attention is received, the rate of mortality due to PE once adequate anticoagulation therapy is initiated is less than 5%.

Oral Health Considerations

The main concern in the provision of dental care for individuals with PE is the patient who is being managed with oral anticoagulants. As a general rule, dental care (including simple extractions) can safely be provided for patients with an international normalized ratio of 2.5. However, it is recommended that any dental care for these patients be coordinated with their primary medical care provider.

Pulmonary Neoplasm

Lung cancer is the leading cause of cancer deaths in both men and women. About 149,000 people in the United States died from lung cancer in 2016.[160] Cigarette smoking remains the primary risk factor for development of lung cancer, with risks now almost identical for both men and women compared with never smokers.[161] Non-small cell types of lung cancers account for about 85% of lung cancers and these include squamous cell, adenocarcinomas, and large cell.[162]

Squamous cell carcinomas account for about one fourth of lung cancers. The neoplasm derives from bronchial epithelial cells that have undergone squamous metaplasia. This is a slow-growing neoplasm that invades the bronchi and leads to airway obstruction.

Adenocarcinomas are the most common type of lung cancer accounting for about 40%. These neoplasms are of glandular origin and develop in a peripheral distribution. They grow more rapidly than squamous cell carcinomas

and tend to invade the pleura. This cancer is not associated with exposure to tobacco smoke.[163]

Large cell carcinomas account for about 10% of lung cancers. They are poorly differentiated tumors that resemble neither squamous cell carcinomas nor adenocarcinomas. They can grow and spread quickly.

Small cell carcinomas account for approximately 15% of all lung cancers. This type of lung cancer has the highest association with smoking, almost never arising in the absence of a smoking history. These derive from neuroendocrine cells in the airways and metastasize rapidly. Most small cell tumors have metastasized prior to diagnosis.[163]

Pathophysiology

Metaplasia of the respiratory epithelium occurs in response to injury, such as that induced by tobacco smoking. With continued injury, the cells become dysplastic, with the loss of differentiating features. Neoplastic change first occurs locally; invasive carcinoma usually follows shortly thereafter.[164]

Clinical and Laboratory Findings

A chronic nonproductive cough is the most common symptom. Sputum production may occur, usually associated with obstructive lesions. Hemoptysis and dyspnea are variably present.[164] Facial edema, cyanosis, and orthopnea indicate the possibility of superior vena cava syndrome, caused by compression of the superior vena cava by tumor. The acute onset of hoarseness may signal tumor compression of the recurrent laryngeal nerve. Shoulder and forearm pain might suggest the presence of Pancoast's tumor, which is found in the apical region of the lungs below the pleura.

Metastatic and paraneoplastic effects are also common. The symptoms of metastasis depend on the sites involved and on the size of the tumor. The bones, the brain, and the liver are common sites of metastasis. Paraneoplastic effects include endocrine abnormalities that are due to tumors that secrete hormones such as antidiuretic hormone, adrenocorticotropic hormone, and parathyroid hormone-related peptides.[165]

Classification

The World Health Organization has differentiated pulmonary neoplasms into histologic types. The major clinical distinction is between small cell types and nonsmall cell types; each type has different therapeutic implications. The above mentioned four major pathologic categories are squamous cell carcinoma, adenocarcinoma, large cell carcinoma, and small cell carcinoma

Diagnosis

Diagnosis is suggested by the history and physical examination. The method of diagnosis of suspected lung cancer depends on the type of lung cancer (i.e., small cell lung cancer or nonsmall cell lung cancer), the size and location of the primary tumor, the presence of metastasis, and the overall clinical status of the patient. CT scanning is the anatomic imaging modality of choice and is performed in virtually all patients with suspected or known lung cancer (Figure 13-9). Other diagnostic modalities include sputum or pleural fluid cytology, excisional biopsy, transthoracic needle aspiration, and bronchoscopy.[166] In recent years, low-dose helical computed tomography (LDCT) for lung cancer screening has been shown to decrease lung cancer and all-cause mortality. The US Preventive Services Task Force currently recommends annual low-dose CT scans for high risk individuals (ages 55 to 80 years who have a 30 pack-year smoking history and

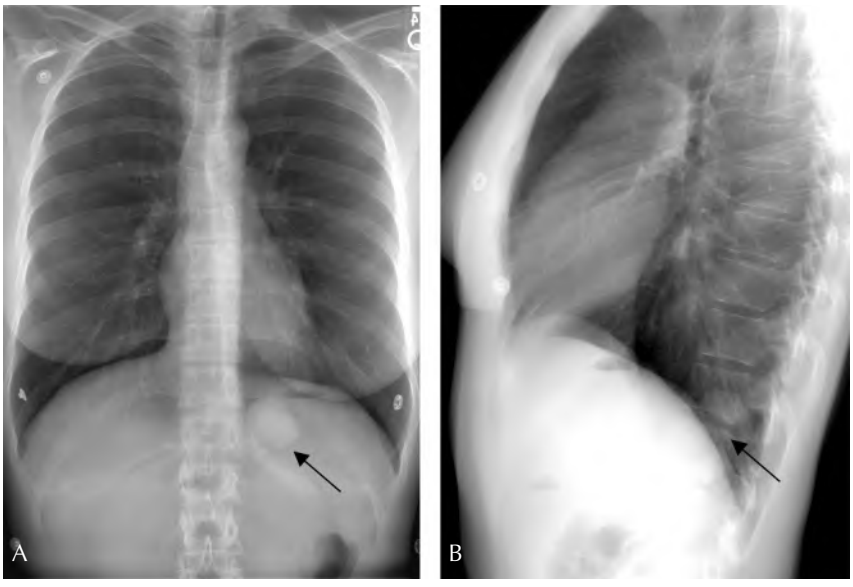

Figure 13-9 Anteroposterior (A) and lateral (B) chest radiographs demonstrate a rounded mass in the medial left costophrenic angle (black arrows) that is seen to be located in the posterior portion of the left lower lobe. This is best seen on the lateral view.

currently smoke or have quit within the past 15 years). Screening can be discontinued once the individual has not smoked for 15 years or there is a limited life expectancy.[167,168]

Management

Complete surgical resection of localized lung cancer offers patients the best chance for cure. However, treatment is based on the stage of the disease and the patient's clinical status. In general, early-stage disease is surgically managed, locally advanced disease is managed with chemotherapy and radiotherapy, and advanced disease is managed with chemotherapy with supportive care or supportive care alone. Radiation therapy is an important palliative measure, especially for patients with superior vena cava syndrome, brain metastases, or bone lesions.

Prognosis

Despite the presence of developed modalities for treatment, the prognosis for patients with lung cancer has remained poor, with the overall 5-year survival being approximately 23%. There is about a 60% 5-year survival when the lung cancer detected is localized. Unfortunately, most pulmonary cancers are found too late for a cure; only about 20% of patients undergo a radical surgical procedure, which is the only curative treatment.[169,170]

Oral Health Considerations

As many lung cancers are associated with smoking, it is important to be vigilant regarding any oral mucosal changes in a patient who has been diagnosed with lung cancer. In addition, with the advent of immunotherapy for various types of lung cancer, it is important to be aware of the type of chemotherapy the patient is receiving and consider these patients as potentially immune compromised (see Chapter 19 "Immunological Diseases").

Diseases of the Cardiovascular System

Peter B. Lockhart, DDS
Yee-Ping Sun, MD

Burket's Oral Medicine, Thirteenth Edition. Edited by Michael Glick, Martin S. Greenberg, Peter B. Lockhart, and Stephen J. Challacombe.

Cardiovascular disease (CVD) is the leading cause of mortality in the world. In 2017, CVD caused an estimated 17.8 million deaths worldwide, representing ~32% of all deaths and 360 million disability-adjusted life years (DALYs) lost.[1] These numbers have climbed steadily both in absolute numbers and relative proportion since 2010. While the global mortality rate from CVD has increased in the past 30 years, the rates of CVD death in high-income countries has decreased and therefore reflects a significant increase in CVD death in low- and middle-income countries. CVD now accounts for the most deaths in all low- and middle-income regions (except in Sub-Saharan Africa where it is the leading cause of death in those >45 years and causes four to five times as many deaths as in high-income countries.[2] As of 2016, CVD remained the leading cause of death in the United States, accounting for ~840,000 deaths. The annual total cost of CVD in 2014–2015 was estimated at $351 billion. It is estimated that in 2019, ~1.1 million Americans will have suffered a new coronary event and ~800,000 will have had a new stroke. This amounts to a coronary event and stroke every 40 seconds. There has been an overall decrease in CVD deaths over the past 30 years in the United States, though gender, socioeconomic, and racial disparities do exist. In particular, it has been estimated that the avoidable CVD death rate in black people is nearly twice as high as in white people.[3]

CVD includes hypertension, coronary artery disease (CAD), valvular heart disease (VHD), congenital cardiovascular defects, congestive heart failure (CHF), congenital cardiovascular defects, heart valve disorders, venous thromboembolic disease, and stroke (Table 14-1).[3] Although these diseases are associated with a high mortality, the associated morbidity and detrimental effect on the quality of life of affected individuals are perhaps even more pronounced, since they affect nearly all populations. This chapter considers common cardiovascular conditions and their implications for the practice of dentistry.

What follows is an overview of the demographics, diagnosis, medical management, and dental management considerations for the more common cardiovascular conditions seen in dental offices.

Table 14-1 Percentage breakdown of deaths attributable to cardiovascular disease in the United States in 2016.

Coronary heart disease	43%
Stroke	17%
Hypertension	10%
Heart failure	9%
Diseases of the arteries	3%
Other	18%

GENERAL CONSIDERATIONS FOR THE DENTAL MANAGEMENT OF THE CARDIAC PATIENT

The high prevalence of cardiac disease in the general population suggests frequent dental management considerations in dental practice. Advances in cardiac surgery and medical management of patients with congenital heart disease (CHD), for example, have resulted in large numbers of adults with a variety of cardiac conditions that may be of concern with regard to stressful, prolonged, or invasive dental procedures. It is therefore important for dentists caring for these patients to understand their cardiac condition as well as medical history.

Multiple longstanding uncertainties and controversies exist concerning the dental management of patients with cardiovascular diseases and conditions. There are, however, multiple guidelines and scientific papers to help dental practitioners with assessment and management issues for specific cardiac patient populations.[4] Additional studies are needed, however, as many of these guidelines are based on small studies and expert opinion.[5] The lack of systematic reviews and formal guidelines does not release the dental healthcare provider from the responsibility to use good clinical judgment in accordance with the provider's training, knowledge base, and experience.

Importance of the Medical History

The patient's medical history should be documented in the patient's chart. Important aspects of the medical history screening include (1) current medications; (2) history of chest pain, arrythmia, or cardiac surgery; (3) indications for antibiotic prophylaxis prior to dental procedures; and (4) primary care physician's and/or cardiologist's name and contact information. For many of these patients, consultation with their primary care physician or cardiologist may be desirable for questions concerning elements in the patient's history that are unclear, the severity of active problems, and potential risks from invasive or stressful dental procedures.

The medical history for patients with cardiac disease or conditions may reveal other medical problems of importance. For example, diabetes mellitus has a direct impact on the progression of CAD and therefore increases the risk of invasive or stressful procedures.[6] The finding of uncontrolled hypertension is of particular concern for patients undergoing dental procedures, and protocols have been proposed to evaluate these patients and carry out dental procedures in the safest manner.[7]

Oral healthcare providers should be aware of medications they prescribe that may have systemic side effects and interact with the patient's medications (e.g., analgesics with anticoagulant properties). Likewise, some cardiovascular medications have side effects that may cause intraoral changes (e.g., oral dryness, gingival overgrowth). Other cardiac medications may have significant implications for dental procedures (e.g., anticoagulants, both antiplatelet therapy and vitamin K antagonists).

Some aspects of dental management are generic to several of the patient populations in this chapter.[8] For example, acquiring blood pressures (BPs) has become standard in many dental practices and it is particularly important for cardiac populations. Additionally, the determination of vital signs prior to dental procedures is an important preventive measure. There is a high prevalence of hypertension in the general population and therefore in dental practices. Although hypertensive crises are extremely rare in the dental office setting, the increased risks associated with painful or stressful procedures support the practice of taking a BP on all new patients and those with significant cardiovascular disease. Many patients will not be aware that they have hypertension and it is important that they be referred to their primary care physician for evaluation.

Given the nature of this patient population, it is desirable for oral healthcare professionals treating patients with cardiovascular disease to be certified in American Heart Association (AHA) basic life support or advanced cardiac life support.[9]

Importance of Preventive Dentistry

Although there may be a weak association between periodontal disease and atherosclerosis, independent of known risk factors (e.g., smoking), a causal link has not been established. Nevertheless, pain and stress from an acute pulpitis or abscess could potentially trigger angina, stroke, or myocardial infarction (MI). Poor oral hygiene is associated with more frequent bacteremia from routine daily activities (e.g., tooth brushing) and this clearly puts some cardiac patients at risk for infective endocarditis.[10,11]

Stress

An overriding focus for dental care is to reduce the risks from long, painful, or stressful dental procedures that increase catecholamine release and induce hemodynamic changes before, during, and following a procedure, to include increased heart rate and BP, and decreased myocardial output. Examples include patients with a history of hypertension, coronary artery bypass grafts (CABG), coronary stents, arrhythmia, and some cardiac medications. Studies have reported that the sound of a dental handpiece alone is enough to increase stress and anxiety.[12] Multiple short appointments may be preferable and premedication with antianxiety agents is commonly used for this purpose. Nitrous oxide/oxygen analgesia can be used for most cardiac patients, though given the mild negative inotropic effect, use in patients with severe left ventricular dysfunction or pulmonary hypertension should be avoided.

Use of Vasoconstrictors for Dental Procedures

Risks from local anesthetics containing epinephrine as a vasoconstrictor are controversial and may be of concern with some cardiac conditions.[13] The benefits of vasoconstrictors (e.g., hemostasis and more profound and prolonged anesthetic effect) likely outweigh the risk of systemic effects from stress-related endogenous epinephrine (e.g., increased heart rate and BP).[14] In the vast majority of stable outpatients with cardiovascular disease, local anesthetics with epinephrine can be used safely. In patients with a very recent MI (within the past month) or history of ventricular arrhythmias (particularly Brugada syndrome if using procaine), it would be reasonable to consult with the patient's cardiologist.[15,16]

Concentrations of epinephrine greater than 1:100,000 are felt to be unnecessary and may carry a higher risk.[17] Clearly, it is important to restrict the total volume of local anesthetics, and especially epinephrine. A small dose of low-concentration epinephrine should not have a significant systemic effect.[14] When using epinephrine, it is important to aspirate, but due to the small diameter of dental anesthetic needles, a negative aspiration does not insure that intravascular injection will not occur.

Nonsteroidal Anti-inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) are effective oral analgesics and anti-inflammatory agents. Their use has been associated, however, with a small but significant increased risk of cardiovascular events. This association is present among all NSAIDs, including both traditional NSAIDs such as diclofenac, ibuprofen, and naproxen as well as selective cyclooxygenase-2 inhibitors such as celecoxib.[18] The risk may be lower with ibuprofen (total daily dose <1200 mg/day) and naproxen (<500 mg/day). The risk appears to be related to duration and dose, though the increased risk can be seen with 8 days.[18] In addition to the risk of cardiovascular events, it is also important to appreciate that use of NSAIDs in patients on antithrombotic medications, including aspirin, clopidogrel, and the direct oral anticoagulants, may also increase the risk of gastrointestinal bleeding.[19] Based on these observations, it is generally recommended that in patients with existing cardiovascular disease, use of nonpharmacologic therapy and acetaminophen be prioritized. There is no adverse cardiovascular risk associated with

use of acetaminophen and the hepatic risk is also extremely low provided the total daily dose is 3–4 g in the absence of significant alcohol intake. If acetaminophen use is not effective, risk–benefit assessment would favor a short course of NSAID use. In patients who are on multiple thrombotic agents, consultation with the treating cardiologist/internist will be important if use is expected to exceed 1 week.

Oral Manifestations of Cardiac Medications

Side effects from cardiac drugs may cause oral mucosal changes. For example, gingival overgrowth can occur with calcium-channel blockers and xerostomia often results from antihypertensive drugs. Altered taste (e.g., metallic) has also been reported with antihypertensives (e.g., an angiotensin-converting enzyme inhibitor, ACEi), and they may be associated with lichenoid reactions. If the side effects are severe enough, a change in antihypertensive medication may avoid the necessity for topical steroids.

HYPERTENSION

Definition, Classification, and Epidemiology

There has been wide variation in the definition of hypertension. The most recent guidelines put forth by the AHA, American College of Cardiology (ACC), and American Society of Hypertension define hypertension as a systolic BP >130 mm Hg or diastolic BP >80 mm Hg.[20] This is in contrast to European Society of Cardiology (ESC) guidelines that have a higher threshold for hypertension definition, with a systolic BP >140 mm Hg or a diastolic BP >90 mm Hg (Table 14-2).[21] Regardless of the precise cut point for defining hypertension, it remains a significant cause of morbidity and mortality worldwide.

Hypertension is classified as primary and secondary. Primary or essential hypertension accounts for ~90%. The precise etiology of primary hypertension is complex and is likely multifactorial, with contributions from genetic factors, age, dietary intake (particularly sodium and potassium), physical inactivity, obesity, and alcohol use. In ~10% of cases, a specific treatable cause of hypertension can be identified; these entities are termed secondary hypertension. The most common causes of secondary hypertension include drug-related causes (in particular NSAIDs, oral contraceptives, and corticosteroids, to name a few), primary renal disease, obstructive sleep apnea, renovascular disease (such as fibromuscular dysplasia), and endocrinologic causes such as a primary hyperaldosteronism (see Table 14-3).

The global prevalence of hypertension was estimated to be ~1.1 billion in 2015 and is estimated to reach 1.5 billion by 2025. From 2013–2016, it was estimated to be present in ~116 million Americans and in 2015, ~150 million across central and eastern Europe. Worldwide, it is estimated to be present in ~30–45% of adults. The high prevalence is consistent across low-, middle-, and high-income countries. The prevalence increases with age, with a prevalence of >60% in those >60 years. Around 35% of patients with hypertension are completely unaware of their diagnosis. The prevalence of hypertension among African Americans is among the highest in the world, with an age-adjusted prevalence of 57.6% in men and 53.2% in women between 2011 and 2016.[20]

Table 14-2 Major guideline definitions for hypertension.

	SBP (mm Hg)		DBP (mm Hg)
ACC/AHA Guidelines			
Normal	<120	and	<80
Elevated	120–129	and	<80
Stage 1 Hypertension	130–139	or	80–89
Stage 2 Hypertension	≥140	or	≥90
ESC Guidelines			
Optimal	<120	and	<80
Normal	120–129	and/or	80–84
High normal	130–139	and/or	85–89
Grade 1 hypertension	140–159	and/or	90–99
Grade 2 hypertension	160–179	and/or	100–109
Grade 3 hypertension	≥180	and/or	≥110
Isolated systolic hypertension	≥140	and	<90

ACC, American College of Cardiology; AHA, American Heart Association; DBP, diastolic blood pressure; ESC, European Society of Cardiology; SBP, systolic blood pressure.

Cardiovascular Risk Association

In 2015, hypertension was the leading global contributor to premature death, accounting for ~10 million deaths and over 200 million DALYs. In addition, despite advances in diagnosis and treatment, the DALYs attributable to hypertension have increased by 40% since 1990. Hypertension has a clear independent and continuous relationship with the incidence of stroke (both hemorrhagic and ischemic), MI, sudden cardiac death, heart failure, peripheral arterial disease, and renal disease. There is also increasing evidence linking hypertension with atrial fibrillation, as well as cognitive decline and dementia. Increases in both systolic and diastolic BP have been associated with adverse cardiovascular events, though elevated systolic BP is more predictive in older patients (>50 years) as opposed to elevated diastolic BP, which is more predictive in younger patients (<50 years). Many adult patients

Table 14-3 Causes of secondary hypertension.

Medication-related
• Alcohol
• Angiogenesis inhibitors (e.g., bevacizumab)
• Amphetamines
• Antidepressants (e.g., monoamine oxidase inhibitors, selective norepinephrine reuptake inhibitors, tricyclic antidepressants)
• Atypical antipsychotics (e.g., clozapine, olanzapine)
• Caffeine
• Cocaine
• Corticosteroids (systemic)
• Decongestants (e.g., phenylephrine and pseudoephedrine)
• Herbal supplements (e.g., Ma Huang, St. John's wort)
• Immunosuppressants (e.g., cyclosporine)
• Nonsteroidal anti-inflammatory drugs
• Oral contraceptives
• Tyrosine kinase inhibitors (e.g., sunitinib, sorafenib)
Renal parenchymal disease
Renovascular disease
• Fibromuscular dysplasia (more common in younger patients)
• Atherosclerotic disease
Obstructive sleep apnea
Endocrinologic causes
• Primary hyperaldosteronism
• Thyroid dysfunction
• Pheochromocytoma
• Cushing's syndrome
• Primary hyperparathyroidism
• Congenital adrenal hyperplasia
• Mineralocorticoid excess syndromes other than primary aldosteronism
• Acromegaly
Aortic coarctation

with hypertension have other CVD risk factors (see Table 14-4). Among patients with hypertension in the United States in 2009–2012, 63% had hypercholesterolemia, 50% were obese, 27% had diabetes, 16% were current smokers, and 16% had chronic kidney disease (CKD).

Diagnostic Evaluation

Diagnosis

Most patients with hypertension are asymptomatic and the sequelae of hypertension are typically seen years after sustained exposure. Because of this, early and accurate diagnosis is critical. BP assessment in the office setting is relatively easy, but often results in misleading assessments. To accurately assess BP in the office, careful attention needs to be paid to appropriate patient preparation, patient positioning, measurement technique, and documentation (see Table 14-5). Before a diagnosis is made, multiple measurements should be taken,

Table 14-4 Cardiovascular risk factors common in patients with hypertension.

Modifiable Risk Factors	Relatively Fixed Risk Factors
• Cigarette smoking	• Chronic kidney disease
• Diabetes	• Family history
• Dyslipidemia/ hypercholesterolemia	• Increased age
• Obesity	• Low socioeconomic and/or educational status
• Physical inactivity	• Male sex
• Poor diet	• Obstructive sleep apnea
	• Psychosocial stressors

Source: Adapted from Whelton PK, Carey RM, Aronow WS, et al. 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA guideline for the prevention, detection, evaluation, and management of high blood pressure in adults: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. *J Am Coll Cardiol*. 2018;71(19):e127–e248.

Table 14-5 Appropriate steps to accurate in-office blood pressure (BP) measurements. Proper technique is key to an accurate BP assessment. Improper technique has been well demonstrated to lead to inaccurate BP measurements.

Key Steps for Proper BP Measurements	Specific Instructions
Step 1: Properly prepare the patient	1) Have the patient relax, sitting in a chair (feet on floor, back supported) for > 5 min 2) The patient should avoid caffeine, exercise, and smoking for at least 30 min before measurement 3) Ensure patient has emptied his/her bladder 4) Neither the patient nor the observer should talk during the rest period or during the measurement 5) Remove all clothing covering the location of cuff placement 6) Measurements made while the patient is sitting or lying on an examining table do not fulfill these criteria
Step 2: Use proper technique for BP measurements	• Use a BP measurement device that has been validated, and ensure that the device is calibrated periodically • Support the patient's arm (e.g., resting on a desk) • Position the middle of the cuff on the patient's upper arm at the level of the right atrium (the midpoint of the sternum) • Use the correct cuff size, such that the bladder encircles 80% of the arm, and note if a larger or smaller than normal cuff size is used • Either the stethoscope diaphragm or bell may be used for auscultatory readings

(*Continued*)

Table 14-5 (Continued)

Step 3: Take the proper measurements needed for diagnosis and treatment of elevated BP/hypertension	• At the first visit, record BP in both arms. Use the arm that gives the higher reading for subsequent readings • Separate repeated measurements by 1–2 min • For auscultatory determinations, use a palpated estimate of radial pulse obliteration pressure to estimate SBP. Inflate the cuff 20–30 mm Hg above this level for an auscultatory determination of the BP level • For auscultatory readings, deflate the cuff pressure 2 mm Hg per second, and listen for Korotkoff sounds
Step 4: Properly document accurate BP readings	• Record SBP and DBP. If using the auscultatory technique, record SBP and DBP at onset of the first Korotkoff sound and disappearance of all Korotkoff sounds, respectively, using the nearest even number • Note the time of most recent BP medication taken before measurements
Step 5: Average the readings	Use an average of ≥ 2 readings obtained on ≥ 2 occasions to estimate the individual's level of BP
Step 6: Provide BP readings to patient	Provide patients the SBP/DBP readings both verbally and in writing

BP, blood pressure; DBP, diastolic blood pressure; SBP, systolic blood pressure.

both at the same visit and averaged over several visits ideally. Since the ideal conditions for in-office measurement are often practically challenging, the use of ambulatory blood pressure monitoring (ABPM) can also be helpful. These monitors are typically programmed to obtain readings every 15–30 minutes throughout the day and every 15–60 minutes in the evening. Testing occurs over a 24-hour period and occurs while patients participate in their normal daily activities. ABPM is particularly helpful in identifying both white-coat hypertension (defined as hypertension in the office setting but no hypertension while at home) as well as masked hypertension (defined as no hypertension in the office but hypertension while at home). While data surrounding the impact of white-coat hypertension on CVD are conflicting (though the majority suggest no increased risk), the risk of masked hypertension is similar to that seen with sustained hypertension.

Clinical Evaluation

The three main goals of the medical evaluation of patients with hypertension are to (1) identify treatable (secondary) or curable causes; (2) assess the impact of persistently elevated BP on target organs; and (3) estimate the patient's overall risk profile for the development of CVD. A routine history and physical examination should be performed, though it is important to note that making a diagnosis of hypertension is beyond the scope of practice of dentistry. The history should focus on the duration of the hypertension and any prior treatment. Asking the patient about the duration of their high BP may be misleading, as in many cases the patient will not have had a BP measurement for many years prior to the discovery of hypertension. Symptoms of organ dysfunction, lifestyle habits, diet, and psychosocial factors should be included. The main goals of the physical examination are to accurately confirm the diagnosis of hypertension, identify signs of end-organ involvement, and evaluate potential causes of secondary hypertension (see Table 14-3). These types of examinations should only be performed by trained and experienced healthcare providers. Once the diagnosis of hypertension is made, it is recommended that patients undergo laboratory testing with measurement of fasting blood glucose, complete blood count, lipid prolife, serum creatinine, sodium, potassium, calcium, thyroid-stimulating hormone, and urinalysis.[20] Electrocardiogram is also recommended and may show signs of left atrial enlargement, left axis deviation, and abnormalities suggestive of left ventricular hypertrophy. Cardiac arrhythmias such as atrial fibrillation may also be seen. Transthoracic echocardiography can be considered in patients with a diagnosis of hypertension. In addition to providing a more sensitive assessment of left ventricular hypertrophy (LVH) and left atrial dilation, it also provides information on left ventricular systolic and diastolic function, valvular function, estimates on pulmonary artery pressures, and can serve as a screening for the presence of aortic coarctation, another potential secondary cause of upper extremity hypertension. The identification of LVH is important as it is an independent predictor of mortality in patients with hypertension. Hypertrophy of the ventricle initially results in the impairment of left ventricular relaxation (diastolic function) and can ultimately progress to weakening of the myocardial pumping function (systolic dysfunction). Impairment in both diastolic and systolic function can result in clinical signs of CHF.

Management

Management should start with lifestyle modifications, including weight reduction, adoption of the DASH (Dietary Approaches to Stop Hypertension) diet, sodium restriction, increased potassium intake, regular physical activity, and reduction in or cessation of alcohol consumption (Table 14-6). Careful attention should be paid to the patient's current medication list during history-taking and concerted efforts should be made to reduce the use of potentially

Table 14-6 Nonpharmacologic management of hypertension.

	Intervention	Recommendation	Approximate Decrease in SBP in Hypertensive Patients
Weight loss	Weight/body fat	Best goal ideal body weight, but aim for 1 kg reduction for overweight adults. Expected about 1 mm Hg reduction for every 1 kg in weight loss	5 mm Hg
Healthy diet	DASH dietary pattern	Consume diet rich in fruits, vegetables, whole grains, and low-fat dairy products with reduced content of saturated and total fat	11 mm Hg
Reduced intake of dietary sodium	Dietary sodium	Optimal goal is <1500 mg/d, but aim for at least 1000 mg/d reduction	5–6 mm Hg
Enhanced intake of dietary potassium	Dietary potassium	Goal 3500–5000 mg/dL, ideally through consumption of a diet rich in potassium	4–5 mm Hg
Physical activity	Aerobic	90–150 min/week	5–8 mm Hg
	Dynamic resistance	90–150 min/week	4 mm Hg
	Isometric resistance	3 sessions/week	5 mm Hg
Moderation in alcohol intake	Alcohol consumption	Reduce alcohol intake (men ≤2, women ≤1 drink(s) daily)	4 mm Hg

DASH, Dietary Approaches to Stop Hypertension; SBP, systolic blood pressure
Source: Adapted from Whelton PK, Carey RM, Aronow WS, et al. 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA guideline for the prevention, detection, evaluation, and management of high blood pressure in adults: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. *J Am Coll Cardiol*. 2018;71(19):e127–e248.

offending medications if clinically possible. Adoption of these changes can be challenging for patients practically. Importantly, even with 100% adherence to these changes, many patients will still require pharmacologic therapy.[20]

There are several classes of antihypertensive medications. The results of an increasing number of trials suggest that at the same level of BP control, most antihypertensive drugs provide similar degrees of cardiovascular protection. In those with uncomplicated hypertension, beginning with a low dose of a thiazide diuretic (e.g., 12.5–25 mg of hydrochlorothiazide or 25–50 mg of chlorthalidone) has the advantages of very low cost and low risk of metabolic complications such as hypokalemia, lipid abnormalities, and hyperuricemia. Use of an ACEi, angiotensin receptor blocker (ARB), or a calcium-channel blocker can also be considered as first-line agents. In patients whose BPs are markedly elevated at first diagnosis (systolic BP >20 mm Hg above target or diastolic BP >10 mm Hg), initiation of a two-drug approach is very reasonable. If the patient remains hypertensive on a thiazide diuretic, ACEi/ARB, and calcium-channel blocker, use of an aldosterone antagonist (such as spironolactone or eplerenone) or a beta-blocker, particularly one with some degree of alpha blockade (such as a carvedilol), can be added as second-line options. It is important to note that certain factors will affect clinical decision-making in the pharmacologic management of hypertension, including ischemic heart disease, heart failure, CKD, diabetes, atrial fibrillation, and race/ethnicity (Table 14-7).[20]

The role of education and the importance of patient contact are paramount in successfully treating hypertension. Self-recorded measurements and ambulatory BP monitoring aid in the physician's titration of medications and monitoring of the 24-hour duration of action of antihypertensive agents. The monitoring of BP by oral healthcare providers will therefore support the overall medical care of their hypertensive patients.

Dental Management Considerations for Patients with Hypertension

Patients with elevated BP are potentially at increased risk for adverse events in a dental office setting, particularly if their BP is poorly controlled or if there is target organ disease involvement (heart, brain, kidney, peripheral arteries).[7] However, the absence of target organ disease does not mitigate a careful evaluation and treatment of patients within safe and appropriate parameters of care. The primary concern for these patients is precipitating a hypertensive crisis, stroke, or MI. Poor compliance with antihypertensive medications and diet is a common problem, and dentists can help by reinforcing the importance of following medical advice and guidelines (Tables 14-4 and 14-5). Dental management guidelines have been proposed based on the medical model for assessment, risk stratification, and treatment of patients with hypertension.[22–24]

Side effects of antihypertensive medications vary and can include orthostatic hypotension, synergistic activity with

Table 14-7 Pharmacologic management of hypertension in specific patient groups.

	Antihypertensive Preference
Ischemic heart disease	• Beta-blockers favored • Dihydropyridines (amlodipine and nifedipine) can also be used to treat anginal symptoms
Heart failure with reduced ejection fraction	• Beta-blockers including metoprolol, carvedilol, and bisoprolol • ACEis or ARBs • Aldosterone antagonists such as spironolactone or eplerenone • Sacubitril-valsartan • Loop diuretics more useful at managing volume status • Non-dihydropyridine calcium-channel blockers (verapamil and diltiazem) should be avoided
Chronic kidney disease	• ACEis or ARBs
Diabetes	• ACEis or ARBs
Atrial fibrillation	• Beta-blockers to provide concomitant rate control • Non-dihydropyridine calcium-channel blockers (verapamil and diltiazem) to provide concomitant rate control • ARBs may be associated with reduction in atrial fibrillation recurrence
African American	• Thiazide diuretics and/or dihydropyridine calcium-channel blockers should be first-line therapy • Multidrug regimens are often necessary
Pregnant women or those contemplating pregnancy	• Use of methyldopa, labetalol, and nifedipine is safe and well-studied in this population • ACEis and ARBs should not be used

ACEi, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker.

narcotics, and potassium depletion. Although safe limits for invasive dental procedures cannot be strictly defined, and they are largely based on an individual patient's overall medical condition, there arc general guidelines depending on whether patients have prehypertension, stage one or stage two hypertension, and target organ disease (Table 14-2). Elective treatment should be avoided if the BP is significantly above the patient's baseline or if it is >180 mm Hg systolic or >100 mm Hg diastolic. If patients have any symptoms potentially related to hypertension, such as chest pain, headache, or focal neurologic symptoms, elective procedures should be canceled. For patients who have an urgent dental problem, it may be desirable to remove the source (e.g., abscessed tooth) if the patient has mildly elevated BP, but if significantly elevated, oral pain and infection can usually be well managed pharmacologically until the BP is brought under control. Patients may have somewhat elevated BP from pain and/or anxiety and they may have some lowering of their BP after local anesthesia, but this is unpredictable.

CORONARY ARTERY DISEASE

Definition and Epidemiology

CAD accounts for approximately 30%–50% of all cases of CVD in the United States. Almost 7% of or ~18 million Americans >20 years of age have CAD (7.4% in males and 6.2% in females). In 2016, CAD-related mortality was ~360,000 individuals, with mortality directly due to an MI ~110,000. It is estimated that each year 730,000 Americans will have a new coronary attack, and 355,000 will have recurrent attacks. While CAD remains a major cause of morbidity and mortality, gains have been made, with a reduction in relative and absolute rates of CAD-related deaths by ~32% and 15%, respectively.[3]

Pathophysiology of Stable Coronary Artery Disease versus Acute Coronary Syndromes

CAD is characterized by progressive obstruction of the epicardial coronary arteries. Atherosclerosis is the pathophysiologic process responsible for the development of these obstructions and begins as a fatty streak in early adolescence. The lesions progress over decades and develop into frank atherosclerotic plaques. This plaque is characterized by disruption of the vascular endothelium, extracellular lipid accumulation, smooth muscle cell migration/proliferation, and inflammation.[25] Atherosclerosis may affect any vascular bed, including the coronary, cerebral, renal, mesenteric, and peripheral vascular systems. In the coronary circulation, progressions in these plaques can result in two distinct clinical entities: stable CAD and an acute coronary syndrome (ACS). In stable CAD, there is gradual progression of plaque growth leading to arterial luminal obstruction over years. Clinically, this manifests as progressive exertional angina due to the mismatch in myocardial oxygen demand and supply with exertion. ACSs, in contrast, are the result of plaque instability. In ACS, the unstable plaque (either obstructive or nonobstructive) ruptures and acute thrombosis occurs, leading to an abrupt decrease in myocardial oxygen delivery. If blood flow is not restored (either spontaneously, pharmacologically, or mechanically), this can result in myocardial injury, termed a myocardial infarction.[26] While these two entities are the clinical result of coronary atherosclerosis, their management differs greatly, thereby making the clinical distinction critical in practice.

Risk Factors

The development of coronary atherosclerosis is influenced by several risk factors, including dyslipidemia, systemic hypertension, diabetes, cigarette smoking, diet, physical activity, obesity, family history, and inflammation. The impact of each of these factors upon CAD risk, however, differs among different subgroups. For example, diabetes and a low high-density lipoprotein (HDL) cholesterol/total cholesterol ratio have a greater impact in women, cigarette smoking has more of an impact in men, and systolic BP and isolated systolic hypertension are major risk factors independent of age or sex. Risk factor assessment is useful as a guide to therapy for dyslipidemia, hypertension, and diabetes; multivariable prediction rules can be used to help estimate risks for subsequent coronary disease events. Current guidelines recommend using the 10-year risk of cardiovascular events as a basis for initiating risk factor–modifying therapy for lipid abnormalities.[27] Based on the increased risk conferred by the various CAD risk factors, concepts of "normal" have continued to evolve from "usual" or "average" to more biologically optimal values associated with long-term freedom from disease. As a result, optimal BP, blood glucose, and lipid values have been continually revised downward in the past 20 years.

Lipids

The total cholesterol concentration in serum is a major and clear-cut risk factor for CAD. In the Multiple Risk Factor Intervention Trial (MRFIT) of more than 350,000 middle-aged American men, the risk of CAD progressively increased with higher values of serum total cholesterol.[28] In addition to total cholesterol, data from the Framingham Heart Study demonstrated that HDL is strongly inversely associated with CAD risk, low-density lipoprotein (LDL) is strongly directly associated with CAD risk, and triglycerides are mildly associated with CAD risk.[29] In the nearly 35 years since the initial observations in the MRFIT trial, it has become clear that there is a linear relationship between LDL reduction and adverse event reduction, such as for every 38 mg/dL reduction in LDL there is ~23% reduction in major cardiovascular events.[30] In the highest-risk population of patients who have suffered multiple cardiac events already, dramatic LDL reductions to as low as 30 and 50 mg/dL have confirmed that this relatively linear relationship holds true even after very low LDL levels.[31–33]

Based on these studies, there has been a paradigm shift away from a single appropriate cut point for lipid therapy, toward tailoring therapy based on overall risk. The most recent guidelines have recommended assessing the overall cardiovascular risk using the Atherosclerotic Cardiovascular Disease (ASCVD) algorithm.[27] In patients who have clinical atherosclerotic cardiovascular disease, including established CAD, stroke, or peripheral vascular disease, use of a high-intensity statin (atorvastatin 40–80 mg daily or rosuvastatin 20–40 mg daily) is recommended. Diabetes is considered an ASCVD equivalent and in those patients use of at least a moderate-intensity statin is strongly recommended. In those patients who have an elevated 10-year risk (>7.5%) of an ASCVD event as predicted by the ASCVD risk calculator, use of a high-intensity statin is recommended. For all others, if the LDL is >190 mg/dL, treatment with a high-intensity statin is recommended. For intermediate-risk patients (5–7.5% 10-year risk), treatment with a moderate-intensity statin is recommended. For low-risk patients (<5% risk), the therapy should be tailored through a shared decision-making process (Figure 14-1).

Hypertension

As previously discussed, hypertension and LVH are well-established risk factors for CAD morbidity and mortality. In patients with established CAD, careful management of hypertension is key to preventing recurrent ischemic events.

Glucose Intolerance and Diabetes Mellitus

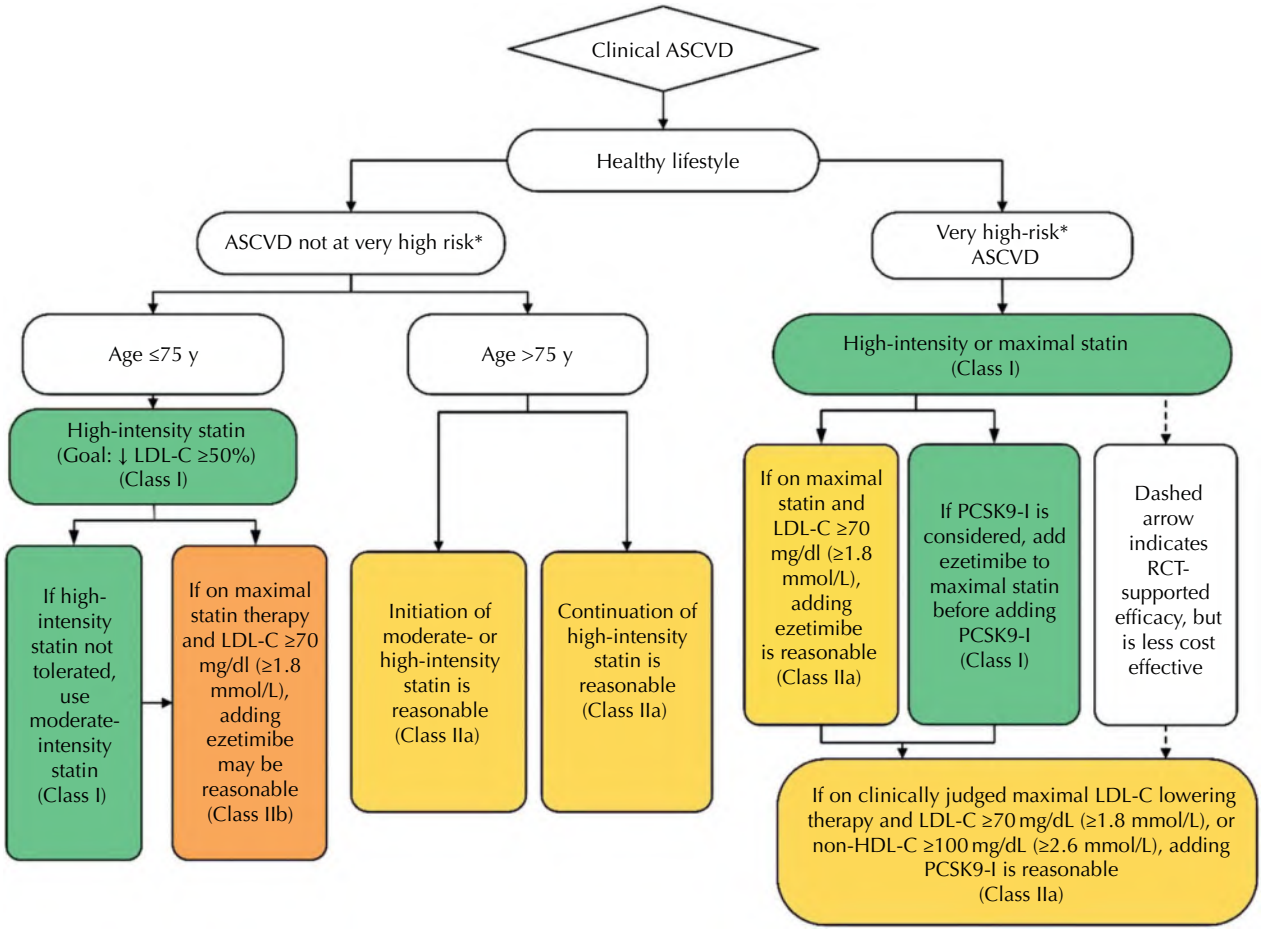
Insulin resistance, hyperinsulinemia, and glucose intolerance all appear to promote atherosclerosis. As diabetic individuals have a greater number of additional atherogenic risk factors (including hypertension, hypertriglyceridemia, increased cholesterol-to-HDL ratio, and elevated levels of plasma fibrinogen) than do nondiabetic individuals, the CAD risk for diabetic persons varies greatly with the severity of these risk factors. Overall, patients with diabetes are at ~2.6-fold increased risk for cardiovascular death than patients without diabetes.[34] Thus, aggressive treatment of these additional risk factors may help reduce cardiovascular events in diabetic patients.

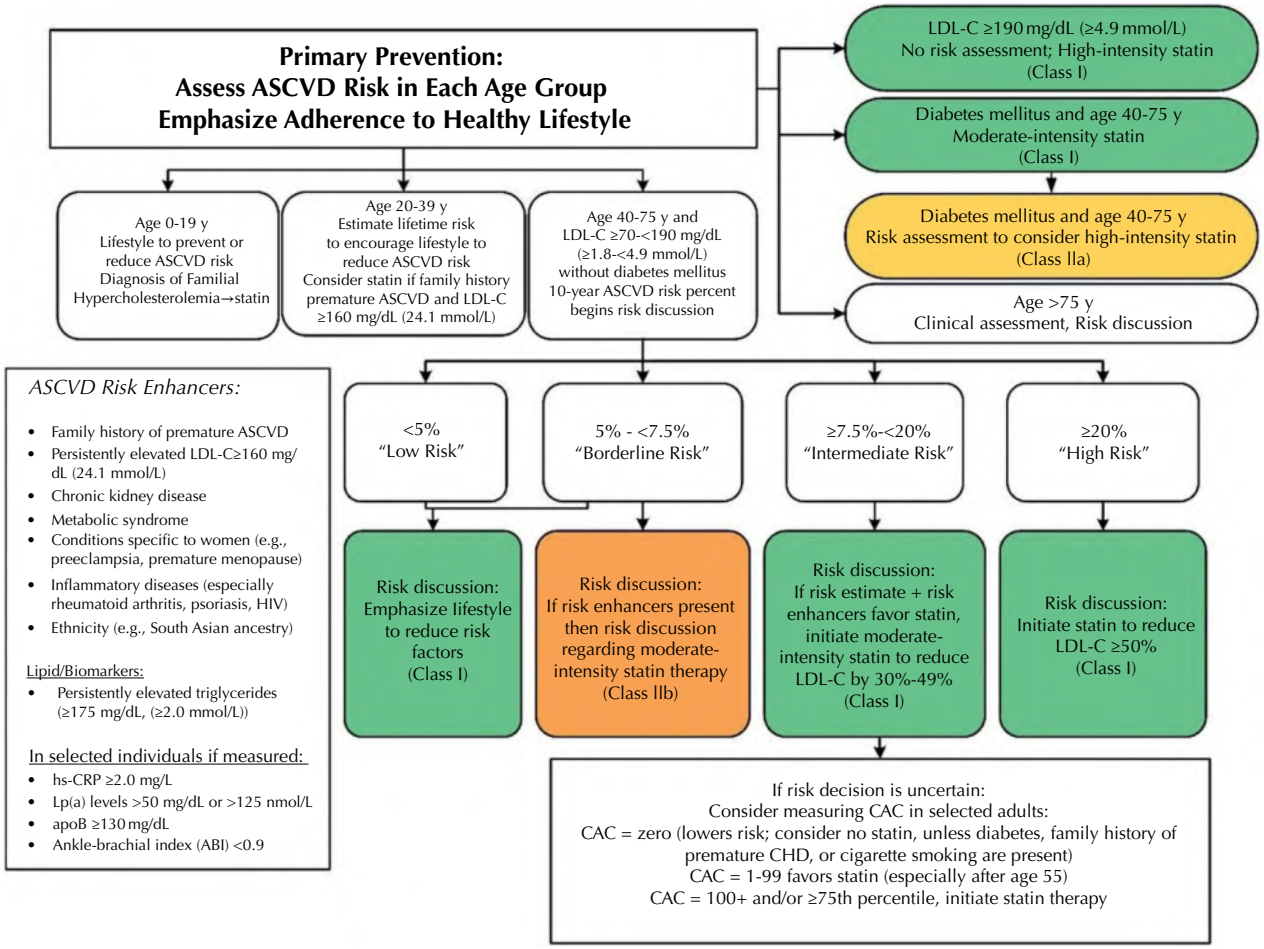
Cigarette Smoking

Cigarette smoking is an important and potentially reversible risk factor for CAD and CAD events such as MI. For both men and women, the risk increases with increasing tobacco consumption.[35] For example, in one study the risk of MI was sixfold increased for women and threefold increased for men who smoked at least 20 cigarettes per day, compared to nonsmoking control patients.[35]

Lifestyle and Dietary Factors

Dietary factors such as a high-calorie, high-fat, and high-cholesterol diet contribute to the development of other risk factors, such as obesity, hyperlipidemia, and diabetes, which predispose to CAD. Red meat consumption too is associated with an increased risk of total, cardiovascular, and cancer mortality.[36] Conversely, a diet that emphasizes fruit and





vegetables, the increased intake of dietary fiber, and the so-called Mediterranean-style diet rich in olive oil and nuts are associated with a decreased risk of CAD.[37,38] Weight gain and obesity directly worsen the major cardiovascular risk factors, whereas weight loss appears to improve them.[39] Epidemiologic data indicate that the moderate intake of alcohol has a cardioprotective effect.[40–42] Elevation of serum HDL levels appears to be the primary mechanism by which alcohol imparts this benefit. It should be stressed that the benefits of alcohol apply only to moderate consumption and are not seen in those who "abuse" alcohol. Furthermore, the protective effects of alcohol do not apply to the risk of hemorrhagic stroke, death due to trauma, or cancer, all of which may be increased in individuals who consume greater amounts of alcohol.

Exercise

Even a moderate degree of exercise appears to have a protective effect against CAD.[43] In one study of middle-aged men, participation in moderately vigorous physical activity was associated with a 23% lower risk of death than that associated with a less active lifestyle, and this improvement in survival was equivalent and additive to other lifestyle measures such as smoking cessation, hypertension control, and weight control.[44] Mechanisms that could account for the benefits of exercise include elevated serum HDL cholesterol levels, reduced BP, weight loss, and a lower incidence of insulin resistance.

Obesity

As already stated, obesity is associated with the development of several risk factors for CAD, including systemic hypertension, impaired glucose metabolism, insulin resistance, hypertriglyceridemia, reduced HDL cholesterol, and elevated fibrinogen. Data from the Framingham Heart Study, the Nurses' Health Study, and other studies have shown the risk of developing CAD that is associated with obesity.[45–47] The distribution of body fat appears to be an important determinant, as patients with abdominal (central) obesity are at greatest risk for subsequent CAD.[48] Patients with central obesity, elevated levels of serum triglycerides, and (to a lesser degree) LDL cholesterol, low HDL cholesterol, insulin resistance, and hypertension are classified as having atherogenic dyslipidemia (metabolic syndrome).[49] This syndrome is more difficult to treat and is associated with a worse prognosis than is an isolated increased LDL level.

Inflammation and Endothelial Dysfunction

Endothelial dysfunction appears to be an early step in the atherosclerotic process and may result from dyslipidemia, hypertension, and diabetes. Recent studies have suggested that coronary artery endothelial dysfunction predicts the long-term progression of atherosclerosis and an increased incidence of cardiovascular events. C-reactive protein (CRP) is an inflammatory biomarker that has been shown to be predictive of cardiovascular events. The JUPITER study has demonstrated that in apparently healthy persons without hyperlipidemia but with elevated CRP levels, rosuvastatin reduced the incidence of major cardiovascular events independent of the LDL-lowering impact.[50] The benefit of statin therapy observed in the JUPITER trial is likely reflective of the plaque-stabilizing effects of statins that have been previously observed.[51] To further assess the role of inflammation in adverse cardiovascular events, the CANTOS trial randomized high-risk patients who had already experienced an MI with elevated CRP to treatment with canakinumab (a monoclonal antibody targeting interleukin-1-beta approved for treatment of several rheumatologic disorders) versus placebo.[52] Treatment with canakinumab in this high-risk group who were already on high-intensity statin therapy resulted in a significant decrease in recurrent cardiovascular events. This benefit, however, came at the expense of life-threatening infection. Due to the high rates of these fatal infections, use of canakinumab is not recommended in the clinical management of these patients, though it does provide further evidence supporting the role of inflammation in cardiovascular disease. While additional studies are clearly necessary, there is a great deal of optimism in targeting inflammation as a novel pathway in the management of cardiovascular disease.

Figure 14-1 Atherosclerotic Cardiovascular Disease (ASCVD) management algorithm. Current guidelines recommend lipid management based on the presence (secondary prevention) or absence (primary prevention) of clinical ASCVD. (a) In patients with clinical ASCVD, moderate- or high-intensity statin is recommended. Addition of ezetimibe or a PCSK9 inhibitor can be considered in very high-risk patients. (b) In patients without clinical ASCVD, current guidelines recommend assessment of 10-year cardiovascular risk in those 40–75 years old and lifetime risk in those 20–39 years old using the ASCVD risk calculator. In patients with LDL >190 mg/dL, high-intensity statin therapy is recommended. In those with diabetes, moderate-intensity statin is recommended. If neither of these is present, consideration for therapy should be based on the 10-year risk as identified by the ASCVD risk calculator with inclusion of risk enhancers. If the risk decision remains uncertain, coronary artery calcium scoring can be considered. CHD, congenital heart disease; CRP, C-reactive protein; HDL, high-density lipoprotein; LDL, low-density lipoprotein; PCSK9, proprotein convertase subtilisin/kexin type 9; RCT, randomized control trial.

Risk Factor Modification

When atherosclerosis is identified, the immediate goals are to relieve symptoms through improvement of organ perfusion and to prevent plaque rupture. Aggressive risk factor modification to retard or prevent ongoing atherosclerosis is among the most important parts of long-term management. Smoking cessation, meticulous control of hypertension and diabetes, weight management, and aggressive lipid-lowering therapy are recommended. Lipid-lowering therapy with 3-hydroxy-3-methylglutaryl coenzyme A (HMG COA) reductase inhibitors has been shown to reduce mortality in patients with CAD, even when total cholesterol and LDL are only modestly elevated, which may reflect the anti-inflammatory role of statins in preventing plaque rupture.[53,54] A low-fat, low-calorie diet may result in improved serum lipid levels as well as improved weight management, and a cardiovascular exercise program may result in reduced morbidity and mortality from CHD.[55]

Diagnosis

The diagnosis of chronic CAD is usually suspected from the clinical presentation. A history of exertional or resting symptoms including (but not limited to) chest tightness, jaw discomfort, left arm pain, dyspnea, or epigastric distress should raise the suspicion of CAD. Many patients deny "chest pain" per se, but the clinician should recognize subtle symptoms (such as dyspnea, diaphoresis, or epigastric distress) that may limit activity. Some patients with CAD have no symptoms that are identified during careful questioning, but have "silent ischemia" that is demonstrated by noninvasive testing.[55] Careful attention should be directed to the risk factor profile for CAD, since the probability of atherosclerosis is increased in these individuals.[56] A statistical extrapolation of the most recent National Health and Nutrition Examination Survey (NHANES) data suggested that oral healthcare professionals can effectively screen and identify patients that are unaware of their risk for developing CHD.[57]

Diagnostic testing begins with baseline 12-lead electrocardiography (ECG). Unfortunately, this is neither sensitive nor specific for the presence of CAD or prior MI. The presence of abnormal Q waves on the ECG may suggest prior MI, though these are not invariably present, and often only nonspecific changes of the ST segments or T waves are observed in patients with chronic CAD. Even a normal ECG does not exclude the presence of severe or even life-threatening CAD. Stress testing, often combined with nuclear or echocardiographic imaging modalities, remains the mainstay of a noninvasive diagnosis, though there is increasing evidence for use of cardiac computed tomography angiography (CTA) as the primary modality.[58–60] Exercise testing with electrocardiographic monitoring is associated with a relatively low sensitivity and specificity for the detection of CAD and should be performed only if the resting ECG is normal. In low-risk patients, however, a negative exercise ECG strongly predicts a favorable clinical outcome.[61] Even in patients with an intermediate to high clinical risk of CAD, achieving a relatively high workload during exercise with no ischemic ST depression in the ECG is also associated with a very low prevalence of significant ischemia.[62]

Single photon emission computed tomography myocardial perfusion imaging (SPECT-MPI) with agents such as thallium 201 and technetium 99m sestamibi is used to assess coronary perfusion at rest and with physical stress. Since the uptake of these agents into the myocardium is an active process, ischemic or infarcted cells exhibit a reduced or absent uptake. A >70% stenosis of a coronary artery typically is associated with decreased myocardial perfusion on the stress images, but with normal myocardial perfusion at rest. This reversible defect is the perfusion pattern associated with stress-induced myocardial ischemia. A fixed defect demonstrates reduced myocardial perfusion both at rest and on exercise. Stress echocardiography detects myocardial ischemia by demonstrating regional differences in left ventricular contractile function during stress. Both myocardial perfusion imaging and stress ECG offer greater sensitivity and specificity than does exercise ECG alone, and they provide important prognostic information as well.

In patients who cannot exercise, exercise can be simulated with use of either coronary vasodilator agents (adenosine, dipyridamole, or regadenoson) or dobutamine, which directly increases myocardial contractility and heart rate. Vasodilator stress tests must be paired with imaging modalities that look directly at myocardial perfusion and therefore can be paired with SPECT-MPI, positron emission tomography (PET), and cardiac magnetic resonance imaging (MRI). Both PET and MRI are superior to SPECT in their sensitivity and specificity.[63,64] While both PET and MRI have superior diagnostic accuracy, they are costlier, not widely available, and are typically reserved for very high-risk patients.

Cardiac CTA has emerged as an important diagnostic tool. Imaging the coronary arteries poses significant challenges owing primarily to the relatively small vessel caliber (2–4 mm) and normal cardiac motion. As such, it requires specialized scanners and protocols to achieve optimal images. It is now, however, a widely available method for detecting CAD, with an excellent sensitivity for detecting clinically significant stenoses. In addition, it has also been shown to be more cost-effective than stress testing.[65] Given that it is a purely anatomic test, however, it does not address the potential physiologic significant of the obstruction, nor does it estimate the ischemic burden, both of which are key in decision-making. When compared to an initial up-front strategy of stress testing, data have been mixed, with the

SCOT-HEART trial demonstrating that cardiac computed tomography (CT) was superior, whereas the PROMISE trial showed no difference.[59] The benefit in the SCOT-HEART trial has been attributed to implementation of more aggressive therapy in patients who were found to have nonobstructive CAD that would have been otherwise missed on a functional test. Because of the apparent clinical equipoise paired with the decreased cost, the UK National Institute for Health and Care Excellence (NICE) guidelines have advocated cardiac CTA as the first-line diagnostic test.[66] While this has not yet become the gold standard globally, it has nonetheless emerged as a very useful tool in select patients presenting with symptoms concerning for CAD.

Despite the multiple noninvasive tools that are currently available to evaluate for the presence of CAD, coronary angiography is often needed to define the anatomy and to assist in planning an appropriate management strategy for selected intermediate- to high-risk patients. At the time of coronary angiography, a purely anatomic assessment, validated functional testing (fractional flow reserve or FFR, instant wave-free ratio or iFR, and resting full-cycle ratio or RFR) can be performed to help assess the physiologic significance of an observed stenosis if indicated.[67–69]

Management

Medical Therapy

The management of chronic, stable CAD depends on several clinical factors, including the extent and severity of ischemia, exercise capacity, prognosis based on exercise testing, overall left ventricular (LV) function, and associated comorbidities such as diabetes mellitus. Patients with a small ischemic burden, normal exercise tolerance, and normal LV function may be safely treated with pharmacologic therapy. The front line of modern medical therapy includes the selected use of aspirin, beta-blockers, ACEis, and statins. These agents have been shown to reduce the incidence of subsequent MI and death.[70,71] Nitrates, calcium-channel blockers, and ranolazine may be added to the primary agents to relieve angina in selected patients.

Revascularization

In the absence of severe disease, percutaneous coronary intervention (PCI) has been shown to improve symptoms of chronic ischemia without preventing death or MI.[72] On the basis of available data, therefore, it seems appropriate to prescribe optimal medical therapy in most patients with CAD and stable angina, and reserve myocardial revascularization for select patients with disabling symptoms despite optimal medical therapy.[73] Patients with a large ischemic burden are likely a specialized subset who may benefit from revascularization.[74] In the highest-risk patients with severe CAD (left main coronary obstruction or diabetic patients with severe multivessel disease), coronary artery bypass surgery is likely superior to PCI,[75–79] though PCI can be performed safely and may be a good option in certain patients.[79,80]

ACUTE CORONARY SYNDROMES

The sudden rupture of an atherosclerotic plaque, with ensuing intracoronary thrombus formation that acutely reduces coronary blood flow, underlies the pathophysiology of an ACS.[81,82] This acute thrombus formation results in myocardial ischemia and subsequent infarction if there is a prolonged and severe reduction in blood flow. ACSs represent a continuous spectrum of disease, ranging from unstable angina (UA) to non-ST-elevation MI (NSTEMI) to acute ST-elevation MI (STEMI). If the intraluminal thrombus following acute plaque rupture is not completely occlusive, the corresponding clinical presentation is that of UA or NSTEMI.[83] An MI is defined by the presence of myocardial necrosis identified by the presence of circulating cardiac biomarkers.[26] The most common biomarker utilized clinically is cardiac troponins, which are a group of proteins found in cardiac myocytes. Troponin elevation is a very sensitive marker capable of detecting very minor levels of cardiac injury. The clinical presentation of both UA and NSTEMI is quite similar, with the latter being distinguished by the presence of a positive troponin. STEMI represents the most severe clinical scenario and reflects acute plaque rupture with prolonged and complete epicardial coronary obstruction.

Diagnosis of Acute Coronary Syndromes

The American College of Cardiology Foundation (ACCF) and the AHA recently updated their guidelines for the management of patients with ACS.[84,85] ACS is typically diagnosed clinically. The patient's history suggests a change in anginal pattern or ischemic symptoms at rest. Acutely, the ECG is the most important diagnostic tool to risk-stratify the patient and to make decisions regarding treatment. The presence of resting ST-segment depressions or dynamic T-wave changes in the distribution of an epicardial coronary artery associated with the typical clinical presentation is highly suggestive of UA or NSTEMI. The presence of ST-segment elevation when associated with classic clinical symptoms is the hallmark of an acute STEMI. Patients presenting with a history suggestive of an acute MI who have a left bundle branch block (LBBB) pattern on the 12-lead ECG are usually treated as if they had STEMI, given the difficulty of interpreting the ECG when this conduction delay is present. It is important to recognize, however, that the presence of a

normal 12-lead ECG does not exclude the possibility of ACS in the correct clinical context.

As indicated earlier, cardiac troponins have emerged as a very sensitive tool to detect myocardial injury as soon as 3 hours after the onset of symptoms.[86,87] The serum levels peak ~24–48 hours after the event and then gradually trend down over the new few days. While troponin elevation is very helpful in the diagnosis of UA and NSTEMI, it is not frequently useful in STEMI presentation when immediate revascularization is indicated. As the assays for troponin have become more and more sensitive, earlier identification of MI is now possible. The high sensitivity of our current troponin assays, however, is a double-edged sword, as low levels of troponin elevation are frequently seen in noncardiac illnesses (type 2 MI).[26] In this setting, an acute stressor such as a gastrointestinal bleed or sepsis can lead to increased myocardial oxygen demand without an abrupt decrease in myocardial oxygen supply, resulting in a troponin elevation. In this setting, the myocardial ischemia is not driven by acute thrombosis but rather by the increased demand of the stressor. Because of the distinct differing pathophysiology, treatments will also be different. Distinguishing between ACS and a type 2 MI therefore is key and is essentially a clinical diagnosis.

Initial Management for Unstable Angina and NSTEMI

The treatment of the unstable coronary syndromes should focus on the relief of myocardial ischemia and the institution of pharmacologic therapy targeting the underlying thrombotic mechanism (Table 14-8). Aspirin should be promptly administered to inhibit platelet function. The selective use of beta-blockers may relieve ischemia by lowering heart rate and BP, which reduce myocardial demand.

Beta-blockers are also antiarrhythmic agents and can suppress associated malignant ventricular arrhythmias. Beta-blockers should not be administered to those with acute decompensated heart failure, bradycardia, heart block, or severe bronchospasm. Sublingual or intravenous nitroglycerin decreases LV preload and dilates the epicardial coronaries arteries, thereby decreasing myocardial ischemia.[84]

In troponin-positive high-risk patients, there is robust clinical evidence of improved outcome when, in addition to aspirin, a second antiplatelet agent is administered. These include clopidogrel (Plavix) or ticagrelor (Brilinta). The choice of these agents depends on the relative degree of ischemic versus bleeding risk. It is important to know that these are potent and long-acting antiplatelet agents whose use is associated with major bleeding risk if a patient is to undergo emergent surgery.[84]

There is some evidence that high-risk patients with ACS will benefit from treatment with intravenous unfractionated heparin or subcutaneous low molecular weight heparin such as enoxaparin (Lovenox).[84] The short-acting intravenous unfractionated heparin is preferred in high-risk patients who may need emergent cardiac catheterization and/or bypass surgery, whereas enoxaparin may have some advantage in all other patients with ACS. Procedural outcomes are improved when dual antiplatelet therapy and heparin are used during angioplasty and stenting (see Table 14-8 for a list of these agents).

In high-risk patients with unstable angina or NSTEMI, implementation of an early invasive strategy (within 24–48 hours) with coronary angiography and PCI is associated with improved outcomes and is the most typical strategy. In lower-risk patients where the diagnosis is less clear clinically or who may be poor candidates for angiography/PCI, further risk stratification with pharmacologic stress testing may also be reasonable.[84]

Table 14-8 Common antithrombotic agents.

Generic Name	Route of Administration
Antiplatelet	
Aspirin	Oral
ADP Receptor Antagonists	
Clopidogrel	Oral
Prasugrel	Oral
Ticagrelor	Oral
Cangrelor	Intravenous
Glycoprotein IIb/IIIa Receptor Asntagonists	
Abciximab	Intravenous
Eptifibatide	Intravenous
Tirofiban	Intravenous
Anticoagulants	
Unfractionated heparin	Subcutaneous/ intravenous
Low molecular weight heparin (enoxaparin, dalteparin)	Subcutaneous
Lepirudin	Intravenous
Bivalirudin	Intravenous
Warfarin	Oral
Direct Oral Anticoagulants	
Dabigatran	Oral
Betrixaban	
Apixaban	Oral
Rivaroxaban	Oral
Edoxaban	Oral

ADP, adenosine diphosphate.

Initial Management for STEMI

Given that the pathophysiology involved in STEMI is due to complete epicardial coronary artery obstruction, the major goals of therapy are to provide revascularization as quickly as possible. In the current era, the therapy of choice is PCI, with a goal to restore perfusion within 90 minutes of clinical presentation (so-called door-to-balloon time). In situations where PCI is not expected to be available within 120 minutes of first presentation, thrombolytic therapy is recommended.[85,88] Thrombolysis with streptokinase, tissue plasminogen activator, and reteplase have all been shown to improve coronary blood flow and to reduce mortality.[89,90] Prospective randomized trials have shown that PCI with stenting in patients with STEMI is superior to thrombolytic therapy when it is completed within 1–2 hours of clinical presentation. Only if a patient with STEMI presents to a center that lacks the ability to perform emergent PCI is thrombolytic therapy the treatment of choice if immediate transfer to a PCI center cannot be arranged. All patients who have received thrombolytic therapy, however, should be immediately transferred to a PCI center.[85,88]

Post-Acute Coronary Syndrome Management

All patients with ACS should be treated with low-dose aspirin (81–100 mg) indefinitely. There is evidence that treatment with a second antiplatelet agent (clopidogrel) is beneficial even if PCI is not performed. If PCI is performed, dual antiplatelet therapy is continued for at least 6–12 months.[84,85,88,91] Treatment for longer duration has been associated with reduced ischemic events, though at the expense of increased bleeding.[92] The Dual Antiplatelet Therapy (DAPT) score has been established as a tool to help guide decision-making, balancing these competing risks on an individual patient basis.[93] In patients for whom the decision has been made to continue dual antiplatelet therapy beyond the initial 6–12 months, temporary interruption if necessary for procedures can be done safely, though consultation with the patient's cardiologist is still recommended. Initiation of a high-intensity statin during the index hospitalization has also been shown to be associated with improved outcomes, though it is not clear that the benefit is necessarily due to the acute exposure to high-intensity statin rather than chronic therapy.[33] Aggressive lipid management after ACS is a key component of secondary prevention, with recent data demonstrating significant incremental risk reduction with LDL lowered to as low as 30 mg/dL with combined use of statins, ezetimibe as well as the proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors evolocumab and alirocumab.[31,32,94] Beta-blockers are typically continued after ACS, and in patients with LV dysfunction, ACEi/ARBs have a demonstrated benefit in preventing adverse remodeling. Outpatient cardiac rehabilitation is key to improving functional outcomes after discharge and should also be routinely recommended after an ACS event.[84,85,88,91]

Dental Management Considerations for Patients with Coronary Artery Disease

Several considerations need to be addressed for dental patients with CAD.[95] The primary concern is to prevent ischemia or infarction. The risk for such an event is determined by several factors, including the degree and type of CAD (i.e., stable vs. unstable, past history of angina or MI). Patients with CAD are at increased risk of demand-related ischemia from an increased heart rate or BP, as well as for plaque rupture and acute unstable coronary syndromes. Anxiety will increase the heart rate and BP, and can provoke angina or ischemia,[96] but this risk is relatively low during outpatient dental procedures.

There is longstanding dogma in dental practice that patients who have had an MI within the past 6 months should not have elective dental procedures, but this concern is largely based on a misinterpretation of a study of patients with CVD undergoing noncardiac surgery under general anesthesia. A study of a large Medicare population who underwent a dental procedure within 30–180 days after an ischemic vascular event were not found to be at increased risk of a second event.[97]

Numerous studies have indicated the influence of circadian variation and other triggers for acute coronary events, to include mental stress, hostility, anger, and depression.[98] Most such events occur between 6:00 am and noon. It has been proposed that sympathetic nervous system activation and an increased coagulative state may be precipitating factors.[99] Medications designed to prevent these events include beta-blockers, aspirin, and antihypertensives. Dental care for high-risk patients might ideally be provided in the early afternoon.

Recent protocols suggest that patients may be safely treated in an outpatient dental setting 30 days after an MI unless the patient has decompensated CHF. Considerations for dental patients who have undergone CABG procedures or coronary stenting are similar to those who have had an MI; that is, there are no data to support waiting as long as 6 months before resuming dental treatment. Following open heart surgery (e.g., CABG), however, sitting in a dental chair may be painful, even several weeks after surgery. Elective dental care should therefore be postponed until the patient can sit comfortably for the required time period.

Elective procedures, especially those requiring general anesthesia, should be avoided for at least a month following an MI, as there is a small increased risk of reinfarction.[100] These dental procedures can be undertaken provided the

patient is able to continue on their current antithrombotic therapy uninterrupted. Limited data suggest that the acute risk of administering local anesthesia without vasoconstrictor for 3 weeks after an uncomplicated MI is low, but if epinephrine-containing local anesthetic is necessary, it may be desirable to discuss this with the patient's primary care physician or cardiologist.

Protocols to reduce anxiety should be considered, according to the level of anticipated stress. The patient's nitroglycerin tablets or spray should be available during the procedure. In some situations, patients may be on one or more drugs that interfere with hemostasis. Antiplatelet drugs, such as aspirin, clopidogrel, prasugrel, or ticagrelor, are frequently used in patients with ACS and in all patients after coronary artery stenting. The combination of dual antiplatelet therapy (e.g., aspirin and clopidogrel) is usually continued for a minimum of 4 weeks after placement of a bare metal stent, and for a minimum of 6–12 months following placement of a drug-eluting stent.[101] There are limited data addressing the risk from dental procedures performed following coronary stenting.[102] If the procedure can be performed safely without interruption of the recommended antithrombotic therapy, it is reasonable to move forward with elective dental procedures after 4 weeks. If the procedure cannot be performed safely on dual antiplatelet therapy, consultation with the patient's cardiologist is recommended to weigh the relative risks of dual antiplatelet therapy interruption with delay in the dental procedure, as these are nuanced conversations. In general, purely elective procedures requiring interruption of dual antiplatelet therapy will be delayed by 6–12 months, though more urgent procedures can be considered after 3 months. The concern with early interruption of dual antiplatelet therapy is related to the risk of stent thrombosis in the early time period. During this time, the stent has not yet been fully endothelialized, making it highly susceptible to thrombosis without use of both aspirin and a second antiplatelet agent. Premature discontinuation of antiplatelet therapy has been significantly associated with adverse cardiac events, such as MI and death.[103]

Dental Management Considerations for Patients with Angina

From the standpoint of the patient's history, it is important to know whether angina occurs at rest, and if there are precipitating factors such as exercise, climbing stairs, or emotional stress. Patients should also be asked about the frequency, duration, timing, severity of attacks, and the response to medication. Dental healthcare providers should be aware that angina may present as jaw discomfort, often on the left side. Other cardiac conditions important to the medical history include the presence of noncoronary vascular disease and if the patient has a pacemaker or defibrillator. Patients with angina may be on one or more of the following drugs: nitrates or beta-blockers, which can cause conduction disturbances and fatigue; and calcium-channel blockers, which have side effects including bradycardia, worsening heart failure, headache, and dizziness. Respiratory depressants such as opioids, barbiturates, and other sedatives can worsen the cardiovascular status and should be avoided.

Elective dental treatment is reasonable if the angina is stable without change in severity or frequency over several months. If there is a change in the pattern of angina with more frequent episodes, more frequent sublingual nitroglycerin use, or angina with less exertion, this is concerning for unstable angina. Elective dental treatments should be avoided, and the patient should be referred to their cardiologist for urgent evaluation.

STRUCTURAL HEART DISEASE

Valvular Heart Disease

VHD occurs in ~2.5% of the American population and each year more than 100,000 heart valve procedures are performed.[3] It is typically first identified by the presence of murmur on auscultation. With early identification and appropriate referral, the majority of patients with VHD will live a normal lifespan.

Mitral Valve Disease

The mitral valve sits between the left atrium and left ventricle and when functioning normally, allows for filling of the left ventricle during diastole and during ventricular systole prevents backward flow back into the left atrium. The mitral valve apparatus is complex and comprises two leaflets (anterior and posterior), the mitral annulus, chordae tendinae, and the papillary muscles (see Figure 14-2). Mitral regurgitation (MR) is the most common heart valve disease and is the result of failure of the mitral valve to prevent backward flow during ventricular systole.[3] Mitral stenosis (MS) results from progressive abnormalities in the mitral valve, leading to impedance of normal blood flow from the left atrium into the left ventricle during filling. In addition to the hemodynamic alterations that are present in patients with these conditions, there are additional issues with regard to the prevention of bacterial endocarditis.

Etiology and Pathophysiology

MR is the result of abnormal closure of the mitral leaflets.[104] It can result from intrinsic abnormalities of the valve leaflets themselves, termed primary MR. The most common causes

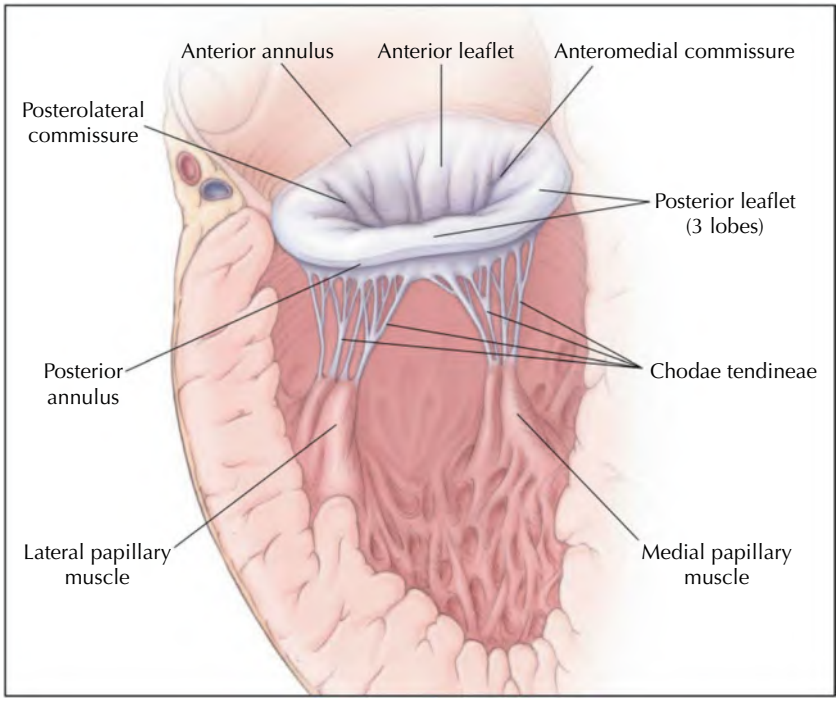


Figure 14-2 Mitral valve anatomy. The mitral valve consists of the mitral annulus, anterior and posterior leaflets, chordae tendinae, and the papillary muscles. Mitral regurgitation (MR) may be due to a disease process that primarily affects the valve leaflets (primary MR) such as a mitral valve prolapse or due to alterations in the structure/function of the left ventricle or atrium (secondary MR) such as those induced with a dilated cardiomyopathy. *Source:* From Otto, C. M. (2001). Evaluation and Management of Chronic Mitral Regurgitation. *New England Journal of Medicine*, 345(10), 740–746. © 2001, Massachusetts Medical Society.

of primary MR include mitral valve prolapse (MVP), calcific degenerative disease, rheumatic heart disease (RHD), endocarditis, and the use of anorectic agents such as fenfluramine and phentermine (fen-phen).[105]

MVP, as mentioned, is a common cause of primary MR, though the clinical syndrome is highly variable. It occurs in ~2.5% of the population[106,107] and is most commonly due to redundant mitral leaflet tissue associated with myxomatous degeneration. MR can occur in the setting of MVP, either due to prolapse of the affected leaflet with associated chordal elongation or due to rupture chordae. The severity of MR is highly variable, with the minority of patients developing severe MR. While this can be seen in patients with connective tissue disorder such as Marfan's and Ehlers–Danlos syndromes, it is typically seen in isolation. MVP may be associated with arrhythmias including premature ventricular complexes, supraventricular tachycardias, and atrial fibrillation, as well as malignant ventricular arrhythmias.[104]

MR can also occur due to structural changes in the left atrium or left ventricle, termed secondary or functional MR. Secondary/functional MR is typically seen in the presence of severe LV dysfunction resulting in apical displacement of the papillary muscles and annular dilation, or in severe left atrial dilation with resultant changes in the mitral valve annular anatomy. This distinction between primary and secondary MR is critical, as treatments vary widely.

In the presence of chronic MR, resistance to ventricular emptying is reduced as the LV is able to eject into the low-impedance left atrium as opposed to the aorta. To preserve forward flow, LV stroke volume and diastolic LV filling increase. This volume load is well accommodated by the LV for quite some time; however, if left unchecked, it ultimately progresses to LV dilation, LV dysfunction, and symptomatic CHF.

The two most common causes of MS are RHD or calcific degeneration. While uncommon in the developed world, RHD remains the dominant form of VHD in developing countries.[108] In RHD, there is characteristic thickening and fusion of the mitral commissures as well as thickening and calcification of the leaflets and subvalvular apparatus. This results in a restriction to LV inflow, subsequent left atrial hypertension and enlargement, atrial arrhythmias, secondary pulmonary hypertension, and right ventricular dysfunction.

Diagnostic Evaluation

MR is typically first identified on physical examination. MR is characterized by a systolic murmur heard best at the apex, while MS manifests as an apical diastolic rumble. Once

identified on physical examination, transthoracic echocardiography (TTE) remains the mainstay of noninvasive diagnosis in patients with mitral valve disease, and Doppler techniques are extremely useful in establishing the severity of stenosis or regurgitation.[109] Because of the dynamic nature of mitral valve disease, exercise stress echocardiography can also be useful to assess for changes in severity of either regurgitation or stenosis at peak exercise, or to look for evidence of exercise-induced pulmonary hypertension, a high-risk feature in both MR and MS. Transesophageal echocardiography (TEE) is useful in further defining the mechanism of MR or MS, better assessing the severity of the hemodynamic lesion,[110] and treatment planning. TEE offers improved image quality due to the proximity of the transducer to the mitral valve and left atrium. Cardiac catheterization has a limited role in the diagnosis of MR and is primarily reserved for those patients who are referred for cardiac surgery to assess for significant CAD.[111] In MS, direct assessment of the pressure gradient across the mitral valve via hemodynamic catheterization can be useful in challenging cases.

Treatment

The ACC, AHA, and ESC have published guidelines for the management of VHD.[112,113] Medical therapy for primary MR is quite limited and decisions regarding treatment typically hinge on the timing of intervention. Surgical valve intervention is currently recommended in patients who are symptomatic from severe primary MR or in asymptomatic patients with progressive LV dilation or dysfunction. There is evidence to suggest that patients with pulmonary hypertension or atrial fibrillation associated with isolated primary severe MR may also benefit from surgical intervention, and guidelines indicate that surgery is also reasonable in this patient population. Primary MR is surgically treated with either repair or replacement. Mitral repair is usually accomplished with the resection of the prolapsing or flail segment and placement of an annuloplasty ring. Due to improved surgical outcomes with repair compared to replacement, repair is preferred if technically possible. If repair is not technically feasible, replacement with either a biologic or mechanical prosthesis may be necessary. In patients who are prohibitive or high-risk surgical candidates, transcatheter mitral valve repair (with use of the MitraClip device) is currently available.[114] In select patients, transcatheter mitral replacement can also be considered.[115] These procedures are performed in a minimally invasive fashion via the femoral veins and do not require cardiopulmonary bypass. Additional devices are currently being investigated for the percutaneous treatment of mitral valve disease.[116,117]

Intervention for secondary MR is more controversial, as the primary driver of the MR in these pathologies is not the mitral valve itself. The benefits for mitral valve surgery in patients with isolated secondary MR have not been demonstrated to outweigh the surgical risks, and therefore it is rarely performed. In patients undergoing cardiac surgery for an alternative reason who also have severe secondary MR, mitral valve replacement (over repair) is typically also performed. The use of the MitraClip in secondary MR has recently been evaluated in two randomized clinical trials with conflicting results, though in the select patient population, transcatheter mitral valve repair is also reasonable.[118,119]

While there are limited medical options for primary MR, patients with MS can benefit from treatment with heart rate–regulating agents such as beta-blockers, calcium-channel blockers, and digoxin (when concomitant atrial fibrillation is also present). Since MS impairs diastolic filling, increasing diastolic filling with heart-rate reduction can improve diastolic filling and thereby relieve symptoms associated with MS. Another important consideration in the management of MS is the risk of atrial fibrillation and the associated thromboembolic risk. Patients with severe MS have a high risk of thromboembolism even when in sinus rhythm. Patients with atrial fibrillation and severe MS should be managed with Coumadin and not direct oral anticoagulant therapy. Anticoagulation can be considered in those with severe MS who have had a prior embolic event and in those with a very severely dilated left atrium. In patients who are symptomatic with severe MS or in those with significant resting pulmonary hypertension despite adequate medical therapy, intervention should be considered. If possible, percutaneous balloon mitral valvuloplasty (PBMV) should be performed, as it can provide lasting benefit with minimal risk. In patients who are not candidates for PBMV, mitral valve repair (if technically possible) versus mitral valve replacement is indicated.[112,113]

Aortic Valve Disease

The aortic valve serves as the gatekeeper between the left ventricle and the aorta. It is comprised of three cusps: left, right, and noncoronary cusps. In 1–2% of the general population, the aortic valve is bicuspid, an anomaly that is associated with accelerated degeneration (either stenosis or regurgitation), thoracic aortic aneurysms, as well as aortic coarctation.[120] Aortic stenosis (AS) accounts for ~25% of all cases of VHD, while aortic regurgitation is less common.[3]

Etiology and Pathophysiology

The most common causes of AS include fibrocalcific degeneration, congenitally bicuspid valve, and RHD. In the United States, fibrocalcific disease is most common, though

worldwide, rheumatic disease remains the most common etiology. Fibrocalcific degeneration is an active disease characterized by inflammation, fibrosis, and calcification, and is not simply an inevitable consequence of aging as was once believed. In the United States, among those <70, bicuspid aortic valve disease is the most common etiology. Regardless of the etiology, AS results in a pressure gradient between the left ventricle and the aorta. In order to overcome this pressure gradient, the left ventricle hypertrophies. While the hypertrophied ventricle can accommodate the pressure gradient for quite some time, it will become maladaptive if left unchecked. The following symptoms can develop in the presence of severe AS: (1) dyspnea, due to stiffening of the hypertrophied myocardium; (2) angina, due to supply–demand mismatch; and (3) syncope, due to inadequate forward flow as a result of the fixed stenosis. These symptoms can occur in the face of normal LV systolic function, though asymptomatic LV dysfunction can also occur.

Aortic regurgitation (AR) results from a wide variety of processes that directly affect the aortic leaflets, including congenital abnormalities, rheumatic disease, infective endocarditis, fibrocalcific degeneration, and the use of anorexigens.[112,113,121] Additionally, abnormalities of the aortic root such as aneurysm or aortic dissection may dilate or disrupt the aortic annulus, resulting in malcoaptation and regurgitation. AR results in an increase volume load on the LV. In acute AR, the ventricle has not had time to adaptively remodel to tolerate this increased volume load and acute heart failure with associated cardiogenic shock is likely. In chronic AR, the increase in volume load is more gradual, thereby enabling the ventricle to adaptively remodel though changes in ventricular compliance. Over time, however, the remodeling becomes maladaptive, with LV dilation, LV contractile failure, and symptoms of CHF.

Diagnostic Evaluation

The auscultatory findings of AS include a harsh crescendo–decrescendo systolic murmur best heard over the right upper sternal border, and a diminished or absent aortic component of the second heart sound. The murmur of AS frequently radiates to the carotid arteries. The carotid pulses are often weak and delayed, and delay between the brachial and radial pulses may also be present. AR is manifested on physical examination by a high-pitched decrescendo early diastolic murmur, heard best at the left sternal border when the patient is sitting upright with breath held after exhalation. Chronic AR often yields findings of a hyperdynamic circulation with bounding or "water hammer" pulses, head bobbing (titubation), "to-and-fro" murmurs heard in the femoral arteries, and Quincke's pulse (visible in the nail beds).

As with mitral valve disease, TTE remains the primary diagnostic modality in the vast majority of patients with aortic valve disease. TEE may be needed to define the mechanism of AR or AS, to evaluate the aortic root and ascending aorta, and to investigate the possibility of endocarditis. Cardiac CT has emerged as a useful adjunctive tool in assessing AS severity when TTE is indeterminate, and is a key component to procedural planning in patients undergoing transcatheter aortic valve replacement (TAVR).[122,123] Cardiac MRI can also be useful in quantify AR severity.[113,124] While cardiac catheterization can be utilized to directly assess AS severity, it is rarely used solely for this purpose given that TTE has been well demonstrated to provide a comprehensive assessment without the associated risk (stroke, vascular injury, etc.). Catheterization is typically reserved to assess for concomitant coronary disease in patients being considered for aortic valve intervention.

Treatment

Management of AS mainly hinges around the decision to pursue aortic valve replacement (AVR). There are no medical therapies that have been shown to prevent progression of AS. It has been well established that the development of symptoms associated with AS is associated with a rapid decline in clinical outcomes. In the era before widespread surgical treatment, the average time to death after the onset of symptoms associated with AS was as follows: angina, 3 years; syncope, 3 years; dyspnea, 2 years; CHF, 1–2 years.[125] Therefore, it is recommended that AVR be performed in any patient with severe AS with symptoms of angina, shortness of breath, or syncope, provided that the symptoms are clinically attributable to the AS. In the absence of symptoms, most patients with AS do quite well, though there is still a low risk of sudden death (<1%).[126] Management of the asymptomatic patient with AS remains complex, though current guidelines recommend careful observation for most patients.[112,113]

In patients with isolated AS, AVR can be performed through either the standard surgical approach (SAVR) or through a percutaneous approach (TAVR). TAVR has been shown to be as effective as SAVR in prohibitive-, high-, moderate-, and low-risk patients.[127,128,129–131] TAVR is typically performed via the femoral artery, though alternative access sites can be used. While outcomes with TAVR have been excellent in general, there remains a risk of vascular injury, stroke (~2%), and the need for permanent pacing (8–12%).[132] Despite advances in TAVR, there is still a significant role for SAVR in patients who are not anatomically candidates for TAVR, those with concomitant complex coronary disease, and in many patients with bicuspid aortic valve disease. Ultimately, the choice between surgical and transcatheter AVR remains a complex one and is best determined by a

multidisciplinary heart valve team that includes cardiologists, interventionalists, imaging specialists, and cardiac surgeons.

Similar to AS, the main treatment decision in managing patients with AR surrounds the timing of AVR. While meticulous hypertension management with diuretics and vasodilators (dihydropyridine calcium-channel blockers, ACEis, ARBs, and hydralazine) can help manage early symptoms and is important in overall cardiovascular care in general, as discussed earlier, surgery remains the only definitive therapy. Surgery is currently recommended in symptomatic patients with severe AR as well as in asymptomatic patients with abnormal contractile function and in those with progressive LV dilation.[113]

Surgical techniques for the management of AR have evolved considerably with a significant reduction in surgical risk.[133,134] If the AR is due primarily due to a dilated aortic root, aortic valve repair is possible and preferred. In the majority of patients with isolated AR, however, SAVR is required. Due to the risk of device embolization and paravalvular regurgitation, TAVR is not currently approved for isolated AR; however, in patients who are not surgical candidates, it can be considered in an off-label fashion.[135]

Prosthetic Heart Valves

There are two types of prosthetic heart valves, mechanical and bioprosthetic. The mechanical valves, which are classified according to their structure, include the oldest type ball-in-cage (Starr–Edwards) valve, the single tilting-disk (Bjork–Shiley) valve, and the currently most widely used bileaflet tilting-disk valves. Bioprosthetic valves are either (1) heterografts made from porcine or bovine tissue or (2) homografts from preserved human aortic valves.

Mechanical valves are extremely durable and fail rarely. As such, they are a good option for younger patients who have a long life expectancy. Patients with mechanical valves do, however, require chronic anticoagulation therapy with warfarin to prevent thromboembolism. Use of direct oral anticoagulants has been shown to be associated with worse outcomes and is contraindicated in patients with mechanical prostheses.[136] The intensity of anticoagulation is based on the overall thromboembolic risk and is influenced by type of mechanical valve (ball-in-cage valves are highest risk and bileaflet tilting-disc valves lowest risk), valve position (mitral position higher risk than aortic position), and other patient factors (presence of atrial fibrillation, prior thromboembolic events, or LV dysfunction). In patients with mechanical valves, the risk of systemic embolization is approximately 4% per patient per year without anticoagulation, 2.2% with aspirin therapy, and 0.796%–1.0% with warfarin therapy.[137] Patients with mitral valve prostheses are at approximately twice the risk of those with aortic valve prostheses.[138] The addition of low-dose aspirin therapy (75–100 mg daily) to warfarin therapy in patients with mechanical prostheses is controversial and definitive modern data are lacking. Currently, the US guidelines have continued to recommend combined aspirin and warfarin therapy in all patients with mechanical prostheses, while the European guidelines have reserved the addition of aspirin only for those patients with concomitant vascular disease.[112,113]

Bioprosthetic surgical valves have a lower thrombogenic potential and do not require long-term anticoagulation. The thromboembolic risk is highest in the early postsurgical period, before full endothelialization, and anticoagulation is recommended for the first 3–6 months after implantation. Despite these recommendations, there is significant variability in real-world utilization due to surgical concerns regarding bleeding.[112,113] Beyond 3 months, low-dose aspirin monotherapy is continued indefinitely. The lack of the need for long-term anticoagulation makes bioprosthetic valves attractive for patients. The disadvantage of bioprosthetic valves when compared to mechanical valves, however, is durability. While data are limited, the average life expectancy of a bioprosthetic valve is ~10–20 years.[139]

Transcatheter valves are also bioprosthetic valves and have a durability that is probably similar to surgical bioprosthetic valves.[127–131] Aspirin and clopidogrel are typically prescribed for the first 6 months after implantation, at which point low-dose aspirin monotherapy is continued indefinitely. Subclinical TAVR leaflet thrombosis detected by cardiac CT has been identified in up to 12% of cases, though the clinical impact on thromboembolic events is not clear.[140] If identified, the antithrombotic therapy is typically intensified to full anticoagulation. In patients who undergo TAVR placement within a failed bioprosthetic valve (valve-in-valve), the risk of thrombosis is similarly elevated and therapy is to full anticoagulation.[141] There remain very limited data on the optimal anticoagulation (warfarin vs. direct oral anticoagulant) strategy in these complex situations and clear guidelines are not yet available.

The recommended anticoagulation therapy for each type of prosthetic valve is summarized in Table 14-9. It is important that although these recommendations serve as broad guidelines, the level of chronic anticoagulation should be individualized and based on the location, type, and number of prosthetic valves, as well as the patient's age, comorbidities, and additional thromboembolic risk factors such as a history of atrial fibrillation or stroke. Thus, the intensity of anticoagulation is determined by weighing the patient's risk of thromboembolic events against the risk of adverse anticoagulation consequences (bleeding risks). It is important to note that direct oral anticoagulants should not be used in patients with mechanical prostheses.[112,113]

Table 14-9 Antithrombotic management in prosthetic valves.

Valve Type	Recommended Therapy
Aortic Valve	
Mechanical AVR without risk factors	Vitamin K antagonist with INR goal 2.5 ± ASA 81–100 mg daily
Mechanical AVR with risk factors	Vitamin K antagonist with INR goal 3 ± ASA 81–100 mg daily
On-X mechanical AVR without risk factors	Vitamin K antagonist with INR goal 1.5–2 ± ASA 81–100 mg daily
Bioprosthetic SAVR	Vitamin K antagonist with INR goal 2.5 for first 3–6 months in low bleeding risk patients, ASA 81–100 mg indefinitely
Aortic valve repair	Vitamin K antagonist with INR goal 2.5 for first 3–6 months in low bleeding risk patients, ASA 81–100 mg indefinitely
TAVR	Clopidogrel 75 mg daily for first 6 months, ASA 81–100 mg indefinitely, *or* Vitamin K antagonist with INR goal 2.5 for first 3 months in low bleeding risk patients, ASA 81–100 mg indefinitely
Mitral Valve	
Mechanical MVR	Vitamin K antagonist with INR goal 3 ± ASA 81–100 mg daily
Bioprosthetic MVR	Vitamin K antagonist with INR goal 2.5 for first 3–6 months in low bleeding risk patients, ASA 81–100 mg indefinitely
Mitral valve repair	Vitamin K antagonist with INR goal 2.5 for first 3–6 months in low bleeding risk patients, ASA 81–100 mg indefinitely

Risk factors include left ventricular dysfunction, atrial fibrillation, hypercoagulable state, prior thromboembolic event, or older-generation valve such as a ball-in-cage. ASA, acetylsalicylic acid; AVR, aortic valve replacement; INR, International Normalized Ratio; MVR, mitral valve replacement; SAVR, surgical aortic valve replacement; TAVR, transcatheter aortic valve replacement.

Prosthetic heart valves increase the risk for infective endocarditis, which typically manifests as fever and as other systemic symptoms.[142] Although endocarditis within 60 days of surgery typically is caused by nonoral bacteria, the cause of endocarditis that occurs 60 days after valve surgery is similar to that of native-valve endocarditis.

Periprocedural Prosthetic Valve Anticoagulation Management

Management of anticoagulation in the periprocedural time period is complex and the risk of procedural bleeding must be weighed against the risk of thrombosis. Due to the high risk of complications without anticoagulation in the setting of mechanical heart valves, it is recommended that patients with mechanical heart valves continue on warfarin therapy uninterrupted when undergoing minor procedures (such dental extractions or cataract removal), provided that bleeding can be controlled easily. If temporary interruption is deemed necessary for the procedure, bridging therapy (with either unfractionated intravenous heparin or subcutaneous low molecular weight heparin) is not necessary in patients with isolated mechanical AVR without additional risk factors (LV systolic dysfunction, atrial fibrillation, or prior thromboembolic events). For patients at highest risk for thromboembolic events (including those with a mechanical mitral valve, older-generation mechanical aortic valve, or mechanical aortic valve with an additional risk factor), bridging therapy is reasonable on an individualized basis, as the specific bleeding and thrombotic risks must be weighed carefully.[112,113] Given that patients with bioprosthetic valves are rarely fully anticoagulated solely for the purpose of the valve, decisions about anticoagulation management should be driven by the primary anticoagulation indication (see below for periprocedural management of anticoagulation for atrial fibrillation).

Congenital Heart Disease

Congenital cardiovascular malformations can be cyanotic (dominant right-to-left shunting), noncyanotic (dominant left-to-right shunting), or without shunting. Cyanotic defects include tetralogy of Fallot, transposition of the great vessels, anomalies of the tricuspid valve, pulmonary atresia, pulmonary stenosis, Eisenmenger's syndrome, and hypoplastic left heart syndrome (aortic atresia). Surgical correction of these defects is often accomplished in infancy and early childhood. Noncyanotic defects include ventricular septal defect, atrial septal defect, patent ductus arteriosus, coarctation of the aorta, aortic valve stenosis, and MVP. Management of these patients is often quite complex and so best done by adult CHD specialists.

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is the most common monogenic cardiovascular disorder and occurs in ~1 in 200–500 individuals in the general population. It is estimated that there are ~750,000 individuals with HCM in the United States and 20 million globally, though these are likely underestimates due to the challenges in diagnosis. HCM is inherited in an autosomal dominant pattern and is associated with mutations in cardiac sarcomeric proteins. Clinically, it presents with a thickened and nondilated left ventricle. Depending on the pattern of hypertrophy, this can cause

obstruction of systolic flow from the left ventricle (70% of cases). Patients with HCM can develop symptoms of CHF and are more prone to the development of atrial arrhythmias. The risk of sudden cardiac death is an important part of the assessment of patients with HCM. Not all patients with HCM are at equal risk of sudden death and several risk factors have been identified. In patients with multiple risk factors for sudden death, consideration of implantable cardiac defibrillators (ICDs) is recommended. HCM remains the most common cause of sudden death in athletes and is typically considered a contraindication to competitive athletics, though noncompetitive recreational activity is typically permitted. There has been a great number of advances in the management of patients with HCM over the past 50 years that has resulted in a 90% reduction in mortality, to an annual HCM-related mortality rate as low as 0.5% per year.[143]

Dental Management Considerations

Patients with higher levels of valve dysfunction, whether from valve insufficiency or stenosis, may require cardiac valve replacement. The primary concerns are for a risk of bleeding and a risk for valve infection. Patients with VHD should be questioned carefully about symptoms and ongoing medical management, to include current medications. The extent to which dental treatment should be altered is determined by the degree of compromise (e.g., decreased cardiac output) and tolerance for stressful or prolonged dental procedures. Patients without symptoms, exercise limitation, or arrhythmias can undergo routine dental procedures without significant risk. Otherwise, these patients should be discussed with their primary care provider or cardiologist prior to dental treatment. Many of these patients have concomitant CAD and this is a separate consideration regarding modifications for dental care.

Considerations Concerning Bacteremia and Antibiotic Prophylaxis

The fact that bacteremia from the mouth could cause infective endocarditis (IE) was first suggested well over 100 years ago and was later reinforced by others who targeted viridans group streptococci from poor oral hygiene and dental extractions.[144,145] IE is initiated by a bacteremia in a susceptible host (e.g., prosthetic valve), and has an overall mortality rate of 20%–30%, depending on several host factors and the bacterial species involved.[146–148] The incidence of IE is increasing in some countries due to the use of intravascular catheters and implanted cardiac devices, and injection drug use.[149,150] Although the literature suggests a wide incidence range (20%–60%) for cases of IE caused by viridans group streptococci, over 30% of cases of native-valve IE may originate from oral bacterial species, most commonly the viridans group of streptococci.[147,151]

The origin of many cases of IE is transient bacteremia from the close approximation of oral bacterial plaque adjacent to diseased gingival tissues. The focus has historically been on invasive dental procedures as the source of many cases of IE, but there is an increased emphasis now on patients with poor oral hygiene. Bacteria can traverse the inflamed periodontal tissues to enter the circulation and this can occur with minimal manipulation of inflamed gingival tissues.[152] Although it has been mentioned in the AHA recommendations for antibiotic prophylaxis since the 1970s, there is an increasing consensus that there has been far too much emphasis on dental procedures as the source of IE. Dental office procedure-generated bacteremia may occur one or two times per year on average and therefore result in far fewer, if any, cases of IE by comparison with activities of daily living (e.g., tooth brushing), which may occur hundreds of times per year. Evidence is accumulating to support an emphasis on improved oral hygiene and resolution of periodontal inflammation as the most effective means of reducing oral bacteria-related IE.[10,152]

AHA guidelines and recent studies reflect the lack of evidence for safety or efficacy from the use of antibiotic prophylaxis prior to invasive dental procedures as a means of preventing IE.[11,146,153,154] It is important to emphasize that the AHA guidelines focus on groups of cardiac populations at high risk for a "bad outcome" (higher morbidity and mortality) from IE (Tables 14-10–14-12).[11] Of interest is that these four groups comprise only about 10% of patients at risk for IE.[11,155,156] The AHA-defined "moderate-risk" groups of cardiac patients therefore represent about 90% of people

Table 14-10 Cardiac conditions associated with the highest risk of adverse outcomes from endocarditis for which antibiotic prophylaxis with dental procedures is reasonable.

1) Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
2) History of infectious endocarditis
3) Unrepair cyanotic congenital heart disease
4) Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the proceduret
5) Repaired congenital heart disease with residual defects at the site or adjacent to the prosthetic patch or prosthetic device (which inhibit endothelialization)
6) Cardiac transplantation recipients who develop cardiac valvulopathy

Except for the conditions listed here, antibiotic prophylaxis is no longer recommended for any other form of congenital heart disease. Prophylaxis is reasonable because endothelialization of prosthetic material occurs within 6 months after the procedure.

Table 14-11 Recommended antimicrobial regimens for dental procedures.

		Regimen: Single Dose 30–60 min before Procedure	
Situation	**Agent**	**Adults**	**Children**
Oral	Amoxicillin		
Unable to take oral medication	Ampicillin	2 g IM or IV	50mg/kg IM or IV
	OR		
	Cefazolin or ceftriaxone	1 g IM or IV	50 mg/kg IM or IV
Allergic to penicillins or ampicillin – oral	Cephalexin*+	2g	50 mg/kg
	OR		
	Clindamycin	600 mg	20 mg/kg
	OR		
	Azithromycin or clarithromycin	500 mg	15 mg/kg
Allergic to penicillins or ampicillin and unable to take oral medication	Cefazolin or ceftriaxone+	1 g IM or IV	50 mg/kg IM or IV
	OR		
	Clindamycin	600 mg IM or IV	20 kg IM or IV

IM, intramuscular; IV, intravenous.
* Or other first- or second-generation oral cephalosporin in equivalent adult or pediatric dosage.
+ Cephalosporins should not be used in an individual with a history of anaphylaxis, angioedema, or urticaria with penicillins or ampicillin.

covered with antibiotic prophylaxis prior to the 2007 change in these guidelines. Antibiotic prophylaxis is no longer recommended for the moderate-risk group, but they remain at risk for IE from oral bacterial species.

HEART FAILURE

Definition and Epidemiology

Heart failure is a complex clinical syndrome that results from an impairment in ventricular filling or ejection of blood.[157] Heart failure may be due to pericardial disease, VHD, or most commonly, myocardial disease resulting in abnormal contractile function (systolic dysfunction) or impaired relaxation (diastolic dysfunction) (Table 14-13). Diastolic dysfunction is characterized by clinical heart failure syndrome with normal LV systolic function on cardiac testing.[158,159] In many series, it represents one of the most common types of heart failure encountered in the general population.[160] Common causes of diastolic dysfunction include hypertension, CAD, longstanding diabetes, and advanced age. In addition, diastolic dysfunction is almost always present in patients with any type of advanced systolic heart failure.

Diagnosis

Dyspnea, orthopnea (shortness of breath while lying flat), bendopnea (shortness of breath when bending forward),

Table 14-13 Heart failure etiologies.

Coronary artery disease (ischemic cardiomyopathy)
Hypertension
Idiopathic dilated cardiomyopathy
Hypertrophic cardiomyopathy
Alcohol
Diabetes
Viruses (Coxsackie virus, enterovirus, human immunodeficiency virus, influenza, SARS-CoV2, etc.)
Infiltrative disorders (amyloidosis, hemochromatosis, sarcoidosis and others)
Toxins (chemotherapeutic agents, etc.)
Metabolic disorders (hypothyroidism, etc.)
Valvular heart disease
Pericardial disease
Tachyarrhythmia-induced
High output states (hyperthyroidism, atrioventricular fistula, thiamine deficiency, etc.)

and paroxysmal nocturnal dyspnea are classic symptoms, but nonspecific complaints such as chest discomfort, fatigue, palpitations, dizziness, and syncope are not uncommon. The onset of symptoms may be insidious, and symptoms may present for medical attention only when an acute decompensation occurs. Asymptomatic patients are sometimes diagnosed when routine testing is performed for other reasons that reveal abnormalities on ECGs, chest radiographs, or echocardiograms.

The physical examination findings in heart failure are numerous. A relative decrease in systolic BP (due to reduced cardiac output) and an increase in diastolic BP (due to peripheral vasoconstriction) may result in a decrease in pulse pressure. Cardiac percussion and palpation reveal an enlarged heart with a laterally displaced and diffuse apical impulse. Auscultation may reveal an apical systolic murmur of MR and the lower parasternal murmur of tricuspid regurgitation. Third and fourth heart sounds can be heard, signifying evidence of systolic and diastolic dysfunction. Rales suggest pulmonary congestion secondary to elevated left atrial and LV end-diastolic pressures. Jugular venous distention, peripheral edema, and hepatomegaly are markers of elevated right heart pressures and right ventricular dysfunction. In advanced heart failure, additional findings may include cool extremities with decreased pulses, generalized cachexia, muscle atrophy, and profound weakness.

Laboratory testing can be helpful at identifying possible etiologies of CHF depending on the specific clinical presentation. Human immunodeficiency virus (HIV), thyroid function testing, iron studies, and tests evaluating for possible light-chain amyloidosis (including serum protein electrophoresis and kappa/lambda light chains) are typically ordered at first diagnosis. Troponin and brain natriuretic peptide may also be helpful from both diagnostic and prognostic standpoints.

Chest radiography may demonstrate cardiac enlargement, pulmonary congestion, and pleural effusions. The ECG is frequently abnormal in a nonspecific manner and may be the only indication of heart disease in asymptomatic individuals. ECG may reveal prolonged repolarization (i.e., interval), and nonspecific ST and T-wave abnormalities. Conduction disturbances such as atrioventricular block, bundle branch blocks, and fascicular blocks are also seen. Criteria for LV hypertrophy with a repolarization abnormality may suggest hypertension as an etiology. ECG may also reveal evidence of arrhythmias such as atrial fibrillation and atrial flutter, as well as premature atrial or ventricular contractions. Supraventricular tachyarrhythmias and nonsustained ventricular tachycardia are also associated with heart failure, as is the development of ventricular fibrillation, usually resulting in sudden cardiac death.

TTE is the most useful noninvasive diagnostic tool for the initial evaluation of a patient with heart failure.[161] TTE provides information not only on overall heart size and function, but also on valvular structure and function, wall motion and thickness, LV mass, and the presence of pericardial disease. Doppler-derived hemodynamic measurements accurately predict the severity of valvular regurgitation seen in heart failure and give a noninvasive estimation of pulmonary artery pressures. Doppler techniques may also be used to evaluate LV diastolic abnormalities, which are frequently present in those with heart failure.

Given that CAD is the most common cause of CHF in the general population, an ischemic evaluation should be performed in all patients. Depending on the pretest probability of ischemic heart disease, this evaluation may be noninvasive (cardiac CTA, nuclear imaging, or cardiac MRI) or with invasive coronary angiography. Cardiac MRI and cardiac PET may be utilized if there is specific clinical concern for infiltrative or genetic cardiomyopathies such as HCM, cardiac sarcoidosis, or cardiac amyloidosis.

Classification

The majority of patients with heart failure have symptoms due to impaired LV myocardial function. While most patients with heart failure have abnormalities in both systolic (contractile) function and diastolic (filling) function, the ejection fraction (EF) is typically used as the main point of classification in patients with heart failure. Patients with heart failure and an LVEF of <40% are classified as heart failure with reduced ejection fraction (HFrEF), 41–49% as heart failure with mid-range ejection fraction (HFmEF), and ≥50% are

classified as heart failure with preserved ejection fraction (HFpEF). Classification stratified by EF is important, as there exist distinct differences among these three groups regarding demographics, comorbid conditions, prognosis, and particularly response to therapy. The ACCF/AHA stages of heart failure classification and the New York Heart Failure (NYHA) functional classification also have important roles in providing useful and complementary information regarding the presence or severity of heart failure. Whereas the ACCF/AHA staging system emphasizes the development and progression of disease in individuals and populations, the NYHA classification focuses on functional capacity and is an independent predictor of mortality (see Table 14-14).[157,162]

Management

Medical Therapy

The optimal management of patients with chronic systolic heart failure is highly evidence based and is associated with dramatic decreases in the risk of heart failure exacerbations, hospitalizations, and death. Both US and European guideline recommendations exist for the optimal treatment of patients with HF.[162,163]

The treatment of heart failure must be individualized to the etiology of the heart failure and to the patient (Table 14-14). Patients with CAD and heart failure should be evaluated for ischemia as well as viable but hibernating myocardium that would improve systolic and diastolic performance with revascularization.[164–166] Patients with alcoholic cardiomyopathy should be advised to abstain from alcohol, in addition to the usual therapeutic options, as this often leads to an improvement in LV performance.[167] Hypertension should be aggressively treated with pharmacologic intervention and dietary measures.

Table 14-14 Classification of heart failure.

NYHA Functional Classification
• Class I—symptoms of HF only at activity levels that would limit normal individuals
• Class II—symptoms of HF with ordinary exertion
• Class III—symptoms of HF with less than ordinary exertion
• Class IV—symptoms of HF at rest
ACCF/AHA Stages of HF
• Stage A—at high risk for HF but without structural heart disease or symptoms of HF
• Stage B—structural heart disease but without signs or symptoms of HF
• Stage C—structural heart disease with prior or current symptoms of HF
• Stage D—refractory HF requiring specialized interventions
Classification by Ejection Fraction
• HFpEF—symptoms of HF with LVEF ≥50%
• HFmEF—symptoms of HF with LVEF 41–49%
• HFrEF—symptoms of HF with LVEF ≤40%

ACC, American College of Cardiology; AHA, American Heart Association; HF, heart failure; HFmEF, heart failure with mid-range ejection fraction; HFpEF, heart failure with preserved ejection fraction; HFrEF, heart failure with reduced ejection fraction; LVEF, left ventricular ejection fraction; NYHA, New York Heart Failure.

The initial treatment in acute decompensated heart failure is stabilization of volume status and end-organ perfusion. In the majority of cases, the presentation is relatively mild, and this can be achieved on an outpatient basis with oral diuretics. For patients who are more acutely ill, inpatient admission with intravenous diuretics, vasodilator therapy, and even intravenous inotropic agents may be necessary. Most patients with symptomatic heart failure will need to stay on oral diuretic therapy, which should be tailored for the specific patient. Doses should be initiated at low levels and gradually titrated up over weeks to months. While diuretic therapy is a key component of symptomatic management, it is important to note that there is no mortality benefit associated with diuretic therapy.

Once the patient has been stabilized, attention should be turned toward therapies that have been demonstrated to improve overall outcomes. In selecting therapies, it is important to accurately classify patients within the HFrEF, HFmEF, and HFpEF categorizations. In patients with HFrEF, there are several medication classes that have been shown to have mortality reduction, including beta-blockers, ACEis/ARBs, aldosterone antagonists, and angiotensin receptor-neprilysin inhibitors (ARNIs). Several beta-blockers have been demonstrated to improve symptoms of CHF and reduce the risk of death and hospitalization from heart failure. These include bisoprolol, carvedilol, and sustained-release metoprolol succinate.[168,169–172]

ACEis and ARBs have also been demonstrated to decrease mortality, reduce symptoms in those with symptomatic HFrEF, and delay the onset of symptoms in asymptomatic patients with LV dysfunction.[173–179] Aldosterone antagonists (spironolactone or eplerenone) have also been shown to improve mortality in patients with symptomatic HFrEF already on beta-blockers and ACEis/ARBs and should be utilized.[180,181] Given the risk of hyperkalemia when used in conjunction with ACEis/ARBs, careful monitoring of potassium is necessary, and an aldosterone antagonist should not be used in those with significant renal dysfunction. The combination of isosorbide dinitrate and hydralazine reduces mortality in African American patients when added to ACEis/ARBs and in all patients who cannot tolerate an ACEi/ARB, and should be considered in these specific subgroups.[182–184]

Most recently, the new class of drugs termed ARNIs has been shown to further improve clinical outcomes when

compared to ACEis/ARBs alone. In patients with mild heart failure with a reduced EF, valsartan-sacubitril was superior to enalapril at reducing heart failure–related mortality and morbidity.[185] Ivabradine is an inhibitor of the If current in the sinoatrial node and is another new addition to the armamentarium in the treatment of HFrEF. In a randomized clinical trial, ivabradine was effective at reducing heart failure hospitalization in those with HFrEF and may be considered in those who are already on maximal doses of beta-blockers.[186]

Several trials have been conducted evaluating the efficacy of digoxin in managing patients with heart failure. While there is evidence that it may help with symptoms and preventing heart failure hospitalizations, there is no evidence to suggest a mortality benefit. The lack of impact on mortality in combination with a relatively narrow therapeutic window limit the broad utilization for digoxin in HFrEF.[187–190]

Pharmacologic therapy specifically aimed at HFmEF and HFpEF is much more limited. Unlike with HFrEF, no specific therapies have been identified that improve mortality in these patients. Aggressive management of hypertension, diuretic use for management of volume overload, and treatment of CAD are recommended. Spironolactone has been specifically studied in HFpEF. While there was no net benefit in heart failure hospitalization of mortality in the study, post-hoc analyses have suggested that there may have been a benefit in the North and South American cohort.[191,192] As such, the 2017 ACCF/AHA guidelines have indicated that spironolactone "might be considered to decrease hospitalizations." In addition to spironolactone, there was also a significant amount of enthusiasm regarding possible benefit of valsartan-sacubitril in HFpEF. The recently published Paragon-HF trial, however, failed to show an overall reduction in mortality and heart failure hospitalization.[193] Among the pre-specific subgroups, there did seem to be a benefit among those with HFmEF and in women, though further studies are necessary to confirm these observations.

In patients with concomitant diabetes and heart failure, sodium-glucose cotransporter 2 (SGLT2) inhibitors have been demonstrated to improve heart failure outcomes.[194–196] The mechanism of impact has not yet been fully elucidated, though it likely includes improvement in filling conditions, changes in LV wall stress, and improved myocardial efficiency.[197,198] As a result of these observations, the US Food and Drug Administration (FDA) has broadened the indication of two of these, empagliflozin and canagliflozin, for use to lower cardiovascular risk in patients with type 2 diabetes and established cardiovascular disease. Additional studies are ongoing evaluating the role of SGLT2 inhibitors in patients with heart failure without diabetes, as there is optimism that this may represent an additional therapeutic pathway among all patients with heart failure regardless of diabetes status.

Anticoagulation with warfarin (Coumadin) in patients with LV dysfunction may reduce morbidity and mortality from cardioembolic events that develop secondary to chamber enlargement and stasis of blood; however, the risks of bleeding need to be considered.[199] Routine anticoagulation in patients with systolic heart failure is generally not recommended.[200, 201] Anticoagulation therapy is likely to be most beneficial for patients with atrial fibrillation or atrial flutter, in patients with severe systolic heart failure who experienced a transient ischemic attack (TIA) or stroke, and in patients in sinus rhythm who were found to have an intracardiac clot in the echocardiogram.

Implantable Cardiac Device Therapy

Patients with systolic heart failure whose ECG shows wide QRS complexes due to LBBB have markedly increased symptomatology, quality of life, and even mortality compared to patients with similar LVEFs but no LBBB.[202] Cardiac resynchronization therapy with implanted biventricular pacemakers has been shown to have a significant beneficial effect on morbidity and mortality in this subgroup of patients with heart failure.[203] ICDs are also increasingly used for primary prevention of sudden death in patients with chronic heart failure whose LVEF remains below 30%–35% despite optimum medical management.[204] Given the challenges of managing volume status in patients with severe CHF (HFrEF, HFmEF, and HFpEF), there has been a great deal of enthusiasm for devices that can detect early changes in cardiac hemodynamics. The CardioMems device is a sensor that is placed in the pulmonary artery percutaneously and has been shown to be effective at detecting early changes in cardiac hemodynamics; when utilized within the context of a robust heart failure clinic, it has been shown to reduce morbidity and mortality associated with CHF.[205]

Advanced Heart Failure Management—Left Ventricular Assist Devices

Left ventricular assist devices (LVADs) are increasingly used to treat end-stage heart failure not only as a bridge to heart transplantation, but also as definitive "destination" therapy.[206] With the most recent generation of LVADs, the 2-year overall survival is ~80%. Full anticoagulation is required for patients with an LVAD to prevent device thrombosis. While overall clinical outcomes with LVADs have improved significantly, bleeding, thromboembolic events, and infectious complications remain important drivers of morbidity in these patients.[207] Despite the technical advances in LVAD design, successful implementation is also dependent upon close monitoring by an experienced heart failure clinic, as well as significant patient and family engagement.

Dental Management Considerations for Patients with Heart Failure

Patients with CHF will often have a history of CAD and they may be on multiple medications and dietary measures to control and balance cardiac function. Anticoagulation with warfarin may reduce morbidity and mortality from cardioembolic events, and the risks of bleeding during and following invasive dental procedures needs to be considered (see subsequent section on anticoagulation and antiplatelet therapy and invasive dental procedures).

Concerning stages of CHF, well-compensated patients need no special modifications for routine dental care.[208,209] However, for patients with decompensated CHF, it is prudent to inquire about the patient's ability to be placed in a supine position, as this may cause shortness of breath. Stressful or prolonged dental procedures put an increased demand on the heart that may exacerbate CHF and result in further inability for ventricles to pump blood. Patients should be questioned about signs of poor compensation, which include paroxysmal nocturnal dyspnea, orthopnea, shortness of breath or dyspnea on exertion, pedal edema, and body weight fluctuations. Appointments should be kept short, and stress reduction and pain control are important for patients who are decompensated.

Cardiac Transplantation

In patients with severe advanced heart failure, heart transplantation remains the treatment of choice in those who are appropriate candidates. The 1-year survival is >90% and the average survival is 13 years.[210] Despite the good outcomes with cardiac transplantation, the increasing numbers of patients with end-stage heart failure coupled with a relatively fixed pool of donors have resulted in a severe mismatch between demand and supply that has significantly hampered implementation of this life-saving therapy.[211] Patients with heart transplants require life-long immunosuppressive therapy. These patients should be closely followed in an advanced heart failure program to monitor for signs of organ rejection, development of transplant-related coronary artery vasculopathy, and other complications from chronic immunosuppressive therapy, such as infectious issues.[212]

Dental Management Considerations for Cardiac Transplantation

Concerns for this patient population are life-long immunosuppression and their current cardiac status. The impact of immune suppression on risks both for and from oral infection, and the risk for infections of the transplant from a bacteremia, are unclear. The focus for immunosuppression is on lymphocytes rather than leukocytes, and lymphocytes have far less to do with suppression of infection due to oral bacterial species than do polymorphonuclear leukocytes. Immunosuppression is maintained at a higher level in the first 3–6 months following transplantation, during which there may be more of a concern for bacteremia from an invasive dental procedure. Tricuspid valve damage can occur as a result of frequent routine surveillance catheter-based endomyocardial biopsies, and these patients are recommended for antibiotic prophylaxis for specific dental procedures (Tables 14-12–14-14).[11] Patients with a heart transplant may be anticoagulated with warfarin, and considerations are similar to those for other anticoagulated patients (see subsequent section on anticoagulation and antiplatelet therapy and invasive dental procedures).

Patients in the precardiac transplant period may have odontogenic infection requiring an invasive and/or stressful dental procedure(s). The first determination is the timing for dental procedures.[213] Patients may be best managed by having dental treatment several weeks following, rather than before, cardiac transplantation, depending on their overall medical status and the nature of the indicated dental treatment. A severely compromised patient in cardiac failure may be at greater risk from stressful dental treatment of any kind before transplantation, in spite of the concern for post-transplant, procedure-related bacteremia in the presence of immunosuppression. Therefore, it is prudent to avoid elective dental treatment with less stable patients. A recent systematic review and dental management guidelines for pre–heart transplant patients failed to show a benefit from pretransplant dental treatment, largely based on a lack of studies on this topic.[214]

These patients should also be observed for oral complications or side effects from medications, such as xerostomia, oral candidiasis (secondary to steroids), and cyclosporine-induced gingival hyperplasia. They may also have orthostatic hypotension as a result of medication or their cardiac condition. If reclined for a procedure, they should be brought to a sitting position in several stages and over several minutes, after which they should sit with their feet on the floor for at least 2 minutes before standing up. Patients may also have urinary urgency during morning appointments in response to a diuretic medication and may want to use the bathroom before the procedure.

ARRHYTHMIA

Definition and Incidence

Typical electrical activation of the heart begins in the right atrium at the sinus node. This initial electrical impulse is

transmitted throughout the atria via specialized tissue until it reaches the atrioventricular (AV) node, which is located in the interatrial septum at the AV junction. The AV node serves as a break signal to allow for atrial systole to complete before ventricular systole ensues. After the physiologic AV delay, the ventricles are activated initially through a unified His-Purkinje system before bifurcating into the right bundle and left bundle. The left bundle splits further into the left anterior and posterior fascicles.

Arrhythmias can be broadly defined as any deviation from the normal cardiac pacemaker and conduction mechanism. Tachyarrhythmias, when the heart rate is >100 bpm, occur as a result of increased automaticity of cardiac pacemaker cells or due to a micro- or macro-reentrant mechanism, where the electrical impulse circulates rapidly in certain areas of the heart. Bradyarrhythmias occur due to sinoatrial node dysfunction or conduction block at any level of the conduction system. Bradyarrhythmias are defined as heart rates of <60 bpm. Both tachyarrhythmias and bradyarrhythmias may be hemodynamically well tolerated in patients with normal cardiac function, or they may result in cardiovascular collapse if cardiac output is significantly compromised.

Bradyarrhythmias

Bradycardias can result from abnormalities at any point in the conduction system and are identified by ECG. While the majority of bradyarrhythmias occur as a result of a degenerative process, they can also occur as a result of severe metabolic derangements, medications, and infections. The most common bradyarrhythmia is sinus bradycardia. This is typically a completely normal rhythm seen commonly in patients who are highly physically active. In the absence of symptoms, no treatment is necessary. Some patients will have an abnormality in the sinus node, termed sinus node dysfunction or sick sinus syndrome, resulting in sinus bradycardia. This is relatively uncommon and occurs in ~0.8 in 1000 patient-years.[215] Sinus node dysfunction may manifest with resting bradycardia or with chronotropic incompetence, whereby patients lack the ability to augment their heart rate with exercise. While the predominant symptoms associated with resting sinus bradycardia are typically dizziness or light-headedness, exertional dyspnea or a decline in exercise capacity may be seen in those with chronotropic incompetence. In minimally or asymptomatic patients with sinus node dysfunction, conservative therapy with avoidance of beta-blockers and non-dihydropyridine calcium-channel blockers is recommended. However, in patients who have symptomatic sinus node dysfunction, implantation of a permanent pacemaker (PPM) is reasonable.[204]

Abnormalities in cardiac conduction below the sinus node represent some degree of AV block. AV block can be further classified into first-degree, second-degree, and third-degree. Third-degree heart block represents a complete lack of communication between the atria and ventricles and is also termed complete heart block. While ventricular activation will still occur as a result of intrinsic pacemaker functions in the ventricular myocytes, this rate is typically quite slow, will not augment with exercise, and is highly likely to lead to cardiac syncope. As a result, implantation of a PPM is indicated for patients with complete heart block without a clear reversible cause.[204]

Identifying the level of conduction block for the remaining types of heart block is key, as block above the level of the AV node (supra-Hisian disease) rarely devolves into complete heart block/syncope, while block below the AV node (infra-Hisian disease) is much higher risk. First-degree and type 1 second-degree AV block are the result of supra-Hisian abnormalities, typically mediated by excessive vagal tone, as can be seen in the setting of good cardiovascular fitness, anesthesia, or obstructive sleep apnea, to name a few. These bradyarrhythmias rarely cause symptoms and their risk for developing into complete heart block is extremely low. In contrast, type 2 second-degree heart block is at high risk for progressing to complete heart block. PPM therapy therefore is typically recommended in these patients as well.[204] Distinguishing between the various bradyarrhythmias is beyond the scope of routine dental practice and interpretation/evaluation should be deferred to either internal medicine or cardiology.

Tachyarrhythmias

Tachyarrhythmias can be physiologic, as is the case with sinus tachycardia in the setting of exercise, infection, or dehydration, or pathologic. Among the pathologic causes, they can be further categorized into supraventricular tachycardias (SVTs) and ventricular tachycardias (VTs).

Supraventricular Tachycardia

Reentrant SVTs such as atrioventricular nodal reentrant tachycardia (AVNRT) occur commonly in the absence of structural heart disease and are usually well tolerated from a hemodynamic standpoint. AVNRT is the most common form, where the AV node is functionally dissociated into two discrete electrical pathways.[216,217] These pathways have different refractory periods and conduction velocities, which are both prerequisites for reentry. AVNRT is usually triggered by a fortuitously timed premature atrial or ventricular impulse, and therefore may be observed in settings where there is increased atrial ectopy due to anxiety or other types of sympathetic stimulation.[218] Interrupting conduction

within the reentrant circuit in the AV node can terminate the tachycardia.[219] This interruption can be achieved with maneuvers that increase vagal tone or use of AV nodal agents such as beta-blockers and/or non-dihydropyridine calcium-channel blockers. In patients who remain symptomatic despite conservative measures, catheter ablation is also reasonable.

Atrioventricular reciprocating tachycardia (AVRT) is another form of reentrant SVT. Unlike AVNRT, however, where the additional pathway is located within the AV node, in AVRT there is an accessory pathway between the atria and the ventricles that is independent of the AV node. The presence of an accessory pathway is characteristic of Wolff–Parkinson–White (WPW) syndrome. An accessory pathway can often be identified on the 12-lead ECG by the presence of a short P-R interval and the slurred onset of the QRS complex (called a delta wave). AVRT results from a reentrant mechanism where the anterograde (atrium to ventricle) conduction is through the normal AV node-His bundle axis, and retrograde conduction from the ventricles to the atria is through the accessory pathway. A less common but more dangerous arrhythmia in WPW syndrome occurs when patients develop atrial fibrillation. Because the accessory pathway cannot filter atrial impulses as well as the AV node, this constellation of atrial fibrillation and WPW can result in excessive ventricular rates and may precipitate ventricular fibrillation. In clinically stable patients, intravenous procainamide can be used; unstable patients must undergo immediate electrical cardioversion.

Atrial tachycardia (AT) is another cause of SVT. ATs occur due to increased automaticity from an atrial focus. These are typically managed conservatively with beta-blockers and/or non-dihydropyridine calcium-channel blockers; however, in refractory cases, catheter ablation is also reasonable. Given the paroxysmal nature of most SVTs, it is rare that the arrhythmia is fully captured on 12-lead ECG and more commonly the SVT is diagnosed on single-lead telemetry. As such, distinguishing between AVNRT, AVRT, and AT is often challenging and invasive electrophysiology study (EPS) is frequently necessary to fully characterize the SVT further. Given that most are typically managed similarly (with the exception of WPW, for which the delta wave is typically present on the resting 12-lead ECG), conservative therapy for most SVTs is preferred, with EPS reserved for medically refractory cases.

Atrial Fibrillation and Atrial Flutter

Atrial fibrillation is the most common sustained dysrhythmia that occurs both with and without structural heart disease (Table 14-15).[220] It represents rapid and chaotic atrial activity with an irregular and rapid ventricular response. In atrial fibrillation, the chaotic atrial activity results in ineffective atrial contraction and in stasis of blood within the left atrium and left atrial appendage. This stasis may lead to thrombus formation and markedly increases the risk of embolic events, including cerebral and peripheral embolization. Patients with MS and mechanical heart valves who also have atrial fibrillation are at highest risk for thromboembolic events. Atrial fibrillation in this setting is termed valvular atrial fibrillation.[221] Atrial fibrillation in all other patients, including those with bioprosthetic valves, AS, and MR, is classified as nonvalvular atrial fibrillation. In patients with nonvalvular atrial fibrillation, yearly thromboembolic stroke can be as high as 15%.[222] Risk factors for stroke in nonvalvular atrial fibrillation include a history of previous TIA or stroke, age above 65, significant hypertension, CHF, diabetes, female sex, and vascular disease (coronary or peripheral), and are reflected in the CHA_2DS_2-Vasc scoring system.[222] Anticoagulation is effective at reducing stroke in patients with atrial fibrillation who are at high risk and is recommended in patients with CHA_2DS_2-Vasc ≥ 2. In nonvalvular atrial fibrillation, anticoagulation with direct oral anticoagulants (DOACs), including dabigatran, rivaroxaban, apixaban, and edoxaban as well as warfarin, is a reasonable option.[223–226] DOACs are at least as effective as warfarin, with equal or less bleeding risk in general. They do not require frequent International Normalized Ratio (INR) monitoring and are not affected by dietary intake or other medications. Cost remains the major barrier for widespread usage, though insurance coverage has improved in recent years. While DOACs are an option for those with nonvalvular atrial

Table 14-15 Etiologies of atrial fibrillation.

Hypertension
Valvular heart disease
Coronary artery disease (including both acute myocardial infarction and ischemic cardiomyopathy)
Congenital heart disease (atrial and ventricular septal defects, Ebstein's anomaly, patent ductus arteriosus, tetralogy of Fallot, etc.)
Hypertrophic cardiomyopathy
Dilated cardiomyopathy
Peripartum cardiomyopathy

Pericardial disease
Primary pulmonary disorders (chronic obstructive pulmonary disease, pulmonary fibrosis, etc.)
Obstructive sleep apnea
Thyrotoxicosis
Autonomic dysfunction
Post-surgical (cardiac and noncardiac surgeries)
Medication induced (theophylline, caffeine, digitalis, etc.)
Familial/genetic
Pheochromocytoma

fibrillation, warfarin remains the recommended treatment option for those with valvular atrial fibrillation.[221]

In many patients with a first episode of atrial fibrillation, the cardiologist will usually try to restore and maintain normal sinus rhythm.[221] In patients who have had atrial fibrillation for more than 48 hours or uncertain duration, cardioversion can be performed, either following at least 3 weeks of adequate anticoagulation (either uninterrupted DOAC use or warfarin at a therapeutic INR), or following a transesophageal echocardiogram that did not reveal a clot in the left atrium or left atrial appendage.[227] Following cardioversion, anticoagulation needs to be continued for at least 4 more weeks, because clots can still form during this period. After the 4-week period, the ongoing requirement for anticoagulation is dictated by the CHA_2DS_2-Vasc score.[221]

In patients with recurrent paroxysmal or persistent atrial fibrillation, there are two treatment options available: rate control and rhythm control. The rate control strategy makes no attempt at restoration or maintenance of sinus rhythm, but simply tries to achieve an asymptomatic or minimally symptomatic condition by controlling the heart rate with beta-blockers, calcium-channel blockers (verapamil, diltiazem), and/or digoxin.[228] In the rhythm control strategies, therapies are aimed to prevent atrial fibrillation from occurring. Several studies have shown an overall similar clinical outcome with rate control and rhythm control, especially in the elderly and in those with a normal EF.[229,230] Younger patients and those with HFrEF may have better outcomes with rhythm control.[230–232]

When a rhythm control strategy is chosen, maintaining sinus rhythm can be attempted with antiarrhythmic drug therapy or with catheter ablation. In experienced centers with contemporary techniques, catheter ablation for atrial fibrillation is probably more effective antiarrhythmic drug therapy and can be performed safely.[233–235] Despite its improved efficacy over pharmacologic therapy, it is rarely curative, as long-term atrial fibrillation recurrence rates are ~50%.[233] While there is no data to suggest a survival advantage to catheter ablation in all-comers, among patients with HFrEF catheter ablation has been demonstrated to reduce mortality and hospitalization.[232] Based on these data, it is reasonable to consider catheter ablation in patients with HFrEF, particularly in symptomatic patients.

Ventricular Tachyarrhythmias

Ventricular tachycardia (VT) and ventricular fibrillation (VF) typically occur in patients with structural heart disease, such as those with CAD, various forms of dilated cardiomyopathy, and HCM. Rarely, VT/VF may occur as an idiopathic event in an individual with a structurally normal heart due to genetic conditions (long QT syndrome, Brugada syndrome, catecholaminergic polymorphic VT, etc.) or as a result of QT prolongation from drug effects.

Patients with sustained VT and resuscitated VT/VF require a thorough evaluation for the underlying structural or functional abnormality. Prevention of subsequent episodes may be achieved by treating the underlying cause if reversible. If such a cause is found, patients with structurally normal hearts and a history of clinically stable VT may undergo antiarrhythmic drug therapy trials. Beta-blockers appear to be the safest and most effective class of medications for this indication.[236] Patients who had a hemodynamically unstable VT or resuscitated VF without reversible cause, on the other hand, are typically treated with an ICD.[237] The indications for ICD therapy will be discussed below.

Dental Management Considerations

As discussed above, the spectrum of arrhythmias is broad and encompasses both benign and very severe disorders. Therefore, being familiar with the specific diagnosis is important in the dental assessment. All patients with a known history of arrhythmia should be asked about dizziness, fatigue, chest pain, exercise intolerance, angina, shortness of breath, and awareness of irregular heart beats, as well as medications taken. If the patient has syncope or near syncope, or sustained periods of irregular rhythm, they should be under medical supervision. It is also important to know whether the patient has an implanted device such as a pacemaker or defibrillator (see the next section on Cardiovascular Implantable Electronic Devices).

Premature atrial or ventricular beats and SVTs are common and are generally not of concern. Patients who are being actively treated for these arrhythmias should continue their current therapy and can typically move forward with dental care safely. The majority of patients with atrial fibrillation or atrial flutter will be treated with anticoagulant therapy, for which decisions regarding continuation or cessation should be tailored on a patient-by-patient basis.[238] In general, with the increased use of direct oral anticoagulant therapy, anticoagulation for atrial fibrillation/flutter can be safely stopped for 24–48 hours prior to invasive dental procedures at low risk, though these decisions should always be discussed with the patient's primary care physician or cardiologist. Aside from antithrombotic management, the vast majority of patients with known atrial fibrillation or flutter will be able to undergo dental treatment without further modification of their medical regimens.

Patients with genetic conditions such as long QT or Brugada syndrome are at risk of VT and sudden cardiac death. These conditions can be triggered by emotional stress, auditory stimuli, and medications, including some used for topical anesthesia.[239] Procaine is contraindicated in this population. Providing adequate analgesia during dental care for these patients, however, is very important, and a recent

randomized study has demonstrated that topical lidocaine with or without epinephrine can be safely used even among these very high-risk patients.[16] Despite this evidence that dental care can be provided safely for these patients, given the potential for life-threatening complications, even if rare, these patients may be best managed in a hospital setting where emergency medical services are readily available.[12]

CARDIOVASCULAR IMPLANTABLE ELECTRONIC DEVICES

Implantable Loop Recorders

Implantable loop recorders (ILRs) are implantable cardiac monitors that provide continuous heart rhythm monitoring for up to 3 years. The device is quite small (at the time of publication, the current device is 2.5 g and has dimensions $45 \times 7 \times 4$ mm) and is placed subcutaneously in the left sternal area. The device is placed under sterile conditions and the risk of complication such as infection is exceedingly rare.[240] The most common indications for ILR placement include evaluation of atrial fibrillation burden, recurrent syncope of unknown origin, and evaluation for ventricular arrhythmias in those with known cardiomyopathies and in the workup for cryptogenic stroke. In patients with cryptogenic stroke without a clear etiology, ILRs were seven times more effective than standard of care at identifying atrial fibrillation in these high-risk patients.[241]

Pacemakers

Permanent cardiac pacing is used in a wide variety of cardiac conditions, most commonly symptomatic bradycardia and heart block. Transvenous pacemakers are most commonly used and allow for atrial and ventricular pacing (both single ventricle and biventricular). In transvenous pacemaking systems, electrodes are placed into the venous system and anchored into the heart. The electrodes are then connected to a generator, which is placed subcutaneously. More recently, leadless pacemakers have been developed that are placed transfemorally. The generator and lead are contained within the device, which is inserted into the right ventricle. Leadless pacemakers have been shown to be safer than standard transvenous devices.[242] Despite these advantages, current leadless pacemaking systems do not allow for synchronized atrial-ventricular pacing, which represents a significant limitation of the current generation of leadless pacemakers. Guidelines for the implantation of cardiac pacemakers have been established by the ACC and AHA joint task force on the basis of available evidence in the medical literature.[243]

Implantable Cardiac Defibrillators

As discussed earlier, ICDs are utilized to detect VT/VF and deliver automatic defibrillation if identified. Most ICDs are transvenous and as such are similar to transvenous pacemakers, though the electrode and generators have different capabilities. While all transvenous defibrillators have the capability to provide backup pacing function, the converse is not true. Recently, subcutaneous ICDs have been developed. These devices do not have any endovascular component and are placed underneath the skin in the chest wall. Subcutaneous ICDs are effective at detecting and terminating VT/VF and offer the advantage of a very low infectious risk.[244] Unlike transvenous ICDs, however, subcutaneous ICDs lack the ability to pace. Nevertheless, these devices remain a good option for those at increased infectious risk and/or younger patients who are low risk for developing an indication for PPM. ICDs are indicated in patients who have had sudden cardiac death due to VT/VF without a clear reversible cause, for secondary prevention, and in patients who are at high risk for VT/VF, for primary prevention. Studies have demonstrated that ICDs improve survival in patients with NYHA class II or worse heart failure symptoms and an LVEF <35%, patients with NYHA class I symptoms with an LVEF <30%, and in those with ischemic heart disease, documented evidence of nonsustained VT, and an LVEF <40%.[237,245,246]

Cardiovascular Implantable Electronic Device Infection

Cardiovascular implantable electronic device (CIED) infection represents a major complication associated with both pacemakers and ICDs. The risk of infection with ILRs is very low. Overall, the rate of cardiac device infection is relatively low at 1–2%. Despite these relatively low rates, when it does occur, CIED infection is a lethal disease with a 1-year mortality of 18%–20%.[247] Leadless pacemakers represent an important innovation in PPM therapy and have been shown to have very low infection rates.[248] Subcutaneous ICDs offer the theoretical advantage of infection reduction given that they have no endovascular component; however, data is not yet available confirming this. Patients with established CIED infection are treated with device removal and antibiotic therapy. The decision to reimplant and the timing will depend on the severity of the infection, concomitant valvular involvement, and the primary indication for the device.

Dental Management Considerations

Implanted devices, such as cardiac pacemakers, ICDs, and LVADs, are increasingly important in the management of heart

failure and the prevention of sudden death from arrhythmia. According to current ACHA guidelines, antibiotic prophylaxis is not indicated for patients with pacemakers or other ICDs, unless the patient presents with an odontogenic abscess.[11,154] The exception to this may be LVADs, because, like patients in the AHA "higher-risk" group, these patients are more likely to have a bad outcome if they get infective endocarditis.

The issue of interference of pacemaker function by ultrasonic scalers and electrosurgical units is controversial. This is of particular concern, however, for patients with cardiac channelopathies that can lead to sudden VF and death. Some studies suggest that modern pacemakers are not influenced by any type of dental equipment, including high-speed rotary instruments or ultrasonic devices, and others suggest that these devices do impact pacemakers.[249]

VENOUS THROMBOEMBOLIC DISEASE

Definition and Epidemiology

Venous thromboembolic (VTE) disease comprises both pulmonary embolism (PE) and deep venous thrombosis (DVT). It is a relatively common disease with an incidence of first acute VTE event of 0.7–1.4 in 1000 person-years.[250] The socioeconomic burden of VTE is substantial, with increasing rates of hospitalization for acute VTE and an estimated annual cost for management of VTE in the United States ranging from $13.5 billion to $27.2 billion.[251,252] Despite improvements in outcomes with management of acute VTE, the 1-year mortality after diagnosis remains ~30%.

VTE occurs as the result of thrombus formation in the venous system, in the case of DVT, and subsequent transit of that thrombus into the pulmonary circulation, in the case of PE. The most important distinction in considering the etiology of VTE is whether it occurred in a provoked versus an unprovoked setting. VTE is commonly seen after prolonged immobilization, such as after surgery or lengthy air/car travel or in the presence of certain medications (particularly estrogen-containing hormonal therapies). VTE in this setting is considered to be a provoked event. VTE that does not occur in these settings is considered unprovoked. Risk factors for unprovoked DVT include inherited thrombophilias such as protein C/S deficiency, acquired thrombophilias such as antiphospholipid antibody syndrome, malignancy, prior episode of VTE, age, obesity, and a family history of VTE.

Diagnosis

Patients with DVT typically present with unilateral leg pain and swelling, while those with PE may present with shortness of breath, pleuritic chest pain, and hemoptysis. Tachycardia is very common and in large PEs, syncope and hypotension can also be present. The diagnosis of VTE is made in several steps. Clinical decision-making tools are available to help assess the likelihood of VTE. If VTE is unlikely clinically, laboratory testing with D-dimer is typically performed. D-dimer testing has excellent sensitivity and a negative test is effective at excluding patients with VTE. If the clinical suspicion for VTE is high, imaging rather than D-dimer testing is recommended. If DVT is suspected, vascular ultrasound is the diagnostic modality of choice. If PE is suspected, CTA protocoled to evaluate for PE is recommended.[253] Given the significant increased risk of VTE in the setting of malignancy, it is recommended that all patients with unprovoked VTE undergo appropriate routine cancer screening. More extensive evaluation, however, is not recommended. Targeted hypercoagulability workup in select patients is reasonable, though it should not be reflexively performed in all patients with VTE, as the yield particularly in older patients is quite low.[254]

Management

Anticoagulation is recommended in all patients with VTE. In those patients with provoked events, 3 months of anticoagulation is recommended. In patients with unprovoked VTE, indefinite anticoagulation, assuming the bleeding risk is not high, is recommended. In patients with cancer, anticoagulation is continued for as long as the cancer remains active. For nonmalignancy-related VTE events, use of DOACs is recommended over warfarin.[255] In patients who continue on long-term anticoagulation, there are data to suggest that dose reduction after 1 year provides significant protection against recurrent events at low bleeding rates.[256,257] Management of cancer-related VTE differs slightly. Low molecular weight heparins have been shown to be superior to warfarin in this patient population.[258] There are increasing data on the safety and efficacy of DOACs in cancer and recent guidelines have included DOACs as an option in cancer-related VTE as well.[259–261]

Dental Management Considerations for Anticoagulation and Antiplatelet Therapy and Invasive Dental Procedures

Most patients with a history of VTE can safely have their anticoagulation interrupted if needed for invasive procedures. In addition, given the short half-lives of DOACs, 24 hours of cessation are typically adequate for minor

procedures and 48 hours for major procedures.[262] This is in contrast to warfarin, which due to its mechanism of action can take 3–5 days before the INR returns to normal. In a select group of patients in whom the risk of recurrent VTE is high (within the first 30 days after an acute VTE event, recurrent events despite anticoagulation, or recurrent events while temporarily off anticoagulation), use of low molecular weight heparin as a bridging agent can be considered. While the majority of patients can undergo temporary interruption if necessary, consultation with the patient's cardiologist is recommended.

Many cardiac patients will have impaired hemostasis due to one or more medications, which may dictate modifications in dental management.[249,263] For example, anticoagulant therapy is used to treat and prevent thromboembolism, and different medications are used based on the patient's underlying condition, for example atrial fibrillation or atrial flutter, VHD, prosthetic heart valves, coronary stents, ischemic heart disease, cerebrovascular accidents, PE, and DVT. The major groups of medications used for anticoagulation are drugs with antiplatelet activity and those with antithrombin activity, and more recently DOACs.

The most common antiplatelet drug is low-dose aspirin (81 mg daily), which irreversibly decreases platelet aggregation. For invasive dental procedures, the dose and duration of aspirin may be irrelevant, since one aspirin tablet essentially blocks platelet aggregation for the lifetime of the platelet.[264] This is the basis for the recommendation by some clinicians that aspirin be stopped for 5 days prior to a procedure because the half-life of the platelet is about 10 days, and so about 50% of the platelets should have been regenerated. The same is true for clopidogrel. Although a bleeding time test is often recommended to evaluate a qualitative defect in platelets, this test has not been shown to have a correlation with impaired intraoral hemostasis unless bleeding time is significantly longer than 15–20 minutes.[265–268] Less is known about the risk of oral bleeding following dental procedures in patients taking the newer class of antiplatelet drugs (e.g., clopidogrel), but there is a growing consensus that these antiplatelet drugs should not be stopped for dental procedures.

The longstanding vitamin K antagonist medications are the dicumarols (warfarin), which inhibit the biosynthesis of vitamin K–dependent coagulation proteins (factors II [prothrombin], VII, IX, and X). The full therapeutic effect of warfarin is reached after 48–72 hours and lasts for 36–72 hours if the drug is discontinued. Efficacy of warfarin therapy is monitored by the INR. The desired therapeutic level of the INR is dependent on the underlying medical condition, but is usually kept in the range of 2.0–3.0. In some patients with mechanical prosthetic heart valves, the target INR is higher, frequently from 2.5 to 3.5. Some of these patients may also be on low-dose aspirin. INR values fluctuate in some patients such that a past result may not reflect the INR value in subsequent days. For an accurate assessment, an INR measurement should be performed within several hours of a planned invasive dental procedure.[269]

The vitamin K antagonists are now often replaced by the DOACs (e.g., dabigatran, rivaroxaban, apixaban, and edoxaban). They are being prescribed to larger numbers of patients for several purposes, such as atrial fibrillation and DVT.[255] They have the benefit of avoiding the need for routine INR testing. Little is known about differences in the dental management of patients on DOAC drugs by comparison with warfarin.[270–272] As with warfarin, there is a consensus that the risk to the patient if these drugs are discontinued or reduced for any period of time far exceeds the problem of prolonged oral bleeding.[273,274]

Dental care for patients on anticoagulation therapy has been discussed in numerous dental and medical publications, and various protocols have been suggested.[265,270,275–278] The debate surrounding invasive dental procedures centers on the potential risk for excessive bleeding during or after the procedure if anticoagulation therapy is not adjusted (i.e., lowered) versus the risk of a thromboembolic event if the anticoagulation therapy is altered.[279,280] In the case of warfarin, there is little or no indication for altering anticoagulation therapy before routine oral surgical procedures when the patient's INR is <3.5.[263,281] This conclusion is based on a minimally increased risk of clinically significant intraoral bleeding at this level of anticoagulation and the ease with which most intraoral bleeding can be stopped with local measures, by comparison with the potentially devastating consequences of thromboembolic events (e.g., embolic stroke) if warfarin therapy is reduced or withheld.

The problem of developing a uniform protocol for anticoagulated patients is the ability to quantify risk using parameters that can be applied to the majority of patients.[265,282–284] Several relevant issues need to be considered, including the underlying medical condition requiring anticoagulation therapy, the type of medication(s) used to achieve anticoagulation, the degree of anticoagulation, the timing of dental care, and the cost and inconvenience to the patient. This consideration is also influenced by the timing of the recent thromboembolic event, and patients can be stratified into high, moderate, or low risk of thrombosis.[285]

Data that address the risks of bleeding from invasive dental procedures in patients who take antiplatelet drugs are limited.[266,286] For patients taking aspirin, current thinking is that the risk of clinically significant bleeding from anything other than highly invasive oral surgical procedures is small, and postextraction bleeding is relatively easy to manage. Antiplatelet therapy should not be discontinued for dental

procedures, to include uncomplicated extractions.[263,287–289] This is especially important for patients taking antiplatelet drugs following placement of coronary stents, as it has been reported to result in stent thrombosis.[103] When used in combination, dual antiplatelet therapy may increase the risk for surgical bleeding, and this risk increases further with the addition of warfarin or other oral anticoagulants. Such anticoagulant combinations may be expected in patients who underwent coronary stenting and for those who have atrial fibrillation, atrial flutter, or a history of DVT or PE. In general, the risk for those patients from prolonged oral bleeding following an invasive procedure (e.g., single extraction) is far less than the risk from altering (lowering) the patient's anticoagulation.

Historically, three different protocols have been used to treat patients who require moderately or highly invasive dental procedures and who have an elevated INR. In the first protocol, warfarin is continued without a change in the dose. This approach virtually eliminates the risk of an adverse thromboembolic event. With the second protocol, warfarin therapy is discontinued for about 5 days prior to surgery and then restarted after surgery. It takes an additional 2–3 days after surgery to regain the full therapeutic effect of the medication, during which patients may be in a hypercoagulable state and at increased risk for a thromboembolic event. In the third protocol, used for patients at high risk of thromboembolism, warfarin therapy is discontinued, and the patient is placed on an alternative anticoagulation therapy such as low molecular weight heparin. This protocol has both advantages and disadvantages. The advantage is that the risk for developing a thromboembolic event is theoretically minimized below that of the second protocol. When unfractionated heparin is used for bridging the warfarin-free period, the patient may be admitted to hospital, have their oral anticoagulation (warfarin) therapy discontinued, be administered vitamin K, and be started on parenteral heparin therapy. Heparin is continued until approximately 6 hours before surgery and is reinstituted after surgery in combination with oral anticoagulation therapy until a desirable INR has been reached. This is both a time-consuming and costly protocol that is rarely indicated for dental procedures. The advantages of using heparin are a short half-life of 4–6 hours and the availability of an antidote, protamine sulfate. An alternative to using standard unfractionated heparin is to have the patient self-administer a subcutaneous injection of low molecular weight heparin on an outpatient basis.

Formal guidelines exist for managing intra- and postoperative bleeding and it is not clear whether there is an increased benefit from one protocol over another. Local measures include the use of resorbable gelatin sponge and sutures and tranexamic acid mouthwash.[284]

If the patient has other underlying medical conditions that predispose to impaired hemostasis, such as uremia or liver disease, and/or takes other anticoagulants (e.g., non-aspirin, NSAIDs), the possibility of oral bleeding following invasive procedures likely increases.[263,265,266,276,287,290,291] Little or no data exist to help with decisions concerning invasive dental procedures in patients with multiple coagulopathies. Nevertheless, altering anticoagulation likely proves a greater risk than the risk of clinically significant bleeding. Given fluctuations in INR test results over time for some patients, the concern for systemic disease, and the impact of medications (e.g., NSAIDs and aspirin), there is increased concern for invasive procedures. There may need to be medical (e.g., hematology, cardiology) consultation beforehand.

Caution should be used with the prescription of antibiotics for patients on warfarin, as they may interfere with the role of intestinal bacteria in vitamin K homeostasis.[285] Concerns also exist for drug toxicity from the use of azole antifungals. Additionally, anticonvulsants (e.g., carbamazepine) may have severe pharmacokinetic interactions. Some dietary changes may alter vitamin K consumption. INR testing may be indicated to identify these alterations in anticoagulation. The DOACs do not have most of these considerations. However, clarithromycin and azole antifungals, as well as carbamazepine, are a concern and medical advice should be sought before their use.[285]

Diseases of the Gastrointestinal Tract

Jeremy Sanderson, MD, FRCP
Michael P. Escudier, MD, MBBS, FRCS Eng., FDS RCS Eng., FDS (OM) RCS, FDS (OM) RCPS Glas., FFD RCSI, FFGDP (UK), FHEA

This chapter aims to review diseases affecting the gastrointestinal tract, with an emphasis on the medical aspects, the oral healthcare professional's (OHCPs) role in screening for undiagnosed conditions, and their role in monitoring patient compliance with recommended medical therapy for gastrointestinal conditions that are likely to be encountered in practice of dentistry. OHCPs are expected to recognize, diagnose, and treat oral conditions associated with gastrointestinal disease, as well as provide dental care for these individuals. To provide safe and appropriate oral care, OHCPs are expected to be able to correctly diagnose oral manifestations of gastrointestinal disorders and their possible implications for homeostasis, risk of infection, drug actions and interactions, as well as any impact on the patient's ability to withstand the stress and trauma of dental intervention and, when necessary, arrange an appropriate medical referral. These management issues are discussed, where appropriate, for each gastrointestinal disorder.

Both OHCPs and gastroenterologists have a primary focus within the gut. While embryologically the oral cavity originates from the ectoderm layer and the gastrointestinal tract from the endoderm layer and they are initially separated by the buccopharyngeal membrane, they share a common function. This commonality is illustrated by the finding of a heterotopic gastric mucosal cyst in the oral mucous membranes or on the tongue.[1] However, in addition to these relatively rare anomalies, gastroenterologists and OHCPs often share mutual patients.

The digestive tract is a long muscular tube that moves food and accumulated secretions from the mouth to the anus. As ingested food is slowly propelled through this tract, the gut assimilates calories and nutrients that are essential for the establishment and maintenance of normal bodily functions. Protein, fats, carbohydrates, vitamins, minerals, water, and orally ingested drugs (prescription and nonprescription) are digested in this tract. This digestive process depends on the hydrolysis of large nonabsorbable molecules into smaller absorbable molecules through secreted enzymes and the absorption of substances through the epithelial lining of the digestive tract. From

Burket's Oral Medicine, Thirteenth Edition. Edited by Michael Glick, Martin S. Greenberg, Peter B. Lockhart, and Stephen J. Challacombe.

there, digested substances are transported by blood vessels and lymphatic channels through the body. The remaining contents of undigested food, typically cellulose fiber, are excreted out of the digestive tract through the rectum and anus. The digestion and absorption of nutrient materials depend on (1) an optimal hydrogen ion concentration (pH) in the gut; (2) the presence of conjugated bile salts; (3) adequate concentrations of enzymes to split fats, proteins, and carbohydrates; (4) adequate intestinal mobility; and (5) a normal gut microbiome.

Some of the foods entering the blood from the digestive tract can be used unaltered by cells. However, the majority of the absorbed food passes to specific organs, such as the liver, where it undergoes intermediate metabolism to prepare it for use by cells. The gastrointestinal tract is also a primary route for drug administration, absorption, biotransformation, detoxification, and excretion. Many dental patients require drug therapy in which pharmacokinetic parameters may be altered by gastrointestinal and hepatobiliary dysfunction. OHCPs therefore require a clear understanding of the gastrointestinal system and how normal and abnormal function may affect the oral health and care of patients.

Digestion normally begins within the oral cavity, where ingested material is moistened with saliva, masticated, formed into a bolus, and swallowed by the coordinated muscular function of the tongue, pharynx, and epiglottis. The digestive system comprises the esophagus, stomach, small intestine, and large intestine. Each of these components, assisted by the exocrine functions of the salivary glands, pancreas, liver, and gallbladder, performs specific functions as ingested substances pass through it, enabling assimilation of dietary calories and nutrients.

This chapter is organized under the following anatomic divisions: esophagus, stomach, small intestine, large intestine, and hepatobiliary tree. A final section addresses gastrointestinal syndromes that can affect both the oral cavity and the gastrointestinal tract, but are not primarily of oral or gastrointestinal etiology.

DISEASES OF THE UPPER DIGESTIVE TRACT

Gastroesophageal Reflux Disease

Medical Aspects

A distinction needs to be made between gastroesophageal reflux (GER) and reflux leading to symptoms or disease (GERD). GER can be a physiologic phenomenon that occurs in asymptomatic individuals. In contrast, GERD is defined as a condition in which reflux leads to "troublesome symptoms and/or complications."[2] Patients may experience mild symptoms with an esophagus that appears to be clinically normal, or they may have severe symptoms with surface abnormalities that can be detected with an endoscope. The process by which GER leads to GERD consists of a sequence of events spanning the esophagogastric junction, the esophageal body, and the central nervous system.

GERD is one of the most commonly occurring upper gastrointestinal tract conditions with up to 10% of the population experiencing symptoms daily. There is no gender difference in a condition that can have a significant effect on daily activities.

"Heartburn" is the cardinal symptom of GERD and is defined as a sensation of burning or heat that spreads upward from the epigastrium to the neck.[3] Although symptoms of GERD are variable, they primarily arise in relation to mucosal injury, for example esophagitis, esophageal ulceration, stricture, and dysplasia. Other symptoms include chest pain, which due to its similarity to that arising from an acute cardiovascular event may prompt the patient to seek medical advice and dysphagia.

Airway problems such as laryngitis, chronic cough, hoarseness, and asthma may arise as a result of microaspiration of refluxate into the airway.[4,5] This constellation of symptoms is known as laryngopharyngeal reflux (LPR) or extraesophageal reflux disease (EERD). However, these symptoms may also arise from disorders of the upper or lower respiratory tracts.

GORD complications include premalignant and malignant conditions of the esophagus. Barrett's esophagus is a variant of GERD in which normal squamous epithelium is replaced by columnar epithelium.[6] Patients with this phenomenon show an increased incidence of adenocarcinoma. This condition may increase the incidence of carcinoma by as much as 10%,[7] although the majority of patients with Barrett's esophagus die from unrelated causes.[8,9] The major reason to evaluate patients with chronic symptoms of GERD is to recognize Barrett's esophagus. Endoscopic screening is recommended for patients with multiple risk factors for cancer in Barrett's esophagus, including chronic GERD, hiatal hernia, advanced age, male sex, white race, cigarette smoking, and obesity with an intra-abdominal body fat distribution. During the last decade, new techniques have been introduced for diagnosis of GERD and Barret's esophagus.[10]

The relaxation of the lower esophageal sphincter for the purpose of relieving pressure in the stomach (from gas and the ingestion of food) is called the "burp" mechanism. This phenomenon is a physiologic process and only occurs when a person is in an erect posture; gastric contents are thereby prevented from flowing into the esophagus and possibly being aspirated. The gastroesophageal junction prevents regurgitation (retrograde or upward flow) of gastric contents and is composed of an internal lower esophageal sphincter. External pressure on the junction by the diaphragm also assists in this

function. When this barrier fails, gastric contents may make their way into the esophagus and cause symptoms. The cause of lower esophageal sphincter incompetence, while not mechanical, remains unclear. However, surgery, scleroderma, and drugs, including anticholinergics, cardiac vasoconstrictors, nicotine, and estrogen-progesterone combinations used in contraceptives, can cause an incompetent sphincter, as may also happen during pregnancy.

Symptoms occur when refluxate proceeds through the junction. The severity of the symptoms depends on the amount of acid in the refluxate, the speed with which the esophagus can clear the refluxate, and the presence of buffering agents, such as swallowed saliva. An insufficient amount of alkaline fluid prohibits the esophagus from properly buffering the acid that has moved up from the stomach. Patients who smoke tobacco, take certain drugs, have had high-dose head and neck radiotherapy, or suffer from diseases such as Sjögren's syndrome may not produce sufficient saliva to protect the esophagus from the acid in the refluxate. Increased abdominal pressure as a result of obesity, pregnancy, or a large meal may predispose patients to gastric content reflux. Moving into or out of various positions, for instance lying down too soon, especially after eating, will also promote reflux.

Medical Management

Lifestyle modification is often effective, with weight loss having a dose-dependent association with symptom reduction: a 3.5 kg/m^2 reduction in the body mass index can achieve nearly a 40% reduction in the risk of having frequent symptoms. Other lifestyle modifications include elevation of the head of the bed and avoidance of meals 2–3 hours before bedtime, if there are nocturnal symptoms. Patients should also avoid foods that specifically trigger their symptoms. Tobacco and alcohol cessation, while often recommended, has not been shown to improve symptoms overall. Drugs with anticholinergic or smooth muscle–relaxing properties may exacerbate reflux symptoms, as may those causing a chemical esophagitis, such as oral bisphosphonates.

If symptoms persist, the addition of acid suppression therapy, in the form of H_2 receptor antagonists, may improve or eliminate the symptoms of "heartburn" and regurgitation and heal mild to moderate esophagitis. However, proton pump inhibitors (PPIs) such as omeprazole, esomeprazole, lansoprazole, pantoprazole, and rabeprazole (available by prescription), which block the final common pathway of acid secretion by irreversibly binding to and inactivating the proton pump (H+/K+-ATPase exchange) are commonly used. These are more effective in reducing symptoms and in healing erosive esophagitis than H_2 receptor antagonists ($84\% \pm 11\%$ vs. $52\% \pm 17\%$).[11] Daily PPI treatment provides the best long-term reduction of symptoms for patients with moderate to severe esophagitis.

Surgical intervention is generally reserved for those patients unresponsive to maximal medical therapy or unable to tolerate treatment. Laparoscopic fundoplication is the most common procedure and is highly effective in well-selected patients. Fundoplication involves construction of a cuff of gastric (fundus) tissue around the lower esophageal sphincter junction.[12] This improves function via a variety of mechanical factors and also modifies the reflexes involved in the pathophysiology. The strongest predictors of success include abnormal 24-hour pH scores, classic symptoms of GERD, and a positive PPI trial.[13] Gastric bypass surgery and laparoscopic gastric banding decrease GERD symptoms primarily through the resulting weight loss.[14]

Oral Health Considerations

Patients who experience GERD may complain of extraesophageal symptoms including laryngitis, asthma, cough, chest pain, dental erosion, dysgeusia (foul taste), halitosis, tongue sensitivity, burning sensations, dental sensitivity related to hot or cold stimuli, and/or pulpitis.[15]

Oral mucosal changes are minimal; however, erythema and mucosal atrophy may be present as a result of chronic exposure of tissues to acid. Noncarious tooth surface loss (NCTSL), comprising erosion, attrition, and abrasion, is multifactorial and it is rarely possible to identify a single etiology in a specific patient.[16] Factors that determine whether an individual with GERD will or will not develop dental erosion have not been clearly identified and the strength and prevalence of the association are highly variable.[17] However, a significantly lower oral pH was found in patients with GERD and bulimia nervosa as compared to healthy individuals.[18] The chemical dissolution of enamel (erosion) may lead to exposed dentin and resultant thermal sensitivity or, if severe, irreversible pulpal (nerve) damage necessitating root canal therapy. The rate of progression and severity of erosion may be exacerbated by associated attrition and abrasion, inadequate oral hygiene, poor or reduced salivary flow, consumption of acidic beverages or foods, occupation, alcoholism, and eating disorders. OHCPs should therefore closely examine their patients for evidence of NCTSL and instigate appropriate prevention and treatment. In particular, patients with erosion on the palatal and lingual surfaces should be questioned for a history of GERD, with a view to onward referral to their primary care physician if appropriate. Dental management should be tailored to the extent and rate of progression of the condition and any associated symptoms, and include early dietary and preventive advice, and topical fluoride applications to ensure optimal dental mineralization and reduction of thermal sensitivity. The restoration of lost tooth structure will provide symptomatic relief as well as enhancing function and esthetics and help to minimize further hard tissue damage.

The medical management of GERD may impact on dental care. Many of the listed potential drug interactions, for example cimetidine and H_2 receptor antagonists with local anesthetic agents, are either theoretical and may not have been seen in dental practice, or are relevant to much higher doses used for different indications. Reports of serious drug interactions associated with currently recommended doses of local anesthetics and vasoconstrictors in the dental setting are exceedingly rare.[19] Similarly, while H_2 receptor antagonists and PPIs may be associated with a degree of xerostomia, this is not usually clinically significant. Likewise, although H_2 receptor antagonists may cause central nervous system effects, from fatigue and lethargy to confusion, delirium, and seizures, these effects are dose dependent and are rarely problematic. As cimetidine inhibits the absorption and therefore the blood concentration of azole antifungal drugs such as ketaconazole (via inhibition of the cytochrome P-450 3A4 [CYP3A4] enzyme system), topical antifungal therapy should be considered in the first instance. Finally, soft tissue changes such as esophageal stricture and fibrosis may complicate intubation if the patient requires general anesthesia for dental treatment.

Hiatal Hernia

Medical Aspects

The esophagus passes through the diaphragmatic hiatus and into the stomach just inferior to the diaphragm. The hiatus causes an anatomic narrowing of the opening into the stomach, which helps prevent reflux of stomach contents into the esophagus. Some patients have a weakened or enlarged hiatus, possibly due to hereditary factors. It may also be caused by increased intra-abdominal pressure, for instance from obesity, or chronic straining when passing stools. When a weakened or enlarged hiatus occurs, a portion of the stomach herniates into the chest cavity through this enlarged hole, resulting in a hiatal hernia.[20] Hiatal hernias are quite common; occurrence rates are between 20% and 60%.[20] The incidence of hiatal hernia increases with age, although the condition is also seen in infants and children. As the diaphragm separates the thorax from the abdomen, symptoms of hiatal hernia often include chest pain, which may mimic those of myocardial infarction. If the hiatal hernia is small, there may be no symptoms, while if the area of the hiatus is very weak, there may be entry of acidic digestive juices into the esophagus.[20]

Hiatal hernias are classified into one of four types (I, II, III, and IV) based on the location of the gastroesophageal junction in relation to the pillars of the crura.[20] A type I hernia is the classic "sliding" form and the most common. In this type, the herniated portion of the stomach slides back and forth through the diaphragm into the chest. These hernias are normally small and often present with minimal (if any) symptoms. The remaining three types are true paraesophageal hernias and account for only 5%–15% of all hiatal hernias.[20] The common feature of these is herniation of the stomach into the thoracic cavity, due to laxity of the gastrosplenic and gastrocolic ligaments in addition to crural deformation.[20] Complications associated with these hernias include obstruction, volvulus, and ischemia.

Infants with hiatal hernia usually regurgitate bloodstained food and may also have difficulty in breathing and swallowing. Adult patients with hiatal hernia may experience chronic acid reflux into the esophagus, with its associated symptoms. Chronic gastroesophageal reflux can erode the esophageal lining, causing bleeding, which may lead to anemia or cause inflammation and scarring, leading to esophageal narrowing. This narrowing may impair the passage of food into the stomach, resulting in dysphagia and an uncomfortable feeling of fullness or "bloating." In contrast to abdominal hernias, hiatal hernias have no outward physical signs and are usually discovered on endoscopy, manometry, or other radiographic studies investigating GERD or other upper gastrointestinal complaints.[20]

Medical Management

Defects present at birth may sometimes correct themselves. Until this occurs, however, the infant should sleep in a crib with the head raised and be given an altered diet consisting of food that has a thicker than normal consistency. In adults the management is similar to that of GERD, for example weight loss, antacids, elevation of the head of the bed, and avoidance of meals 2–3 hours before bedtime (if there are nocturnal symptoms), as well as avoidance of foods that trigger symptoms and H_2 receptor antagonists.

Lifestyle modification and drug therapy usually allow patients to minimize the symptoms of hiatal hernia without significant inconvenience and form the preferred management.[21] When conservative measures fail to control the condition, laparoscopic[22] or open surgical correction, which may be complex, can be considered.

Oral Health Considerations

If a hiatal hernia is associated with reflux into the oral cavity, those oral manifestations seen in GERD may be present. While medical intervention may include xerostomic medication, it is rarely clinically significant.

Disorders of the Stomach

The stomach acts as a reservoir and secretes hydrochloric acid, mucus, pepsinogen, and intrinsic factor. The secreted hydrochloric acid is responsible for killing swallowed organisms, while the mucus helps coat and lubricate the stomach's lining epithelium in order to assist propulsion of the ingested contents through the digestive system.

Pepsinogen, a proteolytic enzyme, helps digest protein, and intrinsic factor, a glycoprotein, facilitates the absorption of dietary vitamin B_{12}. The stomach's role as a reservoir enables the semifluid chyme, consisting of partially digested food, to be released into the duodenum over a period of time.

Peptic Ulcer Disease

Peptic ulcer disease (PUD), often termed "stomach ulcers," is a common benign (nonmalignant) ulceration of the epithelial lining of the stomach (gastric ulcer) or duodenum (duodenal ulcer). PUD is most commonly associated with *Helicobacter pylori* and the use of nonsteroidal anti-inflammatory drugs (NSAIDs) and aspirin; in populations without these risk factors, the incidence of PUD is very low.[23] In the United States, PUD has a significant negative effect on patients' quality of life, activity, and overall work productivity. As PUD includes both gastric and duodenal ulcers, a general discussion of peptic ulcer disease is presented first, followed by specific information on gastric and duodenal ulcers, under the corresponding anatomic region.

PUD accounts for approximately 500,000 new cases and 4,000,000 recurrences each year in the United States, responsible for 2.7 million physician office visits[24] and a total estimated annual treatment cost of $3.1 billion.[25] Beginning in the 1970s, the frequency of inpatient and ambulatory care for PUD declined by 51%, and by a further 68% between 1993 and 2005.[25] However, the increasing geriatric population, coupled with the growing use of NSAIDs, will contribute to the rising costs of this disease.

The lifetime prevalence of peptic ulcers ranges from 11% to 14% for men and 8% to 11% for women. The 1-year point prevalence of active gastric and duodenal ulcers in the United States is about 1.8%.[26] Genetic factors appear to play a role in the pathogenesis of peptic ulcers, with the concordance among identical twins approximately 50%. In first-degree relatives of sufferers, the lifetime prevalence is roughly threefold greater than that in the general population.[26]

Gastric ulcers primarily result from altered mucosal defenses, whereas duodenal ulcers are associated with increased acid production. *H. pylori* plays a pivotal role in peptic ulcer development at both sites. A complex relationship exists between host defense mechanisms, the presence of elevated acid, pepsin levels, and *H. pylori*. Chronic *H. pylori* infection affects approximately half of the world's population and is typically acquired early in life, especially among those in lower socioeconomic groups.[27] Although *H. pylori* infection results in chronic inflammation of the underlying gastric mucosa, most infected patients do not experience any clinically significant symptoms.

The incidence of duodenal ulcers is increased in cigarette smokers, patients with chronic renal disease, and alcoholics. *H. pylori* is observed in the mucosa in duodenal ulcers (90%–100%) and gastric ulcers (70%–90%). The proposal that bacteria play a significant role in PUD is supported by its usual resolution with targeted antimicrobial treatment and elimination of the bacterium.[28]

Many patients with duodenal ulcers have demonstrable hyperacidity, and it is thought that this is the dominant factor in the development of ulcer disease. Concomitant inflammation and chronic infection with *H. pylori* are noted in the non-acid-secreting gastric antrum causing increased gastrin release, which in turn induces excess acid secretion from the fundic mucosa and damage and ulceration of the duodenal mucosa.[27] In gastric ulcers, however, the relative importance of the two major factors of acid amounts and mucosal resistance is reversed. Typically, the concentration of gastric acid is normal or reduced, and prior injury (mucosal) from other causes appears to be a prerequisite for the development of gastric ulcers.

Most patients with PUD have recurrent pain requiring intervention and 10%–20% suffer a life-threatening complication (e.g., hemorrhage, perforation, or obstruction).[29] Overall around 6% of the patients attending an OHCP will have a peptic ulcer and it is important that the OHCP (1) recognizes the symptoms associated with undiagnosed or poorly managed PUD and its associated morbidity and (2) makes an appropriate referral when these symptoms present.

Medical Aspects

The incidence of gastric ulcers is one-tenth to one-fourth that of duodenal ulcers. Gastric ulcers are more common in lower socioeconomic groups and in those over 50 years of age, and are seen at a male to female ratio of 3:1. Gastric ulcers are of more concern, as approximately 3%–8% represent malignant ulceration of the gastric mucosa.[29] Similarly, gastric ulcers with *H. pylori* infection have an increased risk of mucosa-associated lymphoid tissue (MALT) lymphomas, which in the early stages may go into remission after antibiotic eradication of the bacteria.[30]

Accurate diagnosis, in both cases, involves endoscopy to obtain multiple biopsies and brush specimens for cytologic examination. In gastric ulcers, gastric acidity levels are additionally taken to establish the presence or absence of histamine-fast achlorhydria, as it is associated with a very high chance of malignancy.

Patients with gastric ulcers often present with epigastric pain radiating to the back which, unlike the pain of duodenal ulcers, is aggravated by food. The management of gastric ulcers involves antacid compounds, antibiotics to eradicate *H. pylori*, H_2-blocking agents, and other protective drugs. Follow-up studies to confirm healing are essential. Additional information about PUD and its implications for oral healthcare is presented in the following section on duodenal ulcers.

Disorders of the Small Intestines

The small intestine comprises the duodenum, jejunum, and ileum. The duodenum is the principal site of digestion and absorption. When chyme enters the duodenum, it stimulates the pancreas to secrete sodium bicarbonate (to neutralize the gastric acid) and digestive enzymes for normal digestion of food, and the gallbladder to discharge stored bile through the common bile duct. Vitamin B_{12} in the presence of intrinsic factor is absorbed in the distal small intestine (ileum), while the bile acids that promote fat absorption in the duodenum are themselves reabsorbed in the small bowel, returned to the liver, and re-secreted into the bile. The motor activity of the small intestine propels the chyme forward to the large intestine, whose major role is to receive the ileal effluent, absorb most of the water and salt, and thus produce solid feces.

Duodenal Ulcer Disease

Medical Aspects

A duodenal ulcer represents a break through the mucosa into the submucosa or deeper, the base of which is necrotic tissue consisting of pus and fibrin. Continued erosion may lead to hemorrhage from associated vessels, involvement of adjacent organs, or perforation into the peritoneal cavity. When conditions are favorable, the ulcer heals, with granulation tissue and new epithelium. However, chronic ulceration is associated with scar tissue formation and possible deformity.

The incidence of duodenal ulcer is thought to be declining, but it is still a common disorder, developing in about 10% of the US population. Of all peptic ulcers, 80%–85% are duodenal, and duodenal ulcers occur at a male to female ratio of 4:1. The most common primary cause is *H. pylori* infection, but NSAID use can also be an associated etiologic factor. Less commonly, factors such as stress, exogenous glucocorticosteroids, parathyroid disease, malignant carcinoid, cirrhosis, gastrinoma of the pancreas (Zollinger–Ellison disease), polycythemia vera, and chronic lung disease have been associated with duodenal ulcers.[27] The ulceration, which is often recurrent, is usually located in the first part of the duodenum, because the acidic chyme ordinarily becomes alkaline after pancreatic secretions enter the intestines in the second part of the duodenum.

The most common symptom of an uncomplicated ulcer is epigastric pain, frequently perceived as a burning or gnawing sensation, sometimes associated with nausea and vomiting. This usually occurs when the stomach is empty or when not enough of a meal remains in the stomach to adequately buffer the acid stimulated by the meal. The pain is characteristically relieved within a few minutes by buffering or diluting the gastric acid with ingestion of an antacid, milk, or food. When an ulcer perforates and hemorrhages, the patient often vomits gross blood, which on interacting with acid can appear as coffee grounds. Bleeds can also be associated with black or tar-like stools, or these may sometimes contain gross blood. Repeated blood loss can lead to iron-deficiency anemia, while acute, severe blood loss may cause the patient to feel weak, lightheaded, or short of breath.

The early diagnostic cues for duodenal ulcers lie in the history of a periodic pain pattern: duodenal ulcers usually feel better postprandially, while the pain of gastric ulcers is frequently exacerbated by meals. Physical examination is often unremarkable and the mainstay of the diagnosis is an upper gastrointestinal radiologic examination (barium swallow), which will demonstrate the presence of an ulcer in up to 85% of patients, or endoscopy. Endoscopy has a greater sensitivity and offers the opportunity for a biopsy if malignancy or the presence of *H. pylori* is suspected.[31]

Zollinger–Ellison syndrome can cause multiple ulcers and debilitating diarrhea. It is caused by a pancreatic gastrinoma that secretes gastrin, a potent acid producer, and the diagnosis is made on the basis of extremely high levels of gastric acid and elevated levels of serum gastrin.[32] The usual investigations include a full blood count to detect anemia and leukocytosis, an examination of the stool for occult blood, and a serum calcium test to investigate the possibility of an associated hyperparathyroidism or endocrine tumors.

Medical Management

In the absence of complications such as massive bleeding, obstruction due to scarring, or perforation, medical rather than surgical treatment is preferred. Conservative measures include antacids and avoidance of foods that cause discomfort and of substances and drugs that have potent acidogenic properties, including alcohol, tobacco, aspirin, and NSAIDs. If NSAIDs cannot be avoided, the patient should also be treated with misoprostol. Attempts to eradicate *H. pylori* are necessary in all patients with a peptic ulcer in which the organism can be demonstrated. Bismuth, metronidazole, amoxicillin, and tetracycline have been shown to be effective.[31] In addition to elimination of *H. pylori*, medical treatment may include the following six other classes of drugs: (1) sedatives to reduce mental stress if anxiety is thought to be etiologic; (2) antacids to neutralize acid; (3) drugs that act by covering and protecting the ulcer; (4) anticholinergic drugs to decrease the production of acid by the gastric mucosa; (5) histamine H_2 receptor antagonists (cimetidine, famotidine, nizatidine, or ranitidine), which block the action of histamine on the gastric parietal cells, thus reducing food-stimulated acid secretion up to 75%; and (6) omeprazole, which also suppresses gastric acid secretion but has a different mechanism of action from that of anticholinergics or H_2

receptor antagonists. Anticholinergics are sometimes prescribed, particularly for reducing acid production at night. However, limited effectiveness and side effects such as oral dryness make anticholinergics less attractive than histamine H_2 receptor antagonists. In most patients, the pain is controlled within 1 week, and most ulcers heal by the sixth week. Intractable symptoms or complicated duodenal ulcers may require surgery.[32]

Oral Health Considerations

If a patient presents with symptoms of epigastric pain, as described previously, the OHCP should refer them to the primary care physician. Oral manifestations of PUD are rare, but may occur in relation to severe anemia from repeated gastrointestinal bleeding. In this case there may be new or worsening recurrent oral ulceration, depapillation, and soreness of the dorsum of the tongue due to loss of the filiform papillae. Such patients should be referred to an appropriate clinician to establish their hematologic parameters and correct any deficiency that may delay wound healing or otherwise complicate surgical procedures or anesthesia. Anemia also predisposes to oral candidosis, which may cause mucosal or tongue soreness, particularly in denture wearers. Exceptionally, dental erosion of the palatal aspect of the maxillary teeth due to persistent regurgitation of gastric acid as a result of pyloric stenosis has been reported. Vascular malformations of the lip have also been reported and range from a very small macule to a large venous pool.[33,34]

H. pylori has been isolated from dental plaque[35] and its eradication has been reported to reduce the frequency and severity of recurrent aphthous stomatitis (RAS) in patients who tested positive.[36]

OHCPs should avoid administering drugs that exacerbate ulceration and cause gastrointestinal distress, such as aspirin and other NSAIDs where possible. Similarly, exogenous corticosteroid administration may promote or exacerbate PUD via its action on the mucus layer. Corticosteroid therapy should therefore be minimized and appropriate prophylaxis provided to minimize the risk. Similarly, as many antacids contain calcium, magnesium, and aluminum salts that bind antibiotics, for instance erythromycin and tetracycline, patients should be advised to take their antibiotics 1 hour before or 2 hours after their antacids to avoid a significant (75%–85%) reduction in antibiotic absorption.

Hyposalivation and dry mouth (xerostomia) may occur in patients taking anticholinergic drugs. This is most likely to present in those patients who wear either complete or partial acrylic dentures. While denture adhesives and artificial saliva may aid in the retention of their dental prostheses, the reduced salivary flow predisposes them to an increased risk of oral candidosis. Dentate patients are at increased risk of dental caries, particularly affecting cervical margins and exposed root surfaces, if the hyposalivation is prolonged or if they place sugar-containing foods into the mouth in an effort to stimulate saliva flow. In these cases, appropriate preventive measures should be instituted. If the patient specifically complains of dry mouth, it may be possible to alter the specific drug type or dosage in consultation with the patient's physician. Commonly used sialagogues, such as pilocarpine or cevimeline, may be contraindicated due to their parasympathomimetic action.

Cimetidine and ranitidine, which are commonly prescribed for duodenal ulcer patients, have occasionally been associated with thrombocytopenia and may compete with antibiotics or antifungal medications.[19]

DISEASES OF THE LOWER DIGESTIVE TRACT

Inflammatory Bowel Disease

Inflammatory bowel disease (IBD) consists of two not entirely discrete conditions: Crohn's disease (CD) and ulcerative colitis (UC). The etiopathogenesis of IBD involves an immune-mediated inflammatory response, in genetically susceptible individuals, to an unknown environmental trigger, that interacts with the gut microbiome and primarily affects the gut.[37,38]

The genetic influence on IBD is well recognized. Twins studies demonstrate increased concordance for both CD and UC,[39] while first-degree relatives have a fivefold increase in the risk of developing IBD.[40] Genome-wide association studies supports a polygenic process, with 41 CD-specific and 30 UC-specific genetic polymorphisms identified as well as 137 associated with both conditions.[41]

The host-adaptive immune response is also involved with amplified T cell–mediated responses in both conditions. In CD this is via a T-helper (Th) 1 and Th17 response, which increases inflammation via interleukin (IL)-17, interferon gamma (IFN-γ), and tumor necrosis factor alpha (TNF-α). In UC, the response is Th2 mediated, activating B cells and natural killer T cells, via IL-5 and IL-13.[40]

The intestinal barrier is intimately involved with host innate immunity and its disruption has been shown to lead to IBD in animal models.[42] Genetic susceptibility is a key feature in the development of IBD and cell defects, often related to gene abnormalities in NOD2, linked with the development of CD.[43] Environmental factors are also important, with diets high in saturated fat and processed meats and disturbance of the host microbiome, for instance from antibiotics, increasing the risk of IBD,[40] while high-fiber diets decrease the risk of CD.

IBD is frequently associated with extraintestinal manifestations, including a wide range of oral lesions.[44] The orofacial presentation includes cervical lymphadenopathy, lip swelling, angular cheilitis, oral ulceration, mucosal tags, cobblestone appearance of the oral mucosa, full-thickness gingivitis, submandibular duct "staghorning," fibrous banding, and oral ulceration,[45,46] as well as the rarer pyostomatitis vegetans.[47] The oral manifestations of IBD may precede the onset of intestinal radiographic lesions by as much as 1 year or more.[48] Both diseases are of interest to the dentist because of their associated oral findings, the potential overlap in presentation with that of orofacial granulomatosis (OFG),[44] which may occur separately or in association with CD,[45] and the impact of their medical management on dental care.

There is significant variation in the incidence and prevalence of CD and UC around the world.[37,38] The current data, for North America, for these and other parameters are summarized in Table 15-1.

IBD is most common in Western countries, particularly those in northern Europe and North America. There is no gender preference for either condition and the apparent ethnic differences reported in African Americans are due to social and economic inequalities rather than biologic or genetic differences.[54] IBD is, however, more common among Ashkenazi Jews than among the Sephardim and the general population. The prevalence in Israel is between 17 and 80 per 100,000 among the Ashkenazi versus 19 and 55 per 100,000 among the Sephardim.[55] As countries industrialize, their incidence of IBD increases. Similarly, those who live in urban centers are also more likely to be afflicted than those living in a rural setting.

Ulcerative Colitis

Medical Aspects

The inflammation in UC most commonly affects the rectum, but can spread to affect more proximal parts of the colon.[56] Macroscopically, the mucosa may have a granular appearance if the disease is mild, while stripping of the mucosa, with areas of sloughing, ulceration, and bleeding, may be seen when more severe. As the superficial mucosal lesions enlarge, they may be perpetuated by secondary bacterial invasion.[23–32]

Patients usually complain of cramping abdominal pain that is worse prior to a bowel movement, which is associated with rectal bleeding and bloody diarrhea. The frequency and volume of blood present give an indication of the activity of the condition. Typically patients will pass 5–8 movements in a 24-hour period, including at night.[23–32] Extraintestinal manifestations present and include erythema nodosum, characterized by red swollen nodules that are usually on the thighs and legs; ocular changes such as episcleritis, uveitis, corneal ulcers, and retinitis; and joint symptoms usually affecting the ankles, knees, and wrists.[23–32] Severe oral ulceration may be seen secondary to ulcerative colitis (Figure 15.1). A microcytic, hypochromic anemia may result from blood loss, while leukocytosis occurs in active disease, as may electrolyte imbalances, hypoalbuminemia, and low serum magnesium and potassium levels with severe diarrhea.[23–32]

Figure 15-1 Large aphthous-like ulcerations of the soft palate in a 44-year-old female patient with ulcerative colitis.

Table 15-1 Epidemiology of inflammatory bowel disease.

	Crohn's Disease	Ulcerative Colitis
Cases per annum (per 100,000)[49]	0–20	0–20
Population point prevalence (per 100,000)[50]	25–300	35–250
Peak age of onset (years)		
First peak[37,49]	20–30	30–40
Second peak[51]	60–70	60–70
Median age at diagnosis (years)[52]	30	40–45
Mean age at diagnosis (years)[53]	35	40–45

Medical Management

The diagnosis of UC is based on a careful history, physical examination, gastrointestinal radiography, and direct visualization via sigmoidoscopy and endoscopy revealing multiple tiny mucosal ulcers covered by blood and pus.

The aim of therapy is to reduce the inflammation and correct the effects of the disease. Sulfasalazine in the form of its active component 5-aminosalicylic acid (5-ASA) is the standard therapy for mild to moderately active UC[57] and most patients respond to 2–3 g 5-ASA, with higher doses used in those with more severe symptoms or those not responding initially. Oral corticosteroids are superior to 5-ASA,[58] but have significant side effects and are reserved for patients with failure of response or who are intolerant to oral and/or rectal 5-ASA. The current recommended dose is 40 mg once daily[59] and approximately 50% of patients experience short-term adverse events such as acne, edema, sleep and mood disturbance, glucose intolerance, and dyspepsia.[59] The dose should be tapered over 6–8 weeks.

Patients with chronic active UC failing 5-ASA therapy may benefit from ciclosporin[60] or thiopurine therapy in the form of azathioprine or its active metabolites, 6-mercaptopurine or thioguanine.[61] However, as the range of alternatives grows and costs of biologics fall, there is strong justification for moving directly to other immunosuppressive drugs with less toxicity that may be easier to manage.[61] Thiopurines still have a role as combination therapy and to reduce immunogenicity, but the therapeutic pyramid is changing rapidly.[60] Infliximab and other anti-TNF drugs are often effective, but it is also important to consider surgery in patients failing a therapeutic agent, particularly as there is generally a reduction in response to each successive immunosuppressive or biologic drug.[56] Proctocolectomy combined with ileostomy is a curative procedure for UC.

Crohn's Disease

Medical Aspects

CD is an inflammatory disease that can affect any part of the small or large intestine, from the mouth to the anus. Discontinuous segments of disease ("skip lesions"), ileal involvement, and granulomatous inflammation are suggestive of CD, as is a tendency for inflammation to be worse in the proximal colon.[62] Gross examination may reveal mucosal ulceration (aphthous ulcers within the mucosa that appear normal, deep ulcers within areas of swollen mucosa, or long linear serpiginous ulcers). Microscopic examination reveals inflammatory infiltrate in all layers of affected bowel, with plasma cells and lymphocytes predominating in the lamina propria.[23–32]

Epidemiologic evidence suggests that there are two forms of CD: a nonperforating form that tends to recur slowly, and a perforating or aggressive form that evolves more rapidly. Patients with the aggressive perforating type are more prone to develop fistulae and abscesses, whereas the more indolent nonperforating type tends to lead to stenotic obstruction.[23–33] Intestinal fistulas occur in about 20%–40% of patients with CD[63,64] and can link to any adjacent structure, including to the bowel, bladder, skin, or vagina. Strictures can present throughout the gastrointestinal tract and present with obstructive features, including abdominal pain, nausea, and vomiting. Up to one-third of patients with CD have perianal involvement, most commonly presenting as fistulas, fissures, abscesses, or skin tags.[65]

The severity of CD and its location determine the associated symptoms and signs, resulting in a broad spectrum of presentations. The clinical presentation usually involves a young person with colicky abdominal pain, frequently associated with, and relieved after, bowel movements, together with watery diarrhea and weight loss. Involvement of the terminal ileum is common and may result in pain being localized to the right lower quadrant. The pain tends to come and go, reflecting disease activity, but if acute and severe may resemble appendicitis.

Inflammation of the small intestine may impair the absorption of vital nutrients, leading to deficiency states. Duodenal involvement affects calcium, iron, and folate, while disease in the terminal ileum affects bile salts and vitamin B_{12}. Widespread involvement of the small or large intestines may affect fat, fat-soluble vitamins, salt, water, protein, and iron.

Medical Management

The signs and symptoms of CD are often subtle and may delay the diagnosis, which is usually made on the basis of a careful history, physical examination, and diagnostic testing. Ileocolonoscopy with biopsy is the first-line investigation for suspected Crohn's disease.[66] CD is likely where there is (1) involvement of the small intestine or the upper part of the alimentary canal; (2) segmental disease of the colon, with "skip" areas of normal rectum; (3) the appearance of fissures or sinus tracts; and (4) the presence of well-formed noncaseating granulomas.[23–32] Luminal barium fluoroscopic techniques have largely been replaced by cross-sectional imaging techniques.[66] Computed tomography enterography (CTE), magnetic resonance enterography (MRE), and small bowel ultrasound (SBUS) all have high sensitivity and specificity, with no consistent difference in diagnostic accuracy.[67]

Systemic corticosteroids (prednisolone) and immunosuppressive medication in the form of thiopurines (azathioprine [AZA]/5-mercaptopurin [5-MP]) or methotrexate (MTX) are well recognized in the induction of remission in CD. Corticosteroid therapy is associated with multiple adverse effects and is therefore not useful for long-term treatment. Similarly, some patients with severe disease or those who are refractory or intolerant to immunosuppressives require

Figure 15-2 Pseudomembranous plaques of *Candida albicans* in a patient with Crohn's disease treated with sulfasalazine. The plaques were easily removed with wet gauze sponges.

alternatives.[68] The anti-TNF medications such as infliximab and adalimumab are often utilized in these situations, but are associated with primary nonresponse and secondary loss of response.[69]

Patients with CD who have inadequate response, loss of response, or intolerance to therapy with corticosteroids, immunosuppressives, or anti-TNF are now treated with immune cell trafficking or cytokine signaling inhibitors.[70] Vedolizumab, a monoclonal antibody directed against α4β7 integrin,[71] prevents circulating immune cells from homing to the mucosa and is gut-selective through interactions with mucosal adhesion molecules. Ustekinumab, a monoclonal IgG1 antibody against the p40 subunit of IL-12 and IL-23, targets T-helper cell pathways.[72] Both medications are effective in inducing and maintaining remission and are increasingly considered as potential first-line biologic agents in preference to anti-TNF medications.

Oral Health Considerations

The first consideration in both CD and UC is oral manifestations, which can arise either as a direct presentation of the condition or secondary to the effects of the condition or its treatment.[44]

Management of UC and CD often involves the use of corticosteroids or immunosuppressive or other medications, which frequently increase the risk of opportunistic oral infections. These include oral candidosis, especially in the form of angular cheilitis (redness, crusting, and splitting of the corners of the mouth), denture stomatitis (erythema of the mucosa in contact with the fit surface of a denture), acute pseudomembranous candidosis, (Figure 15.2) or oral soreness/burning affecting the tongue or oral mucosa.[44] Similarly, the long-term use of corticosteroids may necessitate monitoring of blood pressure and evaluation of blood glucose, and consideration of the need for replacement therapy prior to stress-inducing procedures. The latter is based on the dosage and length of time on glucocorticoids and the nature of the planned dental treatment.

In contrast, the disease-specific presentations vary:

- *UC*: Oral features are generally secondary to the underlying condition or its treatment. Rarely, pyostomatitis vegetans,[47] a generalized ulceration of the oral mucosa, may be the initial presentation of previously occult UC (see below).
- *CD*: The common oral features of CD include ulceration, diffuse swellings of the lips and/or cheeks, "cobblestoning," mucosal tags, vertical lip fissures, full-thickness gingivitis, angular cheilitis, perioral erythema, cervicofacial lymphadenopathy (Figure 15.3).[45] Other features include minor salivary gland enlargement[73] and altered taste sensation.[74] The orofacial manifestations are more common in cases presenting under the age of 16[75] and may predate any gastrointestinal symptoms by several years.[44] Patients may present with oral and perioral disease ("oro-facial Crohn's disease") without any other apparent gut involvement.[76] However, 10%–48% of such patients may have asymptomatic gut lesions.[77] OFG affects the oral cavity without gut lesions.[45,76] The anterior part of the mouth is most commonly affected, especially enlarged swollen lips. OFG may respond better to exclusion diets than anti-TNF or immunosuppressives.[45]

Several forms of stomatitis have been reported in association with IBD and particularly CD:[44]

- *Pyostomatitis vegetans*: Although rare, this is a highly specific[78] oral marker for IBD (primarily UC). It is characterized by multiple small yellowish pustules on an erythematous mucosa and may be accompanied by small vegetating lesions. The lesions may ulcerate, suppurate, or become necrotic and often demonstrate a snail-track pattern.[79] Most areas of the oral cavity may be involved, although the dorsum of the tongue is rarely affected. Treatment remains difficult and while topical corticosteroid mouth rinses (see below) may be beneficial, resolution is most commonly associated with treatment of the underlying IBD with systemic corticosteroids and azathioprine.[80]
- *Pseudo-pyostomatitis vegetans*: This resembles pyostomatitis vegetans clinically.[81] However, direct immunofluorescence reveals deposits of IgG in the basement membrane zone in a linear pattern and indirect immunofluorescence, on salt-split normal skin, reveals IgG reactive to the roof of the induced split in keeping with pemphigoid. Therefore, pyostomatitis vegetans cannot simply be diagnosed clinically and immunofluorescence studies are essential.

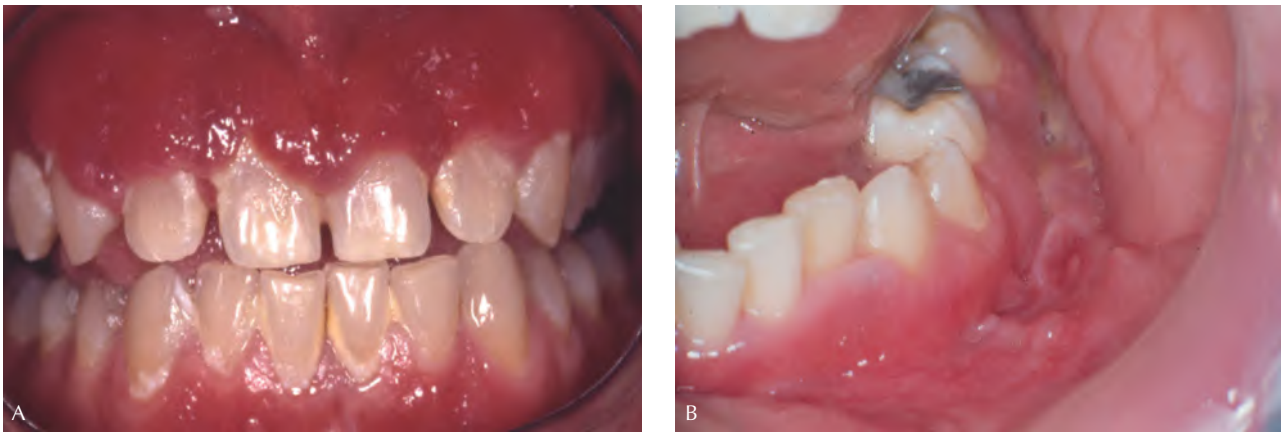

Figure 15-3 (A) Hyperplastic cobblestone-like gingival architecture in a 31-year-old female patient with Crohn's disease. (B) Epithelial tags and linear ulceration in the lower buccal sulcus and cobblestoning of buccal mucosa.

- *Stomatitis gangrenosum*: This condition, associated with CD, presents with often foul-smelling, deep ulcers of varying size with rolled margins and a grayish fibrinous base. Incisional biopsy and histopathologic examination reveal ulceration with a fibrino-purulent membrane and a chronic inflammatory infiltrate.
- *Staphylococcal mucositis*: This is associated with CD and presents as a panoral erythematous stomatitis, from which *S. aureus* can be isolated and for which antimicrobial treatment provides rapid relief.[82]

Malabsorption may lead to iron, vitamin B_{12}, or folate deficiency, while blood loss is most commonly associated with iron deficiency.[23–32] In almost all cases such deficiency states may lead to anemia, which may be associated with delayed healing and necessitate postponing surgical treatment until the disease is under control. Anemia may present orally with depapillation of the tongue (glossitis), burning mouth sensation, angular cheilitis, or oral ulceration.[44] Correction of the underlying deficiency state is usually associated with symptom improvement and resolution.[44]

Numerous medications, including anti-inflammatory and sulfa-containing preparations commonly used to manage IBD patients, have been reported to cause oral lichenoid drug reactions.[83,84] OHCPs are responsible for treatment of oral manifestations of IBD, particularly if the lesions are symptomatic.

Antibiotic-Induced Diarrhea and Pseudomembranous Enterocolitis

Medical Aspects

Antibiotic-associated diarrhea (AAD) is a common condition affecting 5%–39% of people treated with antibiotics.[85] This condition arises from an antibiotic-related imbalance of the gut microbiota, the result of which includes decreased short-chain fatty acid absorption, leading to osmotic diarrhea.[86]

Most cases of AAD are mild and self-limiting, with resolution following cessation of antibiotic therapy. However, one form of AAD, *clostridium difficile* infection (CDI), can cause more severe gastrointestinal disease, including life-threatening pseudomembranous enterocolitis. *Clostridium difficile* is a gram-positive, spore-forming anaerobic bacillus. *C. difficile* is spread via the feco-oral route, and causes disease through the production of two protein exotoxins (toxin A and toxin B), which are cytotoxic to colonic epithelial cells.[87]

The host's adaptive immune response following exposure to *C. difficile* is important in determining the severity of the disease, with high IgG antitoxin level production being protective.[87] Antibiotic-related loss of gut microbial communities, which protect against gut infection, facilitates the germination and vegetative growth of the organism when it enters the gut of vulnerable people. Specific risk factors for CDI include almost all antibiotics (particularly cephalosporins, clindamycin, and some penicillins), acid-suppressant medications (PPIs and H_2 receptor antagonists), increasing age (particularly >65), recent hospitalization, and immunosuppression. The clinical presentation is variable, with diarrhea and fever occurring in almost all cases, while the most severe are characterized by colitis, toxic megacolon (dilatation of the colon, with the risk of perforation), multiorgan failure, or even death.

Diagnosis may be difficult, as most tests lack sensitivity and specificity, although an abdominal radiograph is the preferred test for toxic megacolon and abdominal CT is sensitive for the presence of CDI-related colitis. Lower gastrointestinal endoscopy may demonstrate edema, erythema, or classical pseudomembranes; that is, raised yellowish plaques that may be intermittently scattered throughout affected colonic mucosa.

Treatment of CDI classically required metronidazole administered orally or intravenously or vancomycin

administered orally or per rectum. Intravenous immunoglobulin (IVIg) has also been used for severe disease, with surgical intervention (colectomy) reserved for refractory cases. The increasing failure rate with metronidazole, recurrence following treatment, and hypervirulent strains of *C. difficile*, such as the NAP1/027 strain, have necessitated alternative approaches.[88] These include the orally administered macrocyclic antibiotic fidaxomicin and manipulation of the gut microbiota through probiotics and fecal microbiota transplantation (FMT). Probiotics have proved of limited benefit, while FMT using a stool sample from a healthy screened donor to produce a liquidized bacterial suspension or a capsularized freeze-dried slurry, which is then delivered into the gut of the affected patient, has proved successful in refractory and recurrent cases.[89]

Oral Health Considerations

The primary role of the OHCP is to recognize the signs and symptoms of AAD and consider the possibility of *C. difficile* infection or the more serious condition of pseudomembranous colitis in patients who are either taking, or have recently completed, an antibiotic regimen. Cessation of the antibiotic and prompt referral to the patient's physician to enable a definitive diagnosis should be considered.

Diseases of the Hepatobiliary System

This section will consider the liver, biliary tract, and pancreas, which have interrelated functions in relation to the digestive system. Of these the liver is both the largest structure and has the highest number of roles, and therefore has a greater focus.

The liver serves as the major locus of synthetic, catabolic, and detoxifying activities in the body and is the site of all intermediary metabolism of foodstuffs. The liver is essential in the excretion of heme pigments, and also participates in the immune response. Impairment of the hepatocyte interferes with the liver's ability to synthesize and store glycogen, a major source of glucose. Should glycogen stores be depleted, liver gluconeogenesis from amino acids is initiated to maintain glucose levels.

Lipids are metabolized in the liver to form cholesterol and triglycerides. Cholesterol is the major building block of cell membranes, steroids, and bile salts. Bile salts are essential in the absorption of fat in the small intestine. Proteins, albumin, and clotting factors I, II, IV, VII, IX, and X are synthesized and stored in the liver. Since some of the clotting factors (II, VII, IX, and X) are also dependent on vitamin K, coagulopathy can occur from hepatocyte dysfunction and/or vitamin K malabsorption due to biliary problems.

The metabolism of drugs is principally performed by the cytochrome P-450 microsomal enzyme system in the hepatocyte. Local anesthetics, analgesics, sedatives, antibacterials, and antifungals are all metabolized in the liver. Consequently, cautious use of these drugs in a person with liver dysfunction is essential. Lastly, the liver inactivates or metabolizes hormones such as insulin, aldosterone, antidiuretic hormone, estrogens, and androgens.

Liver dysfunction can manifest through multiple symptoms, most commonly as jaundice, and the disease process can lead to liver failure and cirrhosis.[90–93] Accordingly, jaundice and cirrhosis are considered separately below.

Liver disease may be systemic in etiology or due to traumatic injury. Causes of abnormal liver function tests include trauma, viral or chemically induced hepatitis, alcohol intake, nonalcoholic fatty liver disease, autoimmune liver diseases, and hereditary diseases such as hemochromatosis, α_1-antitrypsin deficiency, and Wilson's disease. Many patients with liver disease are treated with multidrug regimens, compounding the problem of liver toxicity. Knowledge of liver involvement in systemic diseases is important for the accurate diagnosis of liver damage and to avoid unnecessary examination and treatment.[94]

Jaundice

Jaundice (or icterus) is a yellow discoloration most often seen in the skin, mucous membranes, and sclera of the eye, which results from excess bilirubin in the circulation and its resultant accumulation in the tissues. This excess bile pigment may be caused by (1) increased production of unconjugated bilirubin as a result of hemolysis of red blood cells (hemolytic jaundice); (2) disturbances of bile flow caused by diseases either in the hepatocytes, intrahepatic bile ducts, or extrahepatic biliary system, preventing the excretion of bilirubin (obstructive jaundice); or (3) liver parenchymal disease (hepatocellular jaundice). Each of these processes is briefly reviewed in this section, and the role of the OHCP in relation to oral healthcare discussed.

Hemolytic Jaundice

Unconjugated hyperbilirubinemia is usually a result of too much bilirubin presented to the conjugating machinery (from increased red blood cell destruction).[95] Increased red blood cell breakdown may be caused by erythrocyte membrane disorders,[96] erythrocyte enzyme disorders,[97] hemoglobin disorders,[98] autoimmune erythrocyte destruction,[99] and some cancers (Table 15-2).

The excess turnover of red blood cells leads to increased heme metabolism, producing large amounts of bilirubin that overwhelm the conjugating machinery, resulting in decreased excretion (increased circulating unconjugated bilirubin) and clinical jaundice.

Table 15-2 Causes of hemolytic anemia.

Erythrocyte membrane disorders[95]	Elliptocytosis Ovalocytosis, Spherocytosis
Erythrocyte enzyme disorders[96]	Glucose-6-phosphate dehydrogenase deficiency Glucose-6-phosphate isomerase deficiency Pyrimidine-5′-nucleotidase deficiency Pyruvate kinase deficiency
Hemoglobin disorders[97]	Sickle cell anemia Thalassemia
Autoimmune erythrocyte destruction[98]	Cold reactive Drug induced (associated with ~150 drugs) Mixed type Warm reactive
Cancers	Myeloproliferative neoplasms (especially polycythemia vera)

The diagnosis of hemolytic jaundice is based on laboratory investigations demonstrating the presence of anemia with a high reticulocyte count, a decreased level of serum haptoglobins, and elevated serum bilirubin. The specific cause of the increased hemolysis of red blood cells requires additional investigations, such as hemoglobin electrophoresis, erythrocyte fragility studies, and Coombs' test for antibodies to red cells.

Treatment to control the excessive hemolysis is usually associated with a return to normal liver function and resolution of the jaundice without long-term damage to the liver.

Obstructive Jaundice (Cholestasis)

This form of jaundice is associated with partial or complete cessation of bile flow and arises from obstructions of the extrahepatic biliary tree or intrahepatic abnormalities. In either case, the flow of bile through the liver and out of the common bile duct can be impeded, resulting in an increase in bilirubin in the tissues.

Extrahepatic cholestasis is caused by structural abnormalities of the biliary tract, including the obstruction of bile ducts and the gallbladder. Gallstones and malignancies are the causes of most cases of extrahepatic cholestasis. Tumors of the pancreatic head are the most common malignant cause of extrahepatic cholestasis, and adenocarcinoma is the most frequent. Surgical treatments are usually required to restore physiologic function.

The causes of intrahepatic cholestasis include neoplasms (e.g., metastatic carcinomas, lymphomas), toxic drugs and chemicals, hepatitis, parenteral nutrition, sepsis, ischemia, endocrine diseases, and hereditary disorders of metabolism.

Hereditary Disorders of Conjugation

Indirect Hyperbilirubinemia

In healthy individuals unconjugated bilirubin is normally conjugated with one to two molecules of glucuronic acid via the action of uridine 5'-diphosphoglucuronosyltransferase 1A1 (UGT1A1) ready for excretion. Genetic mutations in this enzyme prevent this reaction, leading to accumulation of bilirubin in the liver and blood and hence jaundice.

Gilbert syndrome is one such benign condition affecting approximately 10% of Caucasians.[100] TA repeat polymorphism (UGT1A1*28) in the promoter of the UGT1A1 gene is the most commonly affected region and results in mild intermittent jaundice.[101]

Crigler–Najjar syndrome is also caused by mutations in the UGT1A1 gene.[102] Type I is a rare autosomal recessive disorder with complete loss of enzymatic function, which may necessitate liver transplantation, while type II retains some enzymic activity and may be controlled with medical therapy.

Direct Hyperbilirubinemia

Over 100 inherited diseases have been identified as causing cholestatic liver disease that initially present with jaundice.[101] In each case the underlying genetic mutation has been identified and includes:

- Progressive familial intrahepatic cholestasis (e.g., PFIC1, ATP8B1).
- Bilirubin transport defects, e.g., rotor syndrome (SLCO1B1), Dubin–Johnson syndrome (ABCC2).
- Inborn errors of bile acid metabolisms, e.g., bile acid synthetic defects (HSD3B7).
- Metabolic liver disease, e.g., Wilson's disease (ATP7B), alpha-1-antitrypsin deficiency (SERPINA1), Niemann–Pick disease type C (NPC).

The diagnosis of these conditions requires a careful clinical history and examination coupled with biochemical investigation, including levels of total and direct bilirubin, aspartate transferase, alanine aminotransferase (ALT), gamma-glutamyl transferase (GGT), and alkaline phosphatase (ALP). A low serum GGT level disproportionate to the severity of cholestasis is indicative of inherited cholestasis such as PFIC and inborn errors of bile acid synthesis.[101] The definitive genetic diagnosis is provided by next-generation sequencing (NGS) panels incorporating a limited number of genes[103] and expanded panel-based NGS involving more than 50 genes.

Further investigations of biliary obstruction may involve multiple imaging modalities, including ultrasound, computed tomography (CT), magnetic resonance imaging (MRI), endoscopic ultrasonography, and percutaneous, intraoperative, or endoscopic retrograde cholangiography. Interpreting these examinations and choosing an optimal management strategy can be difficult and may involve nutritional support, biliary diversion surgery, and in some cases liver transplantation.[104]

The OHCP's primary function is the recognition of the clinical signs of jaundice and appropriate referral to a primary care physician for diagnosis and treatment. Once successful disease management is achieved, routine dental care can continue, with appropriate liaison with the patient's physician to ascertain the patient's liver function, ability to undergo dental treatment, and any additional measures required.

Hepatocellular Jaundice

Hepatocellular jaundice can be caused by hepatitis and cirrhosis. Alcoholic hepatitis and drug-induced hepatotoxicity are discussed in the next section, along with cirrhosis.

Alcoholic Liver Disease and Alcoholic Hepatitis

Medical Aspects

Alcoholic liver disease (ALD) represents a spectrum of injury, ranging from steatosis to alcoholic hepatitis to cirrhosis. Regular alcohol use leads to fatty changes in the liver that can develop into inflammation, fibrosis, and eventually cirrhosis. Alcoholic hepatitis (AH) is acute inflammation of the liver, which can occur in patients with ALD, and accounts for 44% of all deaths associated with liver disease.[105]

AH generally occurs with excessive alcohol intake over a period of at least 20 years and so usually presents in the fourth or fifth decade of life.[106] The risk of AH and cirrhosis is increased in those consuming in excess of over 30–60 g/day of alcohol,[107] as is the risk of hospitalization in those exceeding 120 g/day.[106] While alcohol intake plays a role in AH, the fact that only 10% develop cirrhosis suggests that other factors are important. Factors known to increase risk include pattern of drinking (e.g., binge drinking), type of alcohol (e.g., spirits), female sex,[108] and obesity. Genetic factors related to polymorphisms on the genes coding for alcohol metabolism may confer a predisposition to alcoholism and an association with alcoholic cirrhosis.

There are significant geographic differences in the incidence of ALD and AH, which are highest in eastern and southern Europe and the United Kingdom, lower in the United States, and lowest in Muslim populations.[109] AH has a strong association with malnutrition, while nutrient deficiencies are implicated in ALD. Associated liver diseases, particularly hepatitis C, may also accelerate progression.[110]

The pathogenesis of ALD involves multiple factors, including hepatocyte damage due to alcohol and its metabolites, cholestasis, recruitment and activation of innate immune cells by gut-derived pro-inflammatory danger signals, Kupffner cells, and recruited macrophages and neutrophils in the liver.[105] The ongoing presence of these factors triggers ineffective anti-inflammatory pathways, resulting in activation of stellate cells and myofibroblasts in the liver, which lead to fibrosis and alcoholic cirrhosis.[111]

The earliest indication of ALD is an enlarged liver. The patient may also exhibit signs of both AH (jaundice, fever, anorexia, and malaise) and more chronic liver disease, which may include spider angiomas, gynecomastia, jaundice, ascites, changes in mental status, and ethanol intoxication.[91,105] AH, which is at least partially reversible, is often found superimposed on cirrhosis that is already established. Often there is little correlation and sometimes considerable disassociation between the apparent severities of injury, based on clinical findings, relative to the evidence subsequently found on liver biopsy.

The clinical problems associated with AH reflect the disordered metabolism and circulation in the liver. Jaundice reflects the inability of the hepatocyte to conjugate and excrete bilirubin, bleeding the decreased synthesis of clotting factors, and mental confusion the failure of the liver cells to metabolize and excrete toxins such as ammonia. There may be an associated thrombocytopenia in cases of alcoholic jaundice, while spider angiomas and gynecomastia result from elevated levels of estrogen, which is normally metabolized by hepatocytes.[91]

Medical Management

AH requires consideration in the case of any patient who has a history of regular alcohol use. Laboratory investigations include full blood count and differential, clotting studies, liver function tests, and gamma-glutamyl-transpeptidase assay, carbohydrate deficient transferrin, and viral hepatitis serologies.

Abdominal imaging studies, including ultrasound, CT, and MRI, may be useful in the diagnosis of ALD. However, confirmation of the diagnosis and assessment of the extent of injury is best done by performing a liver biopsy.

The treatment of AH is dependent on the patient's prognosis. This can be objectively measured by using the Maddrey Discriminate Function (MDF), which incorporates the prothrombin time and bilirubin at the time of diagnosis. Values of >32 in this measure indicate severe disease and poor prognosis with significant mortality.[112]

Abstinence is the mainstay of the treatment of AH. However, this is difficult or unachievable for most patients

due to addiction, which often requires psychiatric help or participation in formal withdrawal programs.[105] Nutritional support for the malnourished patient is important. Beyond this, the primary therapeutic intervention for AH involves corticosteroids, which is limited to a narrow patient population (MDF >32), has limited benefit, and has a high side effect profile. In these patients the Lille score at day 7 is used to decide whether corticosteroid therapy should be stopped or continued for a 1-month course.[105] More recent therapies aim to inhibit inflammation by targeting cytokine-mediated pathways (e.g., IL-1) and by improving gut barrier function.[113] The use of liver transplantation, while reportedly successful, remains controversial.[105]

Oral Health Considerations

The orofacial manifestations associated with AH are primarily related to dysfunction of the hepatocyte and include jaundice, which usually occurs when total serum bilirubin reaches levels ≥3 mg/dL. There may be extraoral and/or intraoral petechiae, ecchymosis, or gingival crevicular hemorrhage due to clotting factor deficiency. Yellow pigmentation of the mucosa may also be observed, accompanied by cutaneous and scleral jaundice. Additional oral findings such as pallor, angular cheilitis, and glossitis may be present as a result of associated malnutrition, vitamin deficiencies, and anemia.[90]

The presence of sweet ketone breath, indicative of liver gluconeogenesis, should raise the suspicion of hepatotoxicity. This together with the above clinical features, as well as a history or symptoms suggestive of alcohol abuse, should warrant a referral to the patient's primary care physician for evaluation. Any elective dental treatment should not be carried out in a patient who appears intoxicated.

Patients with parenchymal liver disease have impaired hemostasis and a clotting screen including prothrombin, together with any necessary medical preparation, is indicated prior to surgical intervention. The type and severity of the liver disease, as well as induction or inhibition of hepatic drug-metabolizing enzymes, by previous or current medications, mean that the effects of drugs are not entirely predictable.[90] The drug effects may also be enhanced by depressed protein binding due to hypoalbuminemia. Adverse interactions between alcohol or resultant ALD and medications used in dentistry include but are not limited to acetaminophen, aspirin, ibuprofen, some cephalosporins, erythromycin, metronidazole, tetracycline, ketoconazole, pentobarbital, secobarbital, diazepam, lorazepam, chloral hydrate, and opioid analgesics.[114]

The prevalence of dental disease may be increased due to self-neglect. Routine dental treatment for a patient with a history of ALD is not contraindicated unless there is significant cirrhosis and resultant impaired hepatic function. The OHCP should therefore confirm the patient's liver function status with the appropriate physician prior to commencing treatment.

Drug-Induced Hepatotoxicity

Medical Aspects

Drug-induced liver disease is an uncommon but challenging clinical problem that can mimic any acute or chronic liver disease. Patients may present with fulminant hepatic failure from an intrinsic hepatotoxin such as acetaminophen, or may simply present with an incidental finding of an abnormal liver function test result on routine screen. Ingested drugs are absorbed into the portal circulation and pass through the liver en route to distant sites of action. The liver is responsible for the conversion of lipid-soluble drugs, which are difficult to excrete, into polar-soluble metabolites that are easily excreted through the kidneys. This solubilization and detoxification may paradoxically produce toxic intermediates.

The diagnosis of drug-induced liver disease is largely based on exclusion of other causes. The timing of the onset of injury after the implicated agent has been started (latency), resolution after the agent is stopped ("dechallenge"), recurrence on reexposure (rechallenge), knowledge of the agent's potential for hepatotoxicity (likelihood), and clinical features (phenotype) are the major diagnostic elements.[115,116]

Drugs may be conjugated, oxidized, or reduced through the cytochrome P-450 system. This system can be induced by the long-term use of alcohol, barbiturates, or other drugs. With some hepatotoxic drugs, the relative activity of the cytochrome P-450 system is crucial; a drug that exerts its toxic actions through the generation of cytochrome P-450 metabolites may be relatively more toxic in a patient who uses alcohol or other agents that are capable of inducing cytochrome P-450.

Drug-induced hepatotoxicity can be classified as one of three general patterns, direct, idiosyncratic, or indirect, each of which has a typical phenotypic presentation[117] (Table 15-3).

Regardless of the mechanism involved, drug-induced hepatotoxicity can result in hepatocellular injury, cholestatic drug reactions, abnormal lipid storage, cirrhosis, and vascular injury. Hepatocellular injury and cholestatic drug reactions account for the majority of drug reactions encountered in dentistry.

Oral Health Considerations

The OHCP's role in recognizing the potential for drug-induced hepatotoxicity from drugs they prescribe, other medications (either prescribed or over the counter) being taken by the patient, and drug interactions is critical. Herbal

Table 15-3 Drug-induced hepatotoxicity.

Variable	Direct	Idiosyncratic	Indirect
Frequency	Common	Rare	Intermediate
Dose-related	Yes	No	No
Predictable	Yes	No	Partially
Reproducible in animal models	Yes	No	Not usually
Latency (time to onset)	Typically rapid (days)	Variable (days to years)	Delayed (months)
Phenotypes	Acute hepatic necrosis, serum enzyme elevations, sinusoidal obstruction, acute fatty liver, nodular regeneration	Acute hepatocellular hepatitis, mixed or cholestatic hepatitis, bland cholestasis, chronic hepatitis	Acute hepatitis, immune-mediated hepatitis, fatty liver, chronic hepatitis
Most commonly implicated agents	High doses of acetaminophen, niacin, aspirin, cocaine, intravenous amiodarone, intravenous methotrexate, cancer chemotherapy	Amoxicillin-clavulanate, cephalosporins, isoniazid, nitrofurantoin, minocycline, fluoroquinolones, macrolide antibiotics	Antineoplastic agents, glucocorticoids, monoclonal antibodies (against tumor necrosis factor, CD20, checkpoint proteins), protein kinase inhibitors
Cause	Intrinsic hepatotoxicity when agent given in high doses	Idiosyncratic metabolic or immunologic reaction	Indirect action of agent on liver or immune system

Source: From Hoofnagle, J. H., & Björnsson, E. S. (2019). Drug-Induced Liver Injury – Types and Phenotypes. *New England Journal of Medicine*, 381(3), 264–273. © 2019, Massachusetts Medical Society.

and other alternative (nontraditional) drugs have also been reported to elicit hepatocellular toxicity.

As idiosyncratic reactions often have an immuno-allergic basis, the patient may present with fever, dermatitis, arthralgias, and eosinophilia in addition to features associated with the hepatic damage such as jaundice. Amoxicillin-clavulanate is the most frequent cause of idiosyncratic prescription drug-related hepatotoxicity, accounting for 10% of all reported reactions,[118] nearly twice as many reactions as the next most commonly reported drug. Other common oral healthcare medications with an occurrence rate >1% include azithromycin, ciprofloxacin, diclofenac, phenytoin, and azathioprine.[118] Where this follows the commencement of a new medication, the prescribing clinician will need to consider withdrawal of the medication and its replacement with an alternative from a different class. Fortunately, most of the regularly prescribed medications in oral healthcare have safe and effective alternatives and hence stopping the suspected medication is the appropriate course of action. Consideration should also be given to onward referral to enable biochemical assessment.

For those drugs that produce idiosyncratic drug toxicity, there is no way to predict or prevent such reactions.[118] Any patient who experiences an abrupt episode of hepatocellular injury should be considered to have an idiosyncratic drug reaction and should not be challenged again. For those patients who take medications associated with dose-dependent drug reactions, the primary precaution is to prescribe the minimum effective dosage. This is particularly important for those medications where there is a narrow therapeutic window. The use of therapeutic levels (e.g., phenytoin) should also be considered when available, as should biochemical monitoring (e.g., carbamazepine).

Liver Cirrhosis

Cirrhosis results from different mechanisms of liver injury that lead to necroinflammation and fibrogenesis. Histologically it is characterized by diffuse nodular regeneration surrounded by dense fibrotic septa and pronounced distortion of hepatic vascular architecture.[119] This distortion results in increased resistance to portal blood flow, leading to portal hypertension and hepatic synthetic dysfunction. While it was previously regarded as an end-stage disease, there is a widely varying 1-year mortality ranging from 1% to 57%, depending on the occurrence of clinical decompensating events.[120] This, coupled with the fact that fibrosis regresses with specific treatment, such as antiviral treatment for chronic hepatitis B[121] and C,[122] underlines that it is better termed advanced liver disease to reflect its dynamic nature.

Cirrhosis is an increasing cause of morbidity and mortality in more developed countries, being the 14th most common cause of death worldwide but 4th in central Europe. It is the cause of 1.03 million deaths per year worldwide,[123] 170,000 per

year in Europe[124] and 33,539 in the United States.[125] The main causes in more developed countries are infection with hepatitis C virus, alcohol misuse, and, increasingly, nonalcoholic liver disease; infection with hepatitis B virus is the most common cause in Sub-Saharan Africa and most parts of Asia.[126]

Medical Aspects

Most chronic liver disease is asymptomatic until clinical decompensation occurs, when the presenting features include ascites, sepsis, variceal bleeding, encephalopathy, and nonobstructive jaundice.[126] Imaging by ultrasonography, CT, or MRI of an irregular and nodular liver together with impaired liver synthetic function is sufficient for the diagnosis of cirrhosis.[126] Less frequently seen are nonspecific findings of clubbing, cyanosis, and spider angiomas.[91] A liver biopsy is seldom needed, but study of a sample can provide a definitive diagnosis and confirm the etiology in cases of uncertainty.[126] Conventional imaging can lead to false-negative diagnosis in early cirrhosis and noninvasive markers of fibrosis are increasingly used.[126]

In keeping with the dynamic nature of the condition, it is considered to comprise four stages: stage 1 (compensated with no esophageal varices) has an estimated mortality of 1% per year; stages 2 (compensated with varices), 3 (decompensated with ascites), and 4 (decompensated with gastrointestinal bleeding) have annual mortality rates of 3.4%, 20%, and 57%, respectively.[120] Decompensating events are generally triggered by precipitating factors that include infection, portal-vein thrombosis, surgery, and hepatocellular carcinoma.[126]

Medical Management

The medical management of liver cirrhosis is dependent on the underlying etiology. The main objective is to prevent further injury to the liver. Discontinuation of alcohol and other toxins (e.g., cigarette smoking) as well as weight loss for those overweight is essential.[126] Specific treatments include immunosuppression for autoimmune hepatitis, venesection for hemochromatosis, and copper chelators or zinc for Wilson's disease.[126] Patients with viral hepatitis should be assessed for potent antiviral treatment, for example entecavir or tenofovir, which can improve the prognosis.[122]

Specific complications may also require intervention. Beta-blockers are helpful for portal hypertension, with statins added if the patient is hyperlipidaemic,[122] while NSAIDs, PPIs, and aminoglycosides should be avoided. Ascites benefits from a low-salt diet, diuretics, and antibacterial prophylaxis against spontaneous peritonitis. Bleeding esophageal varices can be treated with endoscopic banding, ligation, and nonselective beta-blockers.[126]

Liver transplantation is the therapeutic option for patients who develop decompensation or hepatocellular carcinoma with cirrhosis.[126]

Oral Health Considerations

The oral cavity may show evidence of cirrhosis, with the presence of hemorrhagic changes, petechiae, hematoma, jaundiced mucosal tissues, gingival bleeding, or icteric mucosal changes.[127] Oral mucosa pigmentation is rarely observed in cases of hemochromatosis.[127] Patients with cirrhosis are frequently malnourished and may have nutritional deficiencies or anemia, resulting in mucosal pallor, glossitis, and angular cheilitis, which may be complicated by candidal infection.[127]

Salivary gland dysfunction secondary to Sjögren's syndrome may be associated with primary biliary cirrhosis. Patients with chronic hepatitis C (HCV)–related cirrhosis may report oral and ocular dryness.[128] As the virus has not been shown to directly infect salivary gland tissue,[129] the HCV-related sicca syndrome is considered to be the product of a host immune-mediated mechanism, rather than a direct viral effect.[130] Histologic examination of salivary gland biopsies in HCV-infected patients shows pericapillary and nonpericanalary lymphocytic infiltration with sparing of the glandular canals.[131] Sialosis, a bilateral, painless hypertrophy of the parotid glands, may be associated with cirrhosis. The enlarged glands are soft, nontender, and are not fixed.[128] Ultrasound examination reveals enlarged glands with a homogeneous appearance.

The dental patient who presents with a history of liver cirrhosis can usually undergo routine dental treatment provided any necessary precautions are undertaken in consultation with the patient's physician. Patients with cirrhosis may present several specific challenges:

- Hemostatic defects, because of an inability to synthesize clotting factors and the presence of a secondary thrombocytopenia.[90] The current status and need for any preoperative measures (e.g., fresh frozen plasma or platelets) should therefore be established prior to any surgical procedure.[90]
- Reduced ability to detoxify substances so that drugs and toxins may accumulate.
- Encephalopathy due to an ammonia buildup from the incomplete detoxification of nitrogenous wastes.
- Induction of liver enzymes, leading to a need for increased or decreased dosages of certain medications.
- Ascites, which may make it difficult for them to fully recline in the dental chair because of increased pressure on abdominal vessels.
- Immunosuppression associated with liver transplantation patients and hence an increased risk of opportunistic and postoperative infections as well as acute graft-versus-host disease (mucositis) or chronic graft-versus-host disease, which resembles oral lichen planus.

GASTROINTESTINAL SYNDROMES

Plummer–Vinson Syndrome

Plummer–Vinson Syndrome (PVS; also termed Paterson–Brown–Kelly syndrome) classically presents as a triad of dysphagia, iron-deficiency anemia, and esophageal web. It mostly affects women in the age group of 40–70 years[132] and confers an increased risk of developing squamous cell carcinoma of the pharynx and the esophagus.[133]

The exact etiopathogenesis of PVS and formation of the esophageal web (a thin mucous membrane, composed of squamous epithelia[133]) is uncertain. However, the iron deficiency may induce iron-dependent enzyme dysfunction, leading to oxidative stress and DNA damages in epithelia of esophageal mucosa.[133] This may lead to atrophy of the mucosa and degradation of pharyngeal muscles, resulting in the development of esophageal webs.[134] Other possible factors include nutritional deficiencies (B vitamins), genetic predisposition, or autoimmune processes.[135]

The longstanding iron-deficiency anemia is responsible for the associated clinical features. General findings include dyspnea or difficulty in breathing, tachycardia, weakness, pallor, and koilonychia or spoon nails. Painless dysphagia may also be present, initially to solids but progressing to liquids over several years if untreated. The oral manifestations include atrophic glossitis with erythema or fissuring, angular cheilitis, and the development, or worsening, of oral ulceration.

Evaluation involves hematologic assays to determine the cause of the iron deficiency and the severity of the anemia. The upper gastrointestinal tract is assessed by video-fluoroscopy[136] or fiberoptic endoscopy, which enables assessment and diagnosis of any esophageal web or squamous cell carcinoma (which occurs in 10%–30% of patients[137]).

Medical management includes iron supplementation and will resolve the dysphagia in many patients.[133] Esophageal webs require endoscopic balloon dilatation or the use of dilators.[138,139]

Polyposis Syndromes

The gastrointestinal polyposis syndromes are a group of inherited cancer-predisposing syndromes with complex presentation,[140,141,142] and include those of Gardner, Peutz–Jegher, and Cowden. Despite these often, but not always, being associated with specific germline mutations, the phenotype may vary between individuals.[143] The specific diagnosis and treatment are therefore often determined by a combination of clinical assessment, inquiry of the family history, review of polyp pathology, and germline testing for causative genes.[144]

Gardner Syndrome

Gardner syndrome (GS), a rare autosomal dominant inherited disease, is a subgroup of familial adenomatous polyposis (FAP) and accounts for approximately 10% of FAP patients.[145] It is characterized by the presence of multiple polyps in the intestine as well as bony, cutaneous, dental, and ocular abnormalities,[146] due to mutations of the adenomatous polyposis coli (APC) gene on chromosome 5q21-22. The incidence of FAP is between 1 in 8300 and 1 in 14,025 births, affecting both sexes equally, with a uniform worldwide distribution.[147]

FAP is characterized by premalignant, adenomatous polyps of the colon and rectum, which progress to malignancy in untreated gene carriers. Carcinoma may develop at any age from the second to the seventh decade,[145] with a median age of 40 years.[145]

The clinical diagnosis of GS may be difficult due to the variable presence of extraintestinal features.[145] The extraintestinal manifestations include multiple osteomas, multiple impacted supernumerary teeth, connective tissue tumors, thyroid carcinomas, and hypertrophy of the pigmented epithelium of the retina. These lesions present themselves in a different chronologic order, but typically, cutaneous and bony lesions appear 10 years earlier than intestinal polyposis.[148]

As craniofacial bony and dental signs of GS often precede gastrointestinal symptoms,[146] OHCPs may play an important role in the diagnosis of FAP. In a patient with a family history of GS, dental radiography (such as a panoramic radiograph) can provide the earliest indication of the presence of this condition.[149] Dental abnormalities are present in 30%–75% and osteomas in 68%–82% of GS patients.[150,151]

Osteomas are slow growing and predominantly affect the mandible and maxilla, but can additionally affect the skull and long bones.[151] Bony exostoses, also called peripheral osteomas, can be palpable and be detected by routine radiography.[151,152,153] In the mandible, the osteomas may be central (characteristically near the roots of the teeth) or lobulated arising from the cortex, most commonly at the angle of the mandible.[151,153]

Dental anomalies include impacted teeth, supernumerary teeth, odontoma, congenitally missing teeth, and hypercementosis.[151] The simultaneous presence of osteoma(s) with dental anomalies is highly suggestive of underlying GS.[154]

Peutz–Jeghers Syndrome

Peutz–Jeghers syndrome (PJS) is an autosomal dominant condition characterized by characteristic hamartomatous polyps and distinctive mucocutaneous pigmentation.[155,156,157] It is caused by germline mutations of the STK11 tumor suppressor gene,[158] and has an incidence of between 1:50,000

and 1:200,000 births,[143,158,159] while the age at initial presentation varies from a few months to the fifth decade.[159]

The hamartomatous polyps occur most frequently in the small intestine (60%–90%), followed by the colon (25%–50%), stomach, and rectum.[158] They are characterized histopathologically by the unique finding of mucosa with interdigitating smooth muscle bundles in a characteristic branching tree appearance. They can cause abdominal pain, anemia, and gastrointestinal bleeding by intussusception or obstruction.[155,160].

Almost all patients present with mucocutaneous pigmentation, in the form of macules. These are often the first clinical sign and may affect the perioral tissues, lips, gingiva, hard palate, and buccal mucosa. The perioral pigmentation is distinctive in crossing the vermillion border and, while most of the cutaneous macules fade with age, the buccal mucosal pigmentation often persists.[156] Histologically, increased melanocytes are observed at the epidermal-dermal junction, with increased melanin in the basal cells.

A clinical diagnosis of PJS requires any two of (1) two or more Peutz–Jeghers-type hamartomatous polyps of the gastrointestinal tract; (2) typical hyperpigmentation of the mouth, lips, nose, eyes, genitalia, or fingers; or (3) family history of PJS.[143] Patients fulfilling these criteria warrant germline mutation assessment. Consideration should also be given to esophagogastroduodenoscopy (EGD), colonoscopy, and video capsule endoscopy, no later than the early teenage years,[158] as well as ongoing surveillance, since malignancies in the gastrointestinal tract and elsewhere in the body occur in 10% of patients with this syndrome.[161] No specific oral treatment is necessary.

Cowden Syndrome

Cowden syndrome (CS) is an autosomal dominant disorder caused by a phosphatase and tensin homolog (PTEN) tumor suppressor gene mutation.[143] It has an estimated prevalence of 1:200,000[162] and is said to be a cutaneous marker of internal malignancies.[163–168]

The syndrome was originally described as being characterized by the presence of facial trichilemmomas, acral keratoses, papillomatous papules, and mucosal lesions,[163] and the diagnosis was based on the presence of these "pathognomonic" features together with other "major" and "minor" features. The subsequent identification of the PTEN gene and the ability to molecularly confirm a clinical diagnosis, as well as further research, have identified the association of a broader spectrum of clinical features with PTEN mutations.[143] As a result, an operational diagnosis is now made on the basis of a combination of major and minor criteria.[143]

In an individual this requires either:

- three or more major criteria, but one must include macrocephaly, Lhermitte–Duclos disease, or gastrointestinal hamartomas; or
- two major and three minor criteria.

In a family, where one individual meets PTEN hamartoma tumor syndrome clinical diagnostic criteria or has a PTEN mutation, either:

- any two major criteria with or without minor criteria; or
- one major and two minor criteria; or
- three minor criteria.

The responses of facial papules to different treatment modalities, including topical 5-fluorouracil, oral retinoids, curettage, electrosurgery, cryosurgery, laser ablation, and surgical excision, are variable.[165–168]

Patients with CS require lifelong follow-up and repeat coloscopy in line with current recommendations,[143] while family members should be screened for the disease.

Renal Diseases

Karo Parsegian, DMD, MDSc, PhD
Ruchir Trivedi, MD, MSc, MRCP (UK)
Effie Ioannidou, DDS, MDSc

Kidneys play a vital role in maintaining internal balance (homeostasis) and a pivotal role in a number of basic physiologic functions, including filtration and excretion of metabolic waste products and toxins, blood pressure control, salt and water homeostasis, blood cell production, acid–base balance, and calcium (Ca^{2+}) homeostasis. Therefore, kidney diseases are one of the leading causes of morbidity, mortality, and healthcare expenditure. The traditional view of kidney function is limited and focuses on its regulation of excretory, endocrine, acid–base, and electrolytes domains. The more expanded view encompasses the role of kidneys in determining the composition of blood, contributing to immunologic balance, and engaging in constant cross-talk with the heart, gut, brain, and other vital organs.

This chapter provides a comprehensive and evidence-based overview of the renal structure, function, and diagnostic tools for impaired renal function, as well as oral symptoms and signs observed in patients with chronic kidney disease prior to and during in-center hemodialysis, patients undergoing peritoneal dialysis, and those received

Burket's Oral Medicine, Thirteenth Edition. Edited by Michael Glick, Martin S. Greenberg, Peter B. Lockhart, and Stephen J. Challacombe.

a kidney transplant. Finally, we describe the most current understanding of these diseases' etiology and pathogenesis, provide evidence-based dental therapy approaches, and highlight the importance of the interprofessional interaction between dental practitioners and the nephrology team.

KIDNEY STRUCTURE AND FUNCTION

The human kidneys are bean-shaped organs located in the retroperitoneum at the level of the waist. Each adult kidney weighs approximately 160 g and measures 10–15 cm in length. Coronal sectioning of the kidney reveals two distinct regions: an outer region called the cortex and an inner region known as the medulla (Figure 16-1). Structures that are located at the corticomedullary junction extend into the kidney hilum and are called papillae. Each papilla is enclosed by a minor calyx, which collectively communicates with the major calyces to form the renal pelvis. The renal pelvis collects urine flowing from the papillae and passes it to the bladder via the ureters. Vascular flow to the kidneys is provided by the renal artery, which branches directly from the aorta. This artery subdivides into segmental branches to perfuse the upper, middle, and lower regions of the kidney. Further subdivisions account for the arteriole–capillary–venous network or vas recta. The venous drainage of the kidney is provided by a series of veins leading to the renal vein and ultimately to the inferior vena cava.

The kidney's functional unit is the nephron (Figure 16-2) and each kidney is made up of approximately 800,000–1,600,000 nephrons. For a given individual, nephron endowment depends on maternal health, mainly intrauterine environment; micronutrients and protein deficiencies; exposure to tobacco, alcohol, and certain nephrotoxic medications; genetics; and other environmental factors. Each nephron consists of Bowman's capsule (surrounds the glomerular capillary bed), the proximal convoluted tubule, the loop of Henle, and the distal convoluted tubule (which empties into the collecting ducts). The glomerulus is a unique network of capillaries that is suspended between afferent and efferent arterioles enclosed within Bowman's capsule and that serves as a filtering funnel for waste. The filtrate drains from the glomerulus into the tubule, which alters the concentration along its length by various processes to form urine. The glomerulus funnels ultra-filtrate to the remaining portion of the nephron or renal tubule. Following filtration, the second step of urine formation is the selective reabsorption and secretion of filtered substances, which occur along the length of the tubule via active and passive transport processes.

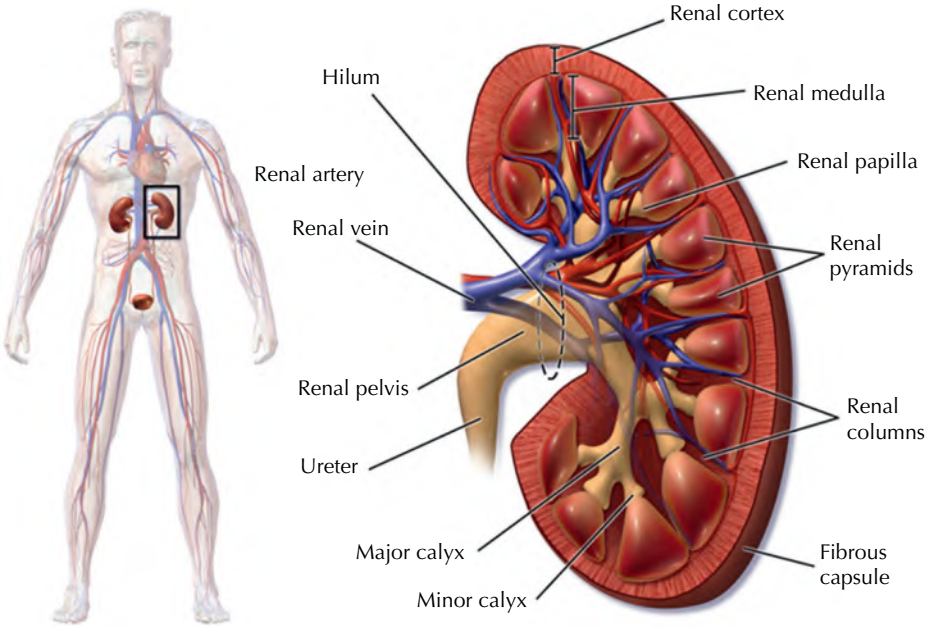

Figure 16-1 Coronal sectioning of the kidney reveals two distinct regions: an outer region called the cortex and an inner region known as the medulla. *Source:* https://commons.wikimedia.org/wiki/File:Blausen_0592_KidneyAnatomy_01.png. Figure 16-2 The kidney's functional unit is the nephron. *Source:* https://commons.wikimedia.org/wiki/File:Physiology_of_Nephron.png. Licensed under the Creative Commons Attribution 3.0 Unported license.

Table 16-1 Major functions of the kidneys.

Nonexcretory functions
Degradation of polypeptide hormones
Insulin
Glucagon
Parahormone
Prolactin
Growth hormone
Antidiuretic hormone
Gastrin
Vasoactive intestinal polypeptide
Synthesis and activation of hormones
Erythropoietin (stimulates erythrocyte production by bone marrow)
Prostaglandins (vasodilators that act locally to prevent renal ischemia)
Renin (important in regulation of blood pressure)
1,25-Dihydroxyvitamin D_3 (final hydroxylation of vitamin D to its most potent form)
Excretory functions
Excretion of nitrogenous end products of protein metabolism (e.g., creatinine, uric acid, urea)
Maintenance of ECF volume and blood pressure by altering Na^+ excretion
Maintenance of plasma electrolyte concentration within normal range
Maintenance of plasma osmolality by altering water excretion
Maintenance of plasma pH by eliminating excess H^+ and regenerating HCO_3^-
Provision of route of excretion for most drugs

ECF, extracellular fluid; H^+, hydrogen; HCO_3^-, bicarbonate; Na^+, sodium; pH, hydrogen ion concentration.

Each day, the kidneys excrete approximately 1.5–2.5 L of urine; although the removal of toxic and waste products from the blood remains their major role, the kidneys are also essential for the production of hormones (such as vitamin D and erythropoietin) and the modulation of salt and water excretion (Table 16-1). Once destroyed, nephrons do not regenerate. However, the kidney compensates for the loss of nephrons by hypertrophy of the remaining functioning units. Low nephron endowment and/or destruction from diseases reduce the number of nephrons significantly enough to cause hypertrophy (nephromegaly) and hyperfiltration of remaining nephrons. Most kidney donors maintain near normal kidney function after kidney donation that results in 50% reduction in nephron mass, with excellent long-term outcome and a very small risk of development of hypertension and albuminuria explaining a successful and orderly pattern of functional adaptation with nephron loss.[1] Structural and functional adaptations of kidneys compel us to rethink our view that progressive kidney diseases are due to the disorderly and inefficient function of nephrons. In reality, progressive kidney diseases such as hypertensive and diabetic nephropathies likely represent an extremely efficient function of too few nephrons unable to carry out their required tasks in spite of maximum functional adaptation in the face of ongoing destructive disease processes. Unfortunately, in the United States, progressive kidney diseases disproportionately affect minorities such as patients of African American and Hispanic origins, hence a preventive focus and treatment of hypertension (HTN) and diabetes mellitus (DM) play a pivotal role in order to decrease their incidence and prevalence.

FLUIDS, ELECTROLYTES, AND ACID–BASE HOMEOSTASIS

With advancing nephron destruction, water and electrolyte regulation becomes increasingly more difficult. Adaptations to sudden shifts in intake occur slowly, resulting in wide

swings in water and solute concentrations. The first clinical sign of diminished renal function is a decreased ability to concentrate the urine (isosthenuria). As a result of this inability to conserve water, dehydration ensues. With early renal insufficiency, sodium is also lost in the urine. This loss is often independent of the amount of water lost. As the renal disease progresses, salt and water handling becomes progressively less efficient, resulting in volume overload and leading to hypertension and congestive heart failure. When glomerular filtration becomes markedly diminished, the distal tubule can no longer secrete sufficient potassium, leading to hyperkalemia.

In a healthy body, the acid–base balance is maintained via buffers, respiration, and the amounts of acid or alkaline wastes in the urine; this is because the daily load of endogenous acid is excreted into the urine with buffering compounds such as phosphates. As the glomerular filtration rate (GFR) progressively decreases, the tubular excretory capacity for positive hydrogen (H^+) ions is overwhelmed because renal ammonia production becomes inadequate. In its early phases, the resultant acidosis usually has a normal anion gap. As the kidney deteriorates, metabolically derived acids accumulate, leading to an increase in the anion gap. Clinically, this metabolic acidosis is manifested as anorexia, nausea, fatigue, weakness, and Kussmaul's respiration (a deep gasping respiration similar to that observed in patients with diabetic ketoacidosis).

DIAGNOSTIC PROCEDURES IN KIDNEY DISEASES

Biochemical Profile

In the presence of kidney dysfunction, changes in homeostasis are reflected in serum chemistry. Sodium, chloride, blood urea nitrogen (BUN), glucose, creatinine, carbon dioxide, potassium, phosphate, and Ca^{2+} levels provide useful tools to evaluate the degree of renal impairment and disease progression. Serum creatinine and BUN are often important markers to the GFR. Both of these products are nitrogenous waste products of protein metabolism that are normally excreted in the urine, but they may increase to toxic levels in the presence of renal dysfunction. A characteristic profile of changes occurs with advancing renal dysfunction, including elevations in serum creatinine, BUN, and phosphate, compared with low levels of serum Ca^{2+}. Laboratory findings commonly seen in renal disease are summarized in Table 16-2.

Creatinine originates from the nonenzymatic hydrolysis of creatine and phosphocreatine found almost exclusively in muscles. This hydrolysis occurs at a constant rate. Serum creatinine concentration not only depends on muscle mass but also on tubular secretions, dietary protein intake, hepatic synthesis (low in liver diseases), and intestinal exchange. BUN and cystatin C also share properties of acceptable markers for renal clearance (Table 16-2). Combined GFR estimates based on creatinine and cystatin C have been presented, and their use will likely increase in future.[2]

Urinalysis

The most important aspects of urine examination in patients with renal disease include the detection of protein or blood in the urine, determination of the specific gravity or osmolality, and microscopic examination. The hallmarks of renal dysfunction detected by urinalysis are hematuria (the presence of blood in the urine) and proteinuria (the presence of protein/albumin in the urine). Hematuria can result from bleeding anywhere in the urinary tract. Rarely, hematuria is a sign of clinically significant renal disease. Microscopic hematuria in patients younger than 40 years is almost always benign, and further workup is rarely indicated. Occasionally, significant underlying disease, such as a neoplasm or proliferative glomerulonephritis, can cause hematuria. However, the accompanying active sediment of proteins and red blood

Table 16-2 Laboratory changes in progressive renal disease.

Laboratory Test	Normal Range	Level in Symptomatic Renal Failure
Glomerular filtration rate	90–120 mL/min/1.73 m^2	< 15 mL/min
Creatinine clearance	85–125 mL/min (female)	10–60 mL/min (moderate failure)
	97–140 mL/min (male)	< 15 mL/min (severe failure)
Serum creatinine	0.6–1.20 mg/dL	> 5 mg/dL
Blood urea nitrogen	8–18 mg/dL	> 50 mg/dL
Serum calcium	8.5–10.5 mg/dL	Depressed
Serum phosphate	2.5–4.5 mg/dL	Elevated
Serum potassium	3.8–5.0 mEq/L	Elevated

cell casts makes the diagnosis relatively straightforward. In older people, hematuria warrants further evaluation, including urologic studies to rule out prostatic hypertrophy and neoplasia, urine cultures to rule out infection, urine cytology, and advanced renal studies (such as renal ultrasound or noncontrast computed tomography [CT] scan of the abdomen and pelvis) to rule out intrinsic abnormalities.

Proteinuria (a urine dipstick will only detect albumin) is probably the most sensitive sign of renal dysfunction. The upper limit of normal urinary protein is 150 mg per day; anything greater should be considered pathologic and warrant further investigation. Patients who excrete >3 g of protein per day have, by definition, a glomerular pathology and carry a diagnosis of nephrotic syndrome (discussed below). However, many benign conditions (including exercise, stress, and fever) can produce transient elevated protein in the urine. Daily proteinuria estimation can be ascertained by measuring the total protein-to-creatinine ratio (expressed in grams of protein/grams of creatinine), which can be extrapolated to grams of proteinuria per day. Should any doubt still exist, or precise quantification is necessary, 24-hour urine collection can be performed. This procedure has fallen out of favor, as it is cumbersome and somewhat difficult for the patient to complete accurately. The 24-hour urine test remains a useful tool for determining daily salt intake, calculating creatinine and urea clearance, and while analyzing the urinary metabolic profile in recurrent nephrolithiasis. Urine specific gravity is measured to determine the concentration of urine. In chronic kidney disease (CKD), the kidney initially loses its ability to concentrate the urine and then loses its ability to dilute the urine, resulting in a relatively fixed osmolality near the specific gravity of plasma. This occurs when approximately 80% of the nephron mass has been destroyed.

Creatinine Clearance Test

The GFR assesses the amount of functioning renal tissue and can be calculated indirectly by the endogenous creatinine clearance test. Creatinine is a breakdown product of muscle, liberated from muscle tissue, and excreted from the urine at a constant rate. This results in a steady plasma concentration of 0.7–1.5 mg/dL (often slightly higher in men because of increased muscle mass). Creatinine is 100% filtered by the glomerulus and is not reabsorbed by the tubule. Although a very small portion is secreted by the tubule, this test is an effective way to estimate the GFR. GFR is estimated by incorporating the serum creatinine into a formula, along with the patient's age, weight, and race, and is expressed in milliliters per minute (min) of clearance (mL/min/1.73 m^2). The two most common equations used are the Cockcroft–Gault formula and the modified diet in renal disease formula (Figure 16-3).

In some instances, it is necessary to measure absolute GFR. To accomplish this, a 24-hour urine specimen and a blood sample in the same 24-hour period are required. This has fallen out of favor, however, as the test is cumbersome and inconvenient for the patient.

Renal Ultrasonography

Grayscale ultrasonography and Doppler ultrasonography are the most commonly used and relied-upon techniques for radiologic examination of the kidneys. These diagnostic procedures use high-frequency sound waves (ultrasound) directed at the kidneys to produce reflected waves or echoes from tissues of varying densities, thereby forming images (sonograms). Ultrasound is a noninvasive method to determine kidney size, presence of retained urine within the renal pelvis or calices (hydronephrosis), identification and limited evaluation of vascular structures, and presence of fluid-filled cysts within the kidney parenchyma.[1–4] Renal ultrasonography is also utilized to localize the kidney during a percutaneous biopsy. Because it is noninvasive, readily available in most imaging centers, does not use radiation or intravenous (IV) contrast, and is quick, renal ultrasonography is the imaging modality of choice for initial evaluation of the kidneys. It is also the modality of choice for pregnant patients because it does not use radiation to obtain clinical images. Doppler ultrasound is used to assess

Cockcroft-Gault Equation:

$$\text{eGFR} = \frac{[\,(140\text{-age}) \times \text{Mass(kg)} \times (0.85 \text{ if female})]}{72 \times \text{SCr (mg/dL)}}$$

MDRD Formula:

$$\text{eGFR} = 170 \times \text{SCr}^{-0.999} \times \text{Age}^{-0.176} \times [0.762 \text{ if female}] \times [1.18 \text{ if Black}] \times \text{BUN}^{-0.170} \times \text{Albumin}^{0.318}$$

vascular function and flow. Grayscale ultrasound also helps identify kidney stones, cysts, and parenchymal disease processes, and in assessment of bladder function in more complex kidney diseases.

Computed Tomography

CT imaging is utilized when the entire genitourinary (GU) tract or retroperitoneum needs evaluation. It provides more information about the structures of the GU tract (ureters, bladder, urethra, and prostate) and retroperitoneum, as well as surrounding structures that could contribute to renal pathology (tumors, lymphadenopathy, masses). Furthermore, because of technologic advances over the years, CT scanners are far more cost-effective, quicker, and more readily available in hospitals or imaging centers. Like other CT scans, the procedure can be performed with or without IV contrast for vascular enhancement; with CKD, caution must be used with IV contrast media, as this can incur further renal decline (see the Acute Kidney Injury section). Contrast-induced nephropathy is likely secondary to a vasoconstrictive effect of contrast media in addition to oxidative kidney injury. A noncontrast CT scan of the abdomen and pelvis is the imaging modality of choice when investigating the presence of kidney stones. A newer modality of CT scan, dubbed CT-urography, can be used for a detailed, three-dimensional evaluation of the GU tract.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is not commonly utilized as the first imaging modality for the diagnosis of kidney disorders. This modality can give much of the same information as a CT scan, with far more detail and information about specific tissues and structures. The cost, time investment, and, to a lesser extent, patient comfort prohibit this modality from becoming mainstream in kidney disease evaluation. Furthermore, the contrast medium used for magnetic resonance angiography (MRA) is gadolinium based. Gadolinium has been linked as a cause of a progressive skin fibrosis called nephrogenic systemic fibrosis (NSF), which is seen exclusively in patients with advanced kidney disease (GFR <30 mL/min/1.73 m^2) or who are on dialysis. This condition carries a high morbidity and mortality burden; therefore, the gadolinium-based contrast medium is generally not administered when the patient's GFR is <30 mL/min/1.73 m^2. Recent data indicate that NSF is exceedingly uncommon when macrocyclic or newer linear gadolinium compounds are used in patients with GFR <30 mL/min/1.73 m^2. This knowledge will improve access to gadolinium-based enhanced MRI when medical benefits clearly outweigh a very small risk.

The primary kidney-related indications for utilizing MRI/MRA is either the evaluation of the renal vasculature if significant renal artery stenosis is suspected, or evaluation of a mass, solid or cystic, when radiocontrast cannot be used with a CT scan.

Intravenous Pyelography

Prior to ultrasonography and CT, IV pyelography was the most commonly used and relied upon radiologic examination of the kidneys. Following the IV injection of a contrast medium, a plain-film abdominal radiograph is taken. Further films are exposed every minute for the first 5 minutes, followed by a film exposed at 15 minutes and a final film exposed at 45 minutes. Since various diseases of the kidney alter its ability to concentrate and excrete the dye, the extent of renal damage can be assessed. The location and distribution of the dye itself give information regarding the position, size, and shape of the kidneys. This examination has limited application, particularly in patients with severe azotemia (the building up of nitrogenous waste products in the blood)—that is, those whose BUN >70 mg/dL); for them this test is deferred because there is sufficiently low glomerular filtration to prevent the excretion of the dye, rendering information about the kidney nondiagnostic.

Nuclear Medicine (Radionuclide Scintigraphy)

While the aforementioned imaging modalities can provide structural information, radionuclide scintigraphy can provide qualitative and quantitative functional information about the kidneys. Using radiolabeled tracers, information can be garnered about renal blood flow, glomerular filtration, or urinary excretion. Several compounds are available that incorporate technetium-99 as the radioactive isotope; these include diethylenetriamine pentaacetic acid, mercaptoacetyl triglycine, and ^{131}I-o-iodohippurate (^{131}I-OIH). Measurement of these radiolabeled substances can be used to calculate true GFR or the presence/absence of renal blood flow. They can also be combined with captopril to investigate possible renal artery stenosis or furosemide to uncover unilateral urinary obstruction. Radionuclide scintigraphy is the modality of choice to accurately measure GFR in patients who have undergone a spinal injury, as serum creatinine is linked to muscle mass, which may be disproportionately lower in this patient population. This modality is frequently used in kidney transplant (KT) evaluation, as IV radiocontrast may be contraindicated and renal ultrasound may be equivocal.

Kidney Biopsy

The development and growing use of renal biopsy have considerably advanced the knowledge of the natural history of kidney diseases. Percutaneous needle biopsy guided by ultrasonography or CT can usually be performed by nephrologists, with the patient lying in a prone position with one to two firm pillows. Approximately 25% of cardiac output flows to the kidney; hence, intrarenal and perirenal bleeding may be common sequelae, with serious postprocedural bleeding and hematuria occurring in 5% of cases. The incidence of postprocedural bleeding also depends on needle size. When a 16G or 18G needle is used, 0.5% of patients require blood transfusion, as opposed to 2% with the use of a 14G needle. Careful assessment of the risk–benefit ratio is required before performing a kidney biopsy. Patients are placed on bed rest for at least 6 hours following the procedure while vital signs and abdominal changes are monitored. Safe conditions for performing kidney biopsy include hemoglobin >9 g/dL, platelets >100,000 × 10^9/L, normal coagulation profile (prothrombin time or PT/partial thromboplastin time or PTT), blood pressure preferably <160/90 mm Hg, and no active urine infection. Single kidney, atrophic kidneys with thin cortex, difficult anatomy with multiple kidney cysts, uncontrolled hypertension, and active pyelonephritis (infection) are relative contraindications of kidney biopsy.

ACUTE KIDNEY INJURY

Acute kidney injury (AKI) is defined by a rapid increase in serum creatinine, a decrease in urine output, or both. AKI occurs in approximately 10%–15% of patients admitted to hospital, while its incidence in intensive care has been reported in more than 50% of patients. Complete recovery following AKI may not occur predisposing patients with residual kidney damage resulting in CKD. AKI is not a single disease, but rather a loose collection of diverse syndromes such as sepsis, cardiorenal syndrome, and urinary tract obstruction. Serum creatinine and urine output can be used to stage AKI based on AKI Network (AKIN) criteria (Table 16-3).

Sepsis, shock, medications, surgery, pregnancy-related complications, and trauma are the most common causes of AKI (Table 16-4). Unlike patients who develop CKD, patients with AKI usually have normal baseline renal function, yet mortality from AKI even with medical intervention, including dialysis, remains high. The causes of AKI are often divided into three diagnostic categories: prerenal failure, postrenal failure, and acute intrinsic renal failure.

Table 16-3 Staging Acute Kidney Injury (AKI) based on AKI Network criteria.

Stage	Serum Creatinine	Urine Output
1	1.5–1.9 times baseline *or* ≥0.3 mg/dL (≥26.5 μM/L) increase	<0.5 mL/kg/hr for 6–12 hrs
2	2.0–2.9 times baseline	<0.5 mL/kg/h for 12 hrs
3	3.0 times baseline *or* Increase in serum creatinine to ≥4.0 mg/dL (≥353.6 μM/L) *or* Initiation of renal replacement therapy *or* In patients <18 years, decrease in eGFR to <35 mL/min/1.73m^2	<0.3 mL/kg/h for ≥24 hrs OR Anuria for ≥12 hrs

Such denominations are increasingly becoming arbitrary, as significant overlap exists between prerenal AKI and acute intrinsic AKI (acute tubular necrosis, or ATN).

Prerenal Acute Kidney Injury or Prerenal Azotemia

Prerenal AKI is by definition caused by inadequate blood flow to the kidneys without significant structural damage, and therefore is rapidly reversible following volume expansion (volume-responsive prerenal AKI) and treatment of the underlying cause that results in volume depletion. Septic shock due to decreased effective circulating volume from endotoxin-mediated vasodilation and loss of extracellular volume from diarrhea, vomiting, blood loss from trauma, and so on are frequent causes of prerenal AKI. Prerenal AKI represents hypoperfusion of kidneys from events occurring "outside" the kidneys. Decreased effective circulating volume is sensed by protective mechanisms such as activation of the sympathetic nervous system (SNS) and renin-angiotensin-aldosterone system (RAAS), resulting in increased sodium reabsorption in the kidneys (Table 16-4).

Prerenal AKI can be diagnosed with urine indices such as low fractional excretion of sodium (FeNa) or low fractional excretion of urea (FeUrea) in the presence of low urine output (oliguria; urine output <400 mL/24 hrs). Etiologies such as heart failure, cirrhosis of liver, radiocontrast exposure, and bilateral renal artery stenosis can result in low FeNa due to

Table 16-4 Pathophysiology and mechanism of injury in select clinical conditions resulting in acute kidney injury.

Mechanism of Injury	Pathophysiology
Renal hypoperfusion Renal hypoperfusion activates sympathetic nervous system (SNS) and renin-angiotensin-aldosterone system (RAAS). Failure of renal autoregulation and resultant renal hypoperfusion lead to ATP depletion that activates epithelial cellular injury and death via necrosis or apoptosis	• Volume depletion (from diarrhea, vomiting, diuretic use, etc.) • Systemic vasodilatation • Increased vascular resistance (inotrope use in ICU, RAS, HTN, etc.) **Result:** Endothelial injury and intrinsic AKI or ATN
Acute worsening of cardiac function	• Reduced effective circulation fluid volume or an increase in central venous pressure **Result:** Cardiorenal syndrome (kidney dysfunction from acute worsening of cardiac function)
Nephrotoxin exposure Nephrotoxic drugs (e.g., antibiotics, contrast media, NSAIDs), and endogenous toxins (e.g., myoglobin, uric acid among others)	• Direct cytotoxic effect on renal tubular epithelial or endothelial cells • Impaired intrarenal hemodynamics • Precipitation of metabolites or crystals, among others **Result:** Acute tubular necrosis
Sepsis and septic shock Capillary microthrombi generation, decreased tissue perfusion, and imbalance in nitric oxide production	• Endothelial damage leading to increased vascular permeability • Suppression of cardiac function **Result**: Increased interstitial edema, redistribution of intrarenal perfusion, inflammation and septic cardiomyopathy leading to ischemic ATN
Major surgery Blood loss, third spacing of fluids, peripheral vasodilation, myocardial depression	• Effect of anesthesia and medications • Increased level of circulating cytokines and reactive oxygen species • Endotoxin load from gut and tissue hypoperfusion **Result:** Impaired renal perfusion and ischemia-reperfusion injury leading to prerenal and intrinsic AKI
Intraabdominal hypertension Sustained intraabdominal pressure >12 mm Hg (volume overload, ascites or interstitial edema of bowel loops)	• Reduced arterial inflow and venous outflow • Elevated hydrostatic pressure in Bowman's space (area of the nephron where filtrate enters after passing through filtration slits, also known as capsular space or urinary space) **Result:** Decreased renal hypoperfusion leading to prerenal AKI and if left uncorrected intrinsic ATN

AKI, acute kidney injury; ATN, acute tubular necrosis; HTN, hypertension; ICU, intensive care unit; NSAID, nonsteroidal anti-inflammatory drug; RAS, renal artery stenosis.
Source: Based on Bellomo R, Kellum JA, Ronco C. Acute kidney injury. *Lancet*. 2012;380(9843):756–766.

perceived decrease in effective circulating volume sensed by the kidneys. In theory, a detailed history, clinical examination of accurate volume status, and, in carefully selected cases, invasive monitoring of volume status may help establish the correct diagnosis. Medications such as diuretics, blockers of the RAAS system, and nonsteroidal anti-inflammatory drugs (NSAIDs) are frequently implicated in prerenal AKI. Newer urinary biomarkers may help in the diagnosis of AKI before the elevation of serum creatinine.[4] When prerenal AKI persists for a long time, continued hypoperfusion of kidneys will lead to ischemia and ATN or intrinsic AKI.

Intrinsic Acute Kidney Injury

Intrinsic AKI or ATN is characterized by the presence of structural damage to the kidneys, which is not rapidly reversible by correcting underlying or causal conditions. The outer medullary parenchymal region of the kidney is metabolically very active with high energy demands, but due to the anatomic arrangement of the renal vasculature, oxygen supply in this area is limited, making it highly susceptible to cellular kidney injury with prolonged ischemia. Firmly establishing cellular damage clinically is difficult. Most clinicians consider prerenal AKI and intrinsic AKI as a continuum, as both often coexist with patchy areas of structural cellular damage (ATN, intrinsic AKI) interspersed with areas of hypoperfusion that may still be structurally intact and upon receiving reperfusion (volume expansion) can rapidly resume normal nephron filtration function (prerenal AKI).

Glomerular disease, vascular disease, and tubulointerstitial disease comprise the three additional causes of acute intrinsic

renal failure and describe the sites of pathology. Glomerulonephritis is an uncommon cause of AKI and usually follows a more subacute or chronic course. However, when fulminant enough to cause AKI, it is associated with active urinary sediment (dysmorphic red blood cells [RBCs], acanthocyturia, RBC casts), oliguria, and rapid deterioration of renal function. Prominent clinical and laboratory findings include hypertension, proteinuria, microscopic hematuria, and RBC casts. Postinfectious, membranoproliferative, and rapidly progressive glomerulonephritis, as well as glomerulonephritis associated with endocarditis, are the most common glomerular diseases to cause a sudden renal deterioration. The pathogenesis of glomerulonephritis appears to be related to the immunocomplex and complement-mediated damage to the kidney.[4]

Vascular diseases that induce AKI cover the spectrum of vessel size from large (renal artery and vein) to microscopic (afferent and efferent arterioles of the glomerulus). Large vessel occlusive processes such as renal arterial or venous thromboses present as a classic triad of severe and sudden lower back pain, severe oliguria, and macroscopic hematuria. Medium- to small-vasculature AKI is often caused by autoimmune vasculitides, thrombotic microangiopathies, or cholesterol crystal embolization.

By far the most common causes of acute intrinsic failure are tubulointerstitial disorders (>75% of cases), including interstitial nephritis and ATN. Infiltrative diseases (such as lymphoma or sarcoidosis), infections (such as syphilis and toxoplasmosis), and medications are the leading causes of interstitial nephritis. With drug-induced interstitial nephritis, there are accompanying systemic signs of a hypersensitivity reaction, and the presence of eosinophils is a common finding in the urine. Although renal function usually returns to normal with the discontinuation of the offending drug, recovery may be hastened with corticosteroid therapy. ATN is a renal lesion that forms in response to prolonged ischemia or exposure to nephrotoxin, among other causes. ATN remains more of a clinical diagnosis of exclusion than a pathologic diagnosis. The period of renal failure associated with ATN can range from weeks to months, and the major complications of this transient failure are imbalances in fluid and electrolytes, as well as uremia. Serum levels of BUN and creatinine peak, plateau, and slowly fall, accompanied by a return of renal function over 10–14 days in most cases.[4]

Sudden renal failure in hospitalized patients is often very apparent from either oliguria or an increase in BUN and creatinine levels. However, renal dysfunction in the outpatient population is frequently more subtle. A patient can present to the dental office with vague complaints of lethargy and fatigue or entirely without symptoms. These patients can go undiagnosed but for abnormal results on routine urinalysis, the most common test for screening for renal disease.

Postrenal Failure

Postrenal causes of failure are less common (<5% of patients) than prerenal causes. Postrenal failure refers to conditions that obstruct the flow of urine from the kidneys at any level of the urinary tract, and that subsequently decrease the GFR. Postrenal failure can cause almost total anuria, with complete obstruction or polyuria. Renal ultrasonography often shows a dilated collecting system (hydronephrosis). Obstructive uropathy is, most commonly, seen in older men as a result of the enlargement of the prostate gland. If present in females, a thorough pelvic examination is warranted to elicit the cause of the obstruction. Although postrenal failure is the least common cause of AKI, it remains the most treatable.[4]

CHRONIC KIDNEY DISEASE

Epidemiology and Progression

The prevalence of kidney diseases worldwide is estimated to be between 8% and 16%.[5] In the United States, over 30 million people or approximately 15% of US adults are estimated to have CKD and are at risk for progression of their renal disease (Figure 16-4).[6] Based on Medicare data assessing patients older than 65 years, the prevalence of recognized CKD in the United States has steadily risen year after year across all stages of CKD. From 2016 to 2017, the proportion of Medicare patients with recognized CKD increased from 13.8% to 14.5%, and these patients used 7.2% of total Medicare expenditure for less than 2% of the eligible Medicare patient population. As a result, CKD remained the ninth leading cause of death in the United States in 2017.

CKD is classified according to the GFR (Table 16-5).[7]

Diabetes and hypertension are major disease processes that lead to CKD and ESRD. The burden of CKD may be examined in several ways, including individual or societal costs, attributable or excess mortality, years of life lost (YLL), and disability-adjusted life years (DALYs). DALYs include YLLs plus years of poor health or disability. Elevated fasting plasma glucose levels, overweight, obesity, diets high in sodium, sugar-sweetened beverages, and elevated systolic BP account for significant healthcare cost burden in CKD progression.[8] Globally, CKD incidence increased by 89% and CKD-attributable deaths swelled by 98%, according to data from the Global Burden of Disease Study, which incorporated kidney disease data from 1990 to 2016.[9] Strong disparities in race, sex, and socioeconomic status continue in the United States and worldwide in the ESRD population. The lifetime risk of ESRD is more than twofold higher among non-Hispanic black and Hispanic men compared

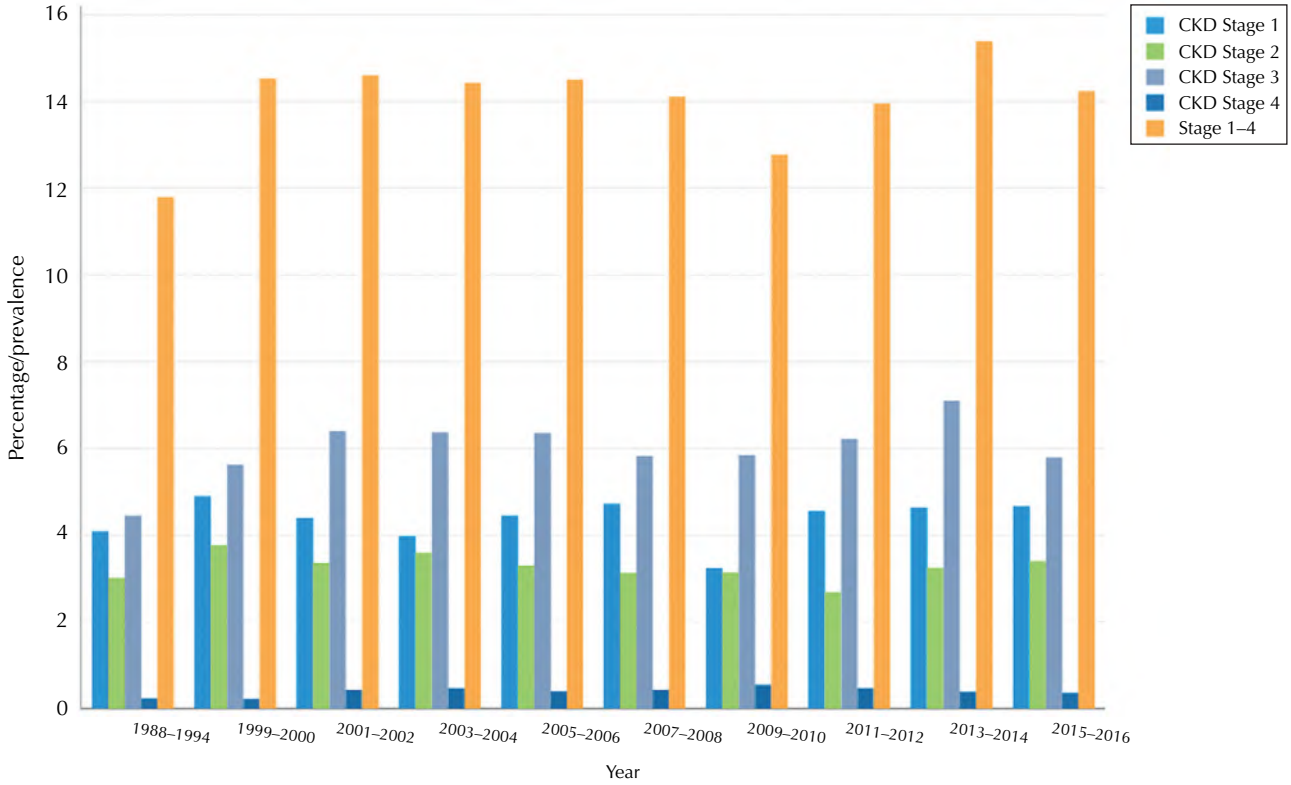

Figure 16-4 Prevalence of CKD Stages 1–4 by Year: Data from the National Health and Nutrition Examination Survey. *Source:* Centers for Disease Control and Prevention. Chronic Kidney Disease Surveillance System website. https://nccd.cdc.gov/CKD. Accessed May 1, 2019.

Table 16-5 Classification of Chronic Kidney Disease (CKD) based on Glomerular Filtration Rate (GFR).

Stage of CKD	Definition	GFR (mL/min/1.73 m^2)
Stage 1	Kidney damage with normal GFR	≥90
Stage 2	Kidney damage with mild decrease in GFR	60–89
Stage 3A	Mild to moderate decrease in GFR	45–59
Stage 3B	Moderate to severe decrease in GFR	30–44
Stage 4	Severe decrease in GFR	15–29
Stage 5	End-stage renal disease (ESRD)	<15
Stage 6	ESRD on dialysis therapy	<15 with symptoms requiring dialysis therapy

with Caucasian men. In recent years, studies have started to examine the role of recreational drug use in CKD progression.[10] Past or present marijuana use is not proven to be associated with an increased risk of kidney disease; however, persistent smoking, heroin, cocaine, or methamphetamine use is associated with increased risk of CKD progression and increased mortality among adults with established CKD. Given the rising incidence of CKD, screening for kidney disease with urinary albumin excretion has been attempted at a population level. Unfortunately, widespread population-based screening models have not proved to be cost-effective except in targeted high-risk individuals with hypertension and DM. Urinary albumin excretion above 300 mg/g of creatinine is associated with a high risk of progression to ESRD and increased cardiovascular mortality.[4]

Some medications such as cimetidine, trimethoprim, corticosteroids, pyrimethamine, salicylates, and active vitamin D metabolites have been reported to increase plasma creatinine without influencing its glomerular filtration via inhibiting the distal secretion of creatinine. Patients may present

with worsening serum creatinine but preserved renal function while taking the above-listed medications. Low thyroid function is associated with decreased GFR by decreasing renal blood flow, but not increased rates of kidney disease progression and ESRD.[11]

Diet and Chronic Kidney Disease

High sodium intake may exacerbate HTN and CKD progression. Motivated patients frequently ask about advice with regard to their fluid intake and diet. A recent study showed that drinking at least two cups of coffee per day was associated with a significantly lower risk of progression to ESRD.[12] The renal benefits of coffee consumption may, in part, be secondary to chlorogenic acids that replenish glutathione and prevent oxidative injury to proximal tubular cells.[12] In contrast, in patients with polycystic kidney disease (autosomal dominant kidney diseases with progressive bilateral kidney cysts and progression to ESRD) a reduction in caffeine intake has been recommended, because caffeine induces cyclic adenosine monophosphate, which is involved with cyst growth and disease progression. Diets low in animal protein and red meat may help preserve kidney function, provided nutritional parameters are carefully monitored and malnutrition is avoided. Increasing water intake has not been shown to reduce the risk of kidney function decline.[13] Patients with kidney stones are advised to drink a sufficient amount of water to maintain urine output in the vicinity of 2.5–3.0 L, in order to minimize recurrent stone formation. For the general population, benefits of prescribed water intake in slowing the progression of CKD have not been identified. Sugar-sweetened and artificially sweetened beverage intake is associated with higher risks of non-dialysis-dependent CKD, and their intake should be minimized.[14] Control of diabetes and HTN will certainly help in slowing the progression of CKD.

Uremic Toxins, the Microbiome, and Chronic Kidney Disease

The term "microbiota" refers to the ensemble of microorganisms (composed of bacteria, bacteriophage, fungi, protozoa, and viruses) that live in or on the human body. The microbiome is the collective genome of the microbes. The interplay between the oral and colonic microbiome and ESRD is an active area of research.

A significant adaptation of gut function can assist in the excretion of solutes and water when kidney function is impaired. The gut assumes a progressively larger role in nitrogen waste excretion and potassium homeostasis that compensates, to a certain extent, for the loss of renal excretory function. Diarrhea was induced to treat uremia when dialysis was unavailable to physicians. Gut dialysis has been successfully used in animal and human renal failure.[15] In addition to its role in salt and water absorption, potassium excretion, and feces propulsion, the colon plays a vital role in protein and energy metabolism in close synergy with the resident colonic microbiome. The gut microbiome has been shown to play a pivotal role in the metabolic derangements seen in patients with CKD.[16]

Chronic Kidney Disease, End-Stage Renal Disease, and Cardiovascular Mortality

Although it is often perceived that standard dialysis treatment has been mostly unchanged for years, the outcomes in patients with ESRD have steadily improved. Even with this improvement, the five-year hemodialysis (HD) survival rate across different nations ranges from 39% in the United States to 60% in Japan.[17] The percentage of deaths in patients undergoing dialysis that can be attributed to cardiac arrest approaches 40%. The rate of sudden cardiac death is nearly 20-fold higher in the dialysis population than in the general population. In patients undergoing dialysis, longer interdialytic interval, coexisting electrolyte abnormalities, mainly hyperkalemia, and massive fluctuation of volume status between dialysis days are all associated risk factors, resulting in higher cardiovascular mortality. Atrial fibrillation may act as a precipitator of heart failure and other dysrhythmias.[18] Patients with CKD and ESRD have a higher incidence of atrial fibrillation and stroke, requiring treatment with Coumadin or one of the newer direct thrombin inhibitors. These patients, on the other hand, also have higher bleeding risk from anticoagulation, requiring careful evaluation of the risk–benefit ratio.

The natural history, progression, and outcomes of associated complications of chronic kidney disease are outlined in Table 16-6.

Renal Replacement Therapy in End-Stage Renal Disease

The human kidney is responsible for the composition of plasma. In addition to its excretory and synthetic functions (production of erythropoietin, activation of vitamin D, and others), the kidney's role as a regulator of immune function is also being recognized. There are well-established communication networks between the heart, brain, liver, gut, endocrine

Table 16-6 Natural history, progression, and outcomes of associated complications of chronic kidney disease.

CKD- and ESRD-Related Complications	Natural History and Progression	Treatments and Outcome
Salt and water retention and HTN	• Progressively worsens HTN and results in concentric left ventricular hypertrophy • Contributes to higher incidences of atrial fibrillation and diastolic heart failure • With the progression of CKD, adherence to a low salt diet is pivotal in maintaining acceptable volume status	• Systolic BP <120 mm Hg can be a target in patients with a high degree of protein loss in urine[19] • Loop diuretics are frequently required to control BP in patients with volume overload and edema; they have no effect on cardiovascular system outcomes
Anemia of CKD and ESRD[20]	• EPO deficiency from progressive CKD • Iron deficiency frequently coexists and can make EPO response suboptimal • Normalization of hemoglobin with supplemental EPO does not improve disease progression and mortality	• Optimal dose of EPO or IV iron not established • Oral iron poorly absorbed in advanced CKD and ESRD • Outcome limited to symptom improvement
CKD-mineral bone disease[21]	• Spectrum includes biochemical abnormalities, renal osteodystrophy, and soft tissue calcifications • Secondary and tertiary hyperparathyroidism ensues if phosphorous control remains suboptimal	• High blood phosphate levels, deficiency in vitamin D, and secondary hyperparathyroidism should be monitored and treated with phosphate binders, nutritional vitamin D, and analogs of 1,25-dihydroxyvitamin D
Metabolic acidosis and electrolyte abnormalities[22]	• In the early stages of CKD, there is a positive acid balance without low plasma bicarbonate due to buffering and renal adaptation • In later stages of CKD and ESRD, chronic metabolic acidosis contributes to skeletal muscle catabolism, insensitivity to endocrine hormones, and bone disease • In advanced stages of CKD and ESRD, hyperkalemia becomes progressively worse	• Alkali therapy with sodium bicarbonate may be required to correct acidosis • Stopping of angiotensin-converting enzyme inhibitors and gut binding of potassium may be required • Intractable metabolic acidosis and hyperkalemia frequently require initiation of dialysis

BP, blood pressure; CKD, chronic kidney disease; EPO, erythropoietin; ESRD, end-stage renal disease; HTN, hypertension; IV, intravenous.

system, and kidneys. With the progression of kidney disease, eventually renal replacement therapy (RRT) may be required. RRT does barely replenish 10%–15% of normal renal function. There are no uniform criteria based on the percentage of kidney function loss that absolutely necessitates the onset of dialysis therapy. Need for dialysis is frequently based on advanced uremic symptoms such as nausea, vomiting, metallic taste, loss of appetite or failure to thrive, intractable volume overload or metabolic acidosis, and life-threatening electrolyte abnormalities such as hyperkalemia.[23] Occasionally, anemia that fails to respond to a maximum allowable dose of erythropoietin (EPO) or uremic bleeding diathesis may require initiation of RRT. Uremic encephalopathy, uremic pericarditis, and pericardial effusion are also acceptable indications to start RRT. RRT includes hemodialysis (HD), peritoneal dialysis (PD), and kidney transplantation (KT). For eligible patients, KT remains the best and most cost-effective form of RRT. Unfortunately, over the last few decades the number of patients waiting for KT has steadily increased, but the number of cadaveric and live kidney donations has lagged behind, making transplant waitlist time progressively longer for all waitlisted patients. Human artificial kidney transplantation and xenotransplantation remain exciting future innovations, but are still far from day-to-day clinical application. While these advances are very promising, existing patients have to make a choice between various forms of dialysis therapy while waiting on a transplant list, or pursue symptoms-guided conservative medical therapy. In elderly patients with significant medical comorbidities and frailty, dialysis seldom adds to a meaningful quality of life. Conservative medical therapy and hospice therapy are the most underdiscussed options of RRT. Home-based dialysis therapy, mainly PD and home HD, remains a very attractive option for working and self-caring patients. Despite these facts, acceptance of home therapy is lower in the United States compared to other industrialized countries.

In-center HD sessions comprise 3–4-hour dialysis treatment, three times a week. Almost 80% of all dialysis patients in the United States undergo in-center hemodialysis as opposed to home-based therapies like peritoneal dialysis or home hemodialysis. Patients undergoing in-center HD frequently describe a feeling of being "wiped out," and almost

40% of patients will take 2–6 hours post dialysis to recover to their usual state of health.[24] Many of these patients have never been offered a formal CKD education program that helps them make an informed decision about dialysis modality choice. For-profit dialysis providers and greater comorbidities of in-center patients undergoing dialysis result in the lowest KT rate in in-center HD patients as opposed to other dialysis modalities.[25] Compared to in-center dialysis, frequent home hemodialysis (HHD) therapy results in fewer episodes of low BP, intradialytic hypotension, and better control of salt and water balance, with fewer BP medications. Advances in HHD and the ability to remotely monitor HHD sessions have reassured many patients, and there appears to be a steady and slow uptake of the HHD modality among patients with ESRD. PD is easy to learn and does not involve contact with blood or self-cannulation of vascular access, and hence remains the most acceptable form of home-based RRT. In the PD modality, dialysis is performed repeatedly via a PD catheter using the osmotic force of sugar water solution. Here, the peritoneal membrane acts as a filter and performs the removal of uremic toxins. PD can be performed with the help of a cycler at night, giving some patients the ability and freedom to control their time during the day when they do not need to perform PD exchanges. PD patients preserve their residual renal function for a longer period of time compared to HD. Regulatory authorities have identified home-based therapy as a preferred dialysis therapy and are putting in place financial and educational incentives to promote better uptake of home-based dialysis therapy.

ORAL CONDITIONS IN PATIENTS WITH RENAL DISEASE

Patients with CKD, those undergoing in-center HD and PD, and those receiving KT can be commonly seen and managed by various oral care professionals. These medical conditions are associated with a broad range of clinical manifestations and lesions affecting soft and hard tissues of the oral and maxillofacial area.[26] These oral conditions can be directly associated with renal impairment or indirectly associated either with medications used in the treatment of renal conditions or various systemic comorbidities.[5] We have categorized all oral clinical conditions into symptoms (subjective abnormalities perceived by a patient) and signs (objective abnormalities observed by a patient and examiner); see Table 16-7.

Table 16-7 Oral symptoms and signs in patients with renal disease.

Oral Symptoms	Oral Signs
• Xerostomia • Altered taste perception • Halitosis • Other oral manifestations	A. Soft tissue lesions 01 Oral mucosa lesions • Uremic stomatitis • Purpura • Fungal infections • Oral mucosal ulcers • Oral malignancies • Other oral mucosa conditions 02 Tongue conditions • Saburral tongue • Dialysis-related amyloidosis • Oral hairy leukoplakia • Other tongue conditions 03 Periodontal conditions • Medication-induced gingival enlargements • Periodontitis • Other periodontal conditions B. Hard tissue lesions 01 Tooth conditions • Dental caries • Edentulism • Tooth periapical lesions • Other tooth conditions 02 Bone conditions • Renal osteodystrophy • Primary hyperoxaluria • Other bone conditions

Oral Symptoms

Epidemiology

Up to 69% of patients with CKD,[27,28] 68% of patients undergoing in-center HD,[29] and 6% of patients received KT[28] displayed oral manifestations, compared to up to 10% in control individuals without renal disease.[30] The data on the prevalence of oral manifestations in patients undergoing PD are missing. These results demonstrate that patients with CKD and those undergoing HD have an increased prevalence of oral manifestations, whereas patients who received KT may have reduced or comparable prevalence compared to control individuals without renal disease.

Xerostomia (ICD-10-CM Diagnosis Code K11.7)

This is a sensation of dry mouth with (objective) or without (subjective) a noticeable decrease in saliva production (Figure 16-5).[31]

- *Patients with CKD (prior to undergoing in-center HD).* Smaller-scale studies on patients with CKD prior to undergoing in-center HD have shown that ~28%–69% of them presented with signs of xerostomia,[27,28] which positively correlated with the increased age and stage of CKD.[32]
- *Patients undergoing in-center HD.* The large-scale prospective multinational ORAL Diseases in Hemodialysis study has

Figure 16-5 Xerostomia (ICD-10-CM Diagnosis Code K11.7).

shown that 45% of dentate patients undergoing in-center HD presented with signs of xerostomia.[33] These findings also correlated with those in smaller-scale studies reporting the prevalence of xerostomia to range from 33% to 56%, compared to 0%–29% in control individuals without renal disease.[29,34–36] However, compared to predialysis levels, the salivary flow rate (SFR) increased after the initiation of HD[37] and PD.[30] No studies reporting the prevalence of oral symptoms in patients undergoing PD have been identified.

- *Patients receiving KT*. In these patients, the SFR improved compared to patients with CKD and those undergoing in-center HD, but was still significantly lower compared to control individuals without renal disease.[38–40] A recent study has shown that the prevalence of xerostomia in KT patients was 35% 24 hours before the transplantation, and significantly decreased to 10.7% and 8.2% 15–20 and 45–60 days after the procedure, respectively.[41]

Etiology and Pathogenesis

- *Xerostomia-inducing medications*. Over 500 medications, including anticholinergic drugs, antihistamines, antihypertensive drugs, tranquilizers, and skeletal muscle relaxants, can affect SFR and induce xerostomia.[31,42–46]
- *Decreased fluid intake and polyuria*. Many patients with renal disease are elderly and naturally tend to drink less fluid. Combined with the reduced ability of the kidneys to reabsorb sodium and subsequent polyuria,[28] this reduced intake of fluids can contribute to fluid loss and xerostomia.[42]
- *Stress and depression*. Both stress and depression can reduce salivary gland activity in patients with CKD and those undergoing in-center HD.[47,48]
- *Subjective xerostomia*. A study that involved patients undergoing in-center HD has shown that signs of xerostomia were reported by 68% of patients with decreased SFR and by 59% of those with normal SFR.[35]
- *Other mechanisms contributing to xerostomia/reduced SFR*. Several other factors, including changes in salivary chemical composition,[49] fibrosis and atrophy of minor salivary glands,[35] and damage to salivary gland cells,[50] have been proposed to contribute to xerostomia/reduced SFR. However, the large difference in the amounts of unstimulated and stimulated saliva (~3.4–3.6 times) suggests that the renal disease did not damage the structure of the salivary glands, but rather affected their functional activity.[51]

Significance

- *Functional impairment*. Significantly more patients undergoing in-center HD and displaying a reduced SFR experienced speech difficulty compared to control individuals without renal disease (22% vs. 15%).[28,31,34,52] In patients undergoing in-center HD, xerostomia was significantly associated with difficulty in chewing (odds ratio [OR] 2.7; 95% confidence interval [CI] 1.7–4.3; $P < .001$) and swallowing (OR 2.3; 95% CI 1.5–3.4; $P < .001$) and consequent avoidance of food intake (32% vs. 18% in nonxerostomic controls; OR 2.1; 95% CI 1.4–3.2; $P < .001$).[53]
- *Intraoral lesions*. Xerostomia is associated with glossitis, fissured lips, and candidiasis.[54]
- *Systemic concerns*. Xerostomia is significantly associated with hypertension (OR 5.24; 95% CI 1.11–24.89; $P = .03$);[46] however, a wide confidence interval in this study should be noted.

Altered Taste Perception (ICD-10-CM Diagnosis Codes R43.8 and R43.9)

These conditions can be categorized into dysgeusia (altered taste perception), hypogeusia (reduced taste perception), and ageusia (absent taste perception).[55]

- *Patients with CKD (prior to undergoing in-center HD)*. There seems to be a significantly higher prevalence of dysgeusia among patients prior to dialysis compared with individuals without renal disease.[56] A questionnaire study of patients with CKD suggested that 31% of them perceived a metallic taste (vs. 0% in the control group without renal disease) and 53% of them felt a taste alteration (vs. 9% in the control group without CKD). These findings did not correlate with the disease duration, but were primarily encountered in elderly patients (88% of all cases).[57]
- *Patients undergoing in-center HD*. A large-scale study has shown that 13.4% of patients undergoing in-center HD had signs of dysgeusia,[33] whereas smaller-scale studies reported its prevalence to be 28%.[28] No studies reporting the prevalence of oral lesions in patients undergoing PD have been identified.
- *Patients receiving KT*. The prevalence of patients with KT and who experienced a metallic taste was lower compared to that in patients undergoing in-center HD (6% vs. 28%), but higher than in control individuals without renal disease (0%).[28]

Etiology and pathogenesis

The proposed mechanisms include changes in salivary flow, pH, and chemical composition,[58] thick tongue coating,[36] and genetic ability to taste thiourea at low thresholds.[59]

Significance

Taste alterations in patients with renal disease can lead to impaired quality of life.

Halitosis (ICD-10-CM Diagnosis Code R19.6)

Halitosis is a perceived malodor with an intensity beyond a socially acceptable level.[60] Six types of halitosis can be distinguished, depending on the mechanisms and origin of its development (physiologic, oral, airway, gastroesophageal, blood-borne, and subjective halitosis).[60] In patients undergoing in-center HD, halitosis was one of the most common observations, with a prevalence of 30%–49% (vs. 0% in controls with normal renal function).[30,36,61] No studies examining the prevalence of halitosis in patients with CKD (prior to undergoing in-center HD), those undergoing PD, and those receiving KT have been identified.

Etiology and pathogenesis

- *Breakdown of organic compounds*. In general, halitosis is attributed to the presence of various volatile organic compounds present in saliva and tongue coating, including volatile sulfur compounds (VSCs).[62,63] These products are enzymatically generated by intraoral bacteria, including periodontal pathogens (*Porphyromonas gingivalis*, *Treponema denticola*, *Tannerella forsythia*, and *Prevotella intermedia*),[62,64,65] and a positive association between poor periodontal health and the levels of VSCs has been demonstrated.[66]
- *Reduced rinsing property of saliva*. In patients with CKD who exhibit a reduced SFR, halitosis could be associated with the accumulated biofilm, bacteria, and desquamative epithelial cells from the tongue. However, no scientific evidence supporting this hypothesis has been shown.
- *Other reasons*. Up to 42% of the general population have signs of subjective halitosis,[67,68] which is a psychologic sensation, but not the objective presence, of halitosis.[62] Since the presence of halitosis in several studies was determined using a questionnaire, its prevalence could be overestimated. Therefore, a series of questions for more objective differentiation between objective and subjective types of halitosis has been developed.[60]

Significance

Halitosis in patients with renal conditions can lead to impaired quality of life.

Other Oral Manifestations

Patients with CKD, especially those exhibiting oral candidiasis and anemia,[69] could also display glossodynia, a chronic debilitating oral condition characterized by the presence of a burning sensation of the oral mucosa,[29,70–72] tongue,[30] and gingiva.[73]

Oral Signs

(A) Soft Tissue Lesions: (1) Oral Mucosa Lesions

Epidemiology

- *Patients with CKD (prior to undergoing in-center HD)*. Sex- and age-adjusted regression analysis has shown that predialysis patients with CKD had a significantly higher likelihood of developing clinically observable oral symptoms compared to controls with normal renal function (OR 153.3; 95% CI 40.1–584.8; $P < .001$)[74]; however, an extremely wide CI makes the interpretation of these results challenging. These patients were also reported to have a significantly higher prevalence of oral manifestations compared to control individuals without renal disease (66% vs. 37%; OR 3.3; 95% CI 1.9–5.6; $P < .001$).[30]
- *Patients undergoing in-center HD*. Smaller-scale studies have shown that the prevalence of oral lesions in patients undergoing in-center HD varied substantially, ranging from 9% to 94%.[28,39,75] A large-scale study has shown that the overall prevalence of oral lesions was 40%,[76] with HD duration (<12 or >12 months) not affecting their prevalence.[28] These patients also had a statistically higher risk of the development of various combinations of oral lesions with oral manifestations, with ORs ranging from 2.6 to 14.0.[30] No studies reporting the prevalence of oral lesions in patients undergoing PD have been identified.
- *Patients receiving KT*. These patients had a higher prevalence of oral lesions compared to control individuals without renal disease (32%–96 vs. 57%)[28,39,77–79] and patients undergoing in-center HD (32% vs. 9%).[39] A recent study has also shown that 24 hours prior to KT, oral lesions were observed in 3.7% of patients, and their prevalence increased substantially, reaching 23.7% and 25.7% 15–20 and 45–60 days after KT, respectively.[41] Their prevalence was not related to post-transplant period duration[28] or patient age.[41]

Uremic Stomatitis (ICD-10-CM Diagnosis Code K12.1)

Inflammation of the oral mucosa (stomatitis) is associated with impaired renal function and urea accumulation. Due to a slow rate of disease progression over a period of years, its incidence is estimated as low, but this has not been confirmed in epidemiologic studies. There are four variants of uremic stomatitis:[80,81]

- *Ulcerative stomatitis* is the most common presentation, characterized by extremely painful ulcerations on the tongue, cheeks, lips, and palate with indefinite margins, often covered by a thick, adherent, yellowish covering on the tongue. Other symptoms include xerostomia, metallic taste, mouth burning sensation, erythematous lingual and palatal mucosa, and fissuring and bleeding at the corner of

the mouth. Tissue biopsy is needed to perform differential diagnosis with vesiculobullous diseases.[81]

- *Erythematosus membranous stomatitis* is characterized by the formation of gray pseudomembranes that consist of a thick, sticky exudate on the erythematous mucosa and overlay painful erythema patches.
- *Hemorrhagic stomatitis* is characterized by the presence of bleeding of the gingival or oral mucosa. In combination with immune deficiency, bacterial infection can cause extremely painful ulcerations and pseudomembranes, often on the ventral surface of the tongue.
- *Hyperparakeratotic stomatitis* occurs rarely and is characterized by hyperkeratosis, sometimes in combination with ulcerations.[82]

Etiology and Pathogenesis

The precise mechanisms of the development and progression of uremic stomatitis remain unclear; however, it has long been associated with higher levels of caustic salivary ammonia, causing a slowly developing "chemical burn."[83] Indirect evidence of the association between salivary urea and stomatitis can be observed in patients with acute necrotic pseudomembranous gingivostomatitis, which develops within a short period of time as a response to rapidly elevated BUN levels.[84] Predisposing factors could be local bleeding, infectious environment, and compromised immune condition.[85] In addition, patients with ESRD may present with white patches intraorally (tongue, mucosa of the floor of the mouth),[86,87] as well as on the skin of the face and lips.[88] These patches represent crystals of urea deposited after the evaporation of saliva or sweat and occur when the blood urea concentration >200 mg/dL.[89] However, direct evidence of the adverse effects of ammonia, causing the "chemical burn" of the oral mucosa, and the role of uremic patches in this process have not been demonstrated.

Significance

Due to painful intraoral lesions, patients with ulcerative stomatitis may have a loss of appetite, dehydration, and weight loss. They can also develop generalized gastrointestinal changes, suggesting that the oral manifestations are local manifestations of generalized mucosal breakdown.[84] Hemorrhagic stomatitis can impair the intactness of the oral mucosa of these patients and contribute to bacterial infection.

Purpura (ICD-10-CM Diagnosis Code D69)

This is the development of extravascular red- or purple-colored spots on the oral mucosa. Depending on the size of the spots, purpura can be classified into petechiae (pinpoint size) and ecchymoses (larger than pinpoint size).[90]

- *Patients with CKD (prior to undergoing in-center HD).* These patients had a significantly higher prevalence of mucosal petechiae compared to control individuals without renal disease (15.1% vs. 0.8%; OR 23.0; 95% CI 3–178; $P < .001$);[30] however a very wide confidence interval should be noted.
- *Patients undergoing in-center HD.* A large-scale study has shown that the prevalence of petechiae in these patients was 7.9%,[76] and a smaller-scale study reported the prevalence of petechiae and/or ecchymoses to be 12%.[36] No studies reporting the prevalence of purpura in patients undergoing PD have been identified.
- *Patients receiving KT.* No studies have been identified.

Etiology and Pathogenesis

The proposed mechanisms include trauma (e.g., physical impact, biting) and platelet dysfunction.[90]

Significance

The purpura might be suggestive of platelet dysfunction or the use of anticoagulants, which are commonly encountered in patients undergoing in-center HD and will be discussed in the Dental Considerations and Multidisciplinary Management section of this chapter.

Fungal Infections (ICD-10-CM Diagnosis Codes B37.0 and B37.9)

These are opportunistic conditions, which can be signs of systemic conditions, side effects of medications (antibiotics, steroids), and local factors (poorly maintained dental dentures, the use of steroid inhalers, and reduced SFR).[91]

- *Patients with CKD (prior to undergoing in-center HD).* A single study reported that significantly more of these patients had oral yeast infections compared to control individuals without renal disease (32% vs. 11%).[92]
- *Patients undergoing in-center HD.* A large-scale study has shown that the prevalence of oral candidiasis in these patients was 4.6%.[76] Smaller-scale studies have shown that the prevalence of yeast infection was markedly higher in these patients compared to control individuals without renal disease (40%–54% vs. 18%–31%),[93–96], especially in those >45 years of age,[97] and with a majority of yeast lesions (23.3%) being chronic erythematous candidiasis.[93] Dorsal tongue coating with yeasts was a common finding in HD patients (78%), with *Candida albicans* and *C. parapsilosis* being the most common yeast species.[75] In PD patients, the prevalence of yeast infections was slightly higher compared to control individuals without renal disease (21% vs. 18%).[96]
- *Patients receiving KT.* These patients have a significantly higher risk (adjusted OR 3.49; 95% CI 1.27–9.18; $P < .05$)[98] and prevalence of yeast infections compared to control individuals without renal disease (10%–32% vs. 0%–2.5%).[41,77,99,100] Erythematous candidiasis was the most prevalent form of yeast

infection (3.8%–13.3%)[77,99] and *C. albicans* was the most common yeast (61.9%). A case of *Histoplasma capsulatum*–associated histoplasmosis in a long-term immunosuppressed patient with KT and a history of maxillary tooth extractions and development of oro-antral communication with maxillary sinus has also been described.[101]

Etiology and Pathogenesis

- *Dental prostheses*. Oral candidiasis in patients undergoing in-center HD was significantly associated with wearing a dental prosthesis (OR 4.5; 95% CI 1.6–12.7; $P = .004$).[94,96] No association between the signs of yeast infection and the number of missing teeth, smoking status, HD duration, KT duration, and antibiotic use was observed.[96]
- *Xerostomia*. In patients with ESRD and those undergoing in-center HD, the prevalence of oral fungal infections was significantly higher when xerostomia was self-reported compared to nonxerostomic patients.[92]
- *Systemic factors*. Aging, endocrine disorders, and broad-spectrum antibiotic therapy have been associated with yeast infection.[102] A recent study has also demonstrated the significant positive correlation between oral candidiasis and the immunosuppressant drug azathioprine.[41]

Significance

- *Oral cavity*. Yeast infections can be associated with denture stomatitis[103] and glossodynia.[104] Although older studies have suggested the association between oral yeast infections and mouth burning, the recent evidence did not establish this association.[105]
- *Systemic health*. While oral candidiasis did not seem to be associated with all-cause mortality (adjusted hazard ratio [HR] 1.37; 95% CI 1.0–1.86), it was significantly associated with cardiovascular mortality (adjusted HR 1.64; 95% CI 1.09–2.46) after adjusting for several critical cofounders.[76] Similarly, the increased prevalence of oral candidiasis (OR 3.1; 95% CI 1.0–9.4; $P = .04$) and wearing dental prostheses (OR 4.1; 95% CI 1.2–13.9; $P = .03$) were associated with a higher risk for advanced coronary artery disease.[94] In both these studies, low lower limits of the CIs should be noted.

Oral Mucosal Ulcers (ICD-10-CM Diagnosis Codes K12 and K13.7)

These are painful lesions in the oral cavity, which can be chronic or acute depending on the underlying mechanisms of their development.[106] In patients undergoing in-center HD, the prevalence of intraoral mucosal ulcers was 1.2%–1.7%.[36,76] However, no studies reporting the prevalence of intraoral ulcers in patients with CKD (prior to undergoing in-center HD) and those receiving KT have been identified.

Etiology and Pathogenesis

Oral ulcers can be a sign of ulcerative uremic stomatitis (see the earlier section on Uremic Stomatitis).

- *Other renal conditions*. Oral ulcers can be associated with the development of lupus nephritis in patients with systemic lupus erythematosus (SLE) affecting kidney functions (rapidly developing glomerulonephritis) and predict their activity.[107,108] Also, oral ulcers can often be presented in patients with Behçet disease[109] associated with rapidly progressive glomerulonephritis.[108]
- *Cytomegalovirus (CMV) treatment*. Oral ulcers can develop secondary to CMV treatment, such as the use of everolimus.[41,73] The presence of ulcers on the oral mucosa, hard and soft palate, and tongue were observed in KT patients who developed CMV infection within the first three years after transplantation.[110]
- *Medications*. Limited evidence suggests that in patients with KT, oral ulcers could be associated with immunosuppressant medications, such as sirolimus or mycophenolate mofetil.[111,112]

Significance

Painful oral ulcers can result in discomfort during meal intake, leading to malnutrition.

Oral Malignancies

The prevalence of intraoral neoplasms in patients undergoing in-center HD was 2%,[76] whereas it was up to 5% in those receiving KT.[78,113] The development of spindle cell carcinoma in the lower lip[78] and squamous cell carcinoma of the tongue after KT[114] have also been described. However, no studies examining the prevalence of intraoral malignancies in patients with CKD (prior to undergoing in-center dialysis) have been identified.

Etiology and Pathogenesis

Longstanding postallograft immunosuppression may predispose patients receiving KT to human herpesvirus 8 (HHV-8) and associated Kaposi's sarcoma.[115,116] Shedding of HHV-8 into the oral cavity was observed after the transplantation of a seropositive HHV-8 kidney.[117] Therefore, intraoral malignancies are likely to be associated with the immunocompromised conditions of these patients.[118–120] During the past two decades, the use of various antiviral medications has reduced the incidence of viral infections substantially.[119,121–124] However, studies examining the association between the reduced viral load and the prevalence of intraoral malignancies in patients with CKD and those on in-center HD are missing.

Other Oral Mucosa Conditions

Patients undergoing in-center HD and those receiving KT might also present with rare cases of other oral mucosa lesions, such as pyogenic granuloma.[28,99] In addition, various

types of viruses, including intraoral herpes simplex (0.5%–7.8% of cases),[33,41,76–78,125] Epstein–Barr virus, cytomegalovirus, and varicella zoster virus, were observed in patients prior to and those undergoing in-center HD, especially in patients with severe periodontal destruction.[126] Studies have shown that patients with CKD might also display a higher prevalence of pale oral mucosa compared to control individuals without renal disease (40% vs. 12%).[30] This could likely be due to the impaired absorption of dietary iron and functional iron deficiency,[127,128] impaired EPO synthesis,[30] and malnutrition.[127,129] A recent large cohort study has shown that anemic conditions positively correlated with the stage of CKD (44%, 64%, and 73% for stages 3, 4, and 5, respectively).[130] Cases of fibroma in patients undergoing in-center HD can also be encountered (Figure 16-6).

(2) Tongue Conditions

Saburral (Coated) Tongue (ICD-10-CM Diagnosis Code K14.9)

This is a yellowish-white, thrush-like coating on the back of the tongue, representing large amounts of normal desquamated epithelial cells and bacterial colonies (more commonly *Staphylococci*), without the presence of yeasts[131] and coexisting with elongated (<3 mm) filiform papillae.[77] Its development is commonly associated with poor oral hygiene;[132] however, the precise mechanisms are still unclear. Initially, these lesions were described in patients during episodes of acute rejection following KT and after treatment with high doses of steroids,[131] but later studies have described their development in other patients with CKD as well.

- *Patients with CKD (prior to undergoing in-center HD).* A series of studies have shown that these patients had a significantly higher prevalence (12%–37% vs. 3%)[28,30,36] and risk for saburral tongue compared to control individuals without renal disease (OR 7.0; 95% CI 2.3–21.4; $P < 0.001$);[30] however, a wide confidence interval makes the interpretation of these results challenging.
- *Patients undergoing in-center HD.* No studies have been identified.
- *Patients receiving KT.* Studies have shown that 22%–42% of patients with KT developed saburral tongue, especially within the first year after the transplantation.[28,77]

Figure 16-6 Other oral mucosa conditions.

Etiology and Pathogenesis

The precise mechanisms of the development of saburral tongue in patients with renal disease are unclear. Patients with renal disease prior to in-center HD (especially those >50 years) displayed a thick tongue coating, which, however, had no significant association with changes in blood levels of urea, creatinine, and albumin.[133] It is likely that similar to individuals without renal disease,[132] the development of saburral tongue in patients with renal disease is associated with poor oral hygiene. However, systemic disturbances, especially those resulting from immunosuppressive medications, should also be considered.

Significance

Patients with saburral tongue may have a compromised taste perception and a risk for biting the tongue due to its enlargement.

Dialysis-Related Amyloidosis (ICD-10-CM Diagnosis Code E85.4)

This is a rare and late complication of long-term HD,[134,135] characterized by multiple soft, painful, whitish-to-yellow nodules of various sizes >1 mm and with a cobblestone appearance on the dorsum and lateral borders of the tongue, causing macroglossia.[136] However, cases of HD-related amyloidosis with asymptomatic nodules have also been described.[134,137] The nodules gradually enlarge over time, consistent with HD-related amyloidosis,[137–139] which is not degraded in patients undergoing in-center HD and cannot pass through a dialysis membrane.[140] Depending on the intraoral location and extent, two types are described, lateral and diffuse, with no differences in the HD duration between them.[135]

- *Patients with CKD (prior to undergoing in-center HD).* An older large-scale study that included 236 patients with CKD (prior to undergoing in-center HD) with systemic amyloidosis showed that macroglossia was the most common intraoral sign, observed in 17% of these patients.[141] A recent case report study described a case of lingual amyloidosis in an 82-year-old patient with CKD (prior to undergoing in-center HD).[142]
- *Patients undergoing in-center HD.* Older studies have reported that some patients undergoing in-center HD

have a sensation of an enlarged tongue associated with amyloidosis.[36,143,144] In patients undergoing long-term (>10 years) in-center HD, the prevalence of tongue amyloidosis was 1.7% compared to 0% in control individuals without renal disease.[135] Rare cases of amyloid-associated macroglossia in the HD patient with Fabry disease (inherited lysosomal storage disease due to α-galactosidase A deficiency)[145] and combined β_2-microglobulin and light chain deposits in a patient undergoing long-term (18 years) HD have recently been reported.[146]

- *Patients receiving KT*. A recent study has reported that 28% of patients with KT had macroglossia compared to 22% of patients undergoing in-center HD; however, it is unknown whether or not this was associated with amyloidosis.[147]

Etiology and Pathogenesis

In patients undergoing in-center HD, polyphosphate released from the activated platelets can induce precipitation of β_2-microglobulin, leading to the formation of amyloid.[148]

Significance

Dialysis-related amyloidosis can lead to significant speech, taste, and swallowing difficulty.[135,139,142,145] Macroglossia can be the first sign of amyloid-associated renal dysfunction.[149] Studies also suggest that the presence of macroglossia and progressive renal failure may be indicative of systemic amyloidosis with multiple myeloma.[149]

Oral Hairy Leukoplakia (ICD-10-CM Diagnosis Code K13.3)

This is a painless white patch with an irregular surface and prominent folds and projections, which cannot be scraped off. It can be unilateral or bilateral and typically involves the lateral and dorsolateral tongue.[99]

- *Patients with CKD (prior to undergoing in-center HD)*. No studies have been identified.
- *Patients undergoing in-center HD*. No studies have been identified.
- *Patients receiving KT*. In these patients, oral hairy leukoplakia (OHL) was the second most common oral lesion, with a prevalence of 6.8%–12.2% compared to a lack of cases in control individuals without renal disease.[77,99,150]

Etiology and Pathogenesis

OHL is probably caused by drug-induced reactivation of the Epstein–Barr virus (EBV) in the basal layers of the oral epithelium.[82] It is often observed in patients undergoing cyclosporine A (CsA) therapy, including patients receiving KT.[99] A single OHL case on the lateral borders of the tongue in a patient with KT was associated with EBV.[151]

Significance

In some cases, OHL can be mimicked by uremic stomatitis with white tongue coating,[82] and therefore can represent a diagnostic challenge.

Other Tongue Conditions

In patients undergoing in-center HD, the prevalence of fissured tongue and geographic tongue was 10.7% and 4.9%, respectively.[76] Patients receiving KT also presented with various tongue conditions (fissured tongue, geographic tongue, and black hairy tongue[28,99]); however, their prevalence has not been reported, except geographic tongue (11.1% vs. 5.6% compared to patients undergoing in-center HD).[147]

(3) Periodontal Conditions

Medication-Induced Gingival Enlargements (ICD-10-CM Diagnosis Code K06)

This is a subcategory of gingival diseases associated with medications that can induce overgrowth of gingival tissues.[152] Clinically, medication-induced gingival enlargement (MIGE) is characterized by enlarged gingiva with an irregular gingival margin, shorter clinical crowns, and periodontal pseudopockets (pockets with an increased probing depth [PPD] but without clinical attachment loss [CAL]).

- *Patients with CKD (prior to undergoing in-center HD)*. No studies have been identified.
- *Patients undergoing in-center HD*. A recent study has shown that MIGE was observed in 17% of these patients.[153] Another study has demonstrated that in these patients, MIGE was observed only after the failure of KT and not prior to the KT procedure.[154]
- *Patients receiving KT*. The prevalence of MIGE in these patients ranged from 22% to 67.5%, thus making it their most common oral lesion, typically in the area of anterior teeth.[77,78,99,125,153,155,156] The prevalence of gingival overgrowth is approximately similar between patients taking calcium-channel blockers (e.g., nifedipine, amlodipine, felodipine; up to 34% of patients)[157] and those receiving immunosuppressants (e.g., CsA, tacrolimus; up to 33% of patients).[158] Some studies have reported that the intake of more than one medication has a cumulative effect;[29,78] however, other studies could not establish that correlation.[99]

Etiology and Pathogenesis

In patients undergoing in-center HD, MIGE was related to calcium-channel blockers (e.g., amlodipine, nifedipine, verapamil) used as antihypertensive medications.[154] In patients receiving KT, MIGE was associated with immunosuppressive therapy aimed to prevent allograft rejection following KT (e.g., using CsA, tacrolimus, azathioprine,

cyclophosphamide, prednisone).[154] Among patients who received KT, 55% took mycophenolate, 42% took glucocorticoids, 36% took CsA, and 34% took tacrolimus,[159] thus predisposing a large cohort of them to MIGE. The severity and extent of gingival overgrowth in these patients were positively associated with the dosage of CsA, but not with the duration of its intake.[160] In patients who received KT, there was a positive association of CsA-induced MIGE with IL-1α polymorphism[161] and red complex microbiota.[162]

There are controversies surrounding the role of dental biofilm in MIGE. Some studies showed that the higher prevalence of gingival overgrowth significantly correlated with poor oral hygiene,[77,163] whereas others observed gingival overgrowth even in the presence of meticulous oral hygiene.[164] A double-blinded randomized control study showed that 67.5% of CsA-treated patients receiving KT developed MIGE, and a 7-day course with metronidazole or azithromycin had no significant effects on gingival overgrowth,[155] suggesting that overgrowth was primarily due to medications and not bacterial colonization of periodontal pockets.

Significance

MIGE conditions can impair the quality of a patient's life by affecting their functional and esthetic demands.

Periodontitis (ICD-10-CM Diagnosis Code K05—Multiple Codes)

This is a polymicrobial multifactorial inflammatory disease of tooth-supporting tissues (periodontium)[165] and is one of the most common human infectious diseases, estimated at 42% in dentate US adults.[166]

- *Patients with CKD (prior to undergoing in-center HD).* A recent 10-year large-scale study showed that CKD was not associated with severe (interproximal CAL ≥5 mm) periodontal breakdown (adjusted OR 1.01; 95% CI 1.005–1.015).[167] Similar findings were reported in smaller-scale studies.[168] Other studies, however, have shown that patients with CKD (prior to undergoing in-center HD) had a significantly greater extent of CAL (a surrogate measure of periodontitis) and higher risk for tooth-specific progression of total (slight, moderate, and severe) CAL, compared to control individuals without renal disease (OR 1.73; 95% CI 1.15–2.60; $P < .05$).[169] A recent study has also shown that the risk of severe periodontitis was significantly associated with the advanced stages of CKD.[170]
- *Patients undergoing in-center HD.* Similar to studies on patients with CKD (prior to undergoing in-center dialysis), studies on patients undergoing in-center HD also report controversial findings on the prevalence of periodontitis. A recent study has shown that these patients had significantly greater mean CAL (1.8 mm vs. 1.2 mm), deeper mean PPD (2.3 mm vs. 1.8 mm), and prevalence of periodontitis (slight, moderate, and severe).[34] Gingival index, plaque index, and PPD (but not CAL) were positively associated with the duration of HD (especially after 10 years).[171] Other studies, however, have shown that the prevalence of periodontitis was similar between these patients and control individuals without renal disease. Periodontitis was observed in 41% of patients undergoing in-center HD; however, average PPD of 1 mm questions the validity of the periodontal exam and periodontal status of these patients;[33] in addition, the prevalence of periodontitis in this patient cohort was similar to that reported by a recent National Health and Nutrition Examination Survey (NHANES) III–based study (42%).[166] Long-term (11 years), large-scale,[172] and smaller-scale[173] studies have also shown no significant association between CKD and periodontitis.
- *Patients receiving KT.* Studies on the prevalence of periodontitis in these patients were controversial and included both a positive association[159] and the lack of it.[40]

Etiology and Pathogenesis

Poor oral hygiene. Periodontitis is developed as a result of dysbiosis of the commensal microflora (present in dental biofilm/plaque) in a susceptible host organism.[174,175] Studies have shown that significantly more patients with CKD,[92,168,176,177] those undergoing in-center HD,[178] and those receiving KT[179] had poor oral hygiene compared to control individuals without renal disease. It has been shown that only 8.2% of HD patients use dental floss, 30% had a dental appointment within the past 6 months, 66% brush teeth twice a day, 21% were edentulous, and 42% had dental prostheses.[33] Another study has shown that greater numbers of patients undergoing in-center HD[180] and those receiving KT[179] wore dentures that could alleviate plaque retention and periodontal inflammation. Discrepancies between their compromised dental conditions and oral health–related quality of life might also suggest that patients undergoing in-center HD did not realize their worse oral hygiene condition and therefore did not seek to see a dentist.[181] Finally, due to their significantly lower income, these patients might not be able to afford dental treatment to the same extent as control individuals without renal disease.[72,182,183] A recent review study has also summarized the current evidence for the kidney damage induced by oral microorganisms, primarily *Streptococci*; however, a majority of the included studies are extremely outdated.[184]

- *Increased salivary pH.* Selected periodontal pathogens such as *P. gingivalis*, *P. intermedia*, and *Fusobacterium nucleatum* show optimal growth in alkaline pH.[185] Urea

can be hydrolyzed to alkaline ammonia by oral bacteria's ureases, thus resulting in the increased pH levels.[56,186–189] Studies have shown that patients with CKD had significant and stage-dependent increases in salivary pH compared to control individuals without renal disease.[56,190] Similarly, patients undergoing in-center HD also had significantly higher salivary pH compared to control individuals without renal disease,[36,56,187] which positively correlated with the duration of HD.[191] Interestingly, patients with severe periodontitis had significantly increased salivary urea concentrations,[192] further supporting the role of urea in dysbiosis of periodontal microflora. Therefore, increased salivary pH in patients with CKD and those undergoing in-center HD can lead to conditions providing more favorable growth of periodontal pathogens.

- *Systemic effects of urea*. Uremia alters host response by several mechanisms, including functional abnormalities of neutrophils, monocytes/macrophages, and dendritic cells,[193–196] abnormal neutrophil activity,[197] impaired maturation of T-helper cells,[198] and increased oxidative stress.[199,200] Since periodontitis develops in a susceptible host environment, impaired immune responses will favor its development.

Significance

In patients with ESRD, periodontitis was associated with poorer quality of life, including physical and physiologic impairment.[201]

Other Periodontal Conditions

The limited and inconclusive evidence of the presence of gingival diseases other than MIGE (non-dental biofilm-induced gingival diseases[30,40] and necrotizing gingivitis[202]) in patients with ESRD has been reported in the literature. Recent case series studies have reported that the prevalence of biofilm-induced gingivitis was observed in 17%–61% of patients undergoing in-center HD compared to 61%–75% of those who received KT.[147,153]

(B) Hard Tissue Lesions: (1) Tooth Conditions

Dental Caries (ICD-10-CM Diagnosis Code K02—Multiple Codes)

To quantify the prevalence of dental caries and characterize it further, DMF (missing teeth, and teeth with fillings), DMFS (dental caries, missing, and filled tooth surfaces), and DMFT (dental caries, missing teeth, teeth with fillings, and tooth loss) indices/scores are commonly used (Figure 16-7.)[203]

- *Patients with CKD (prior to undergoing in-center HD)*. The impact of CKD on the prevalence of dental caries remains controversial, as studies have shown that CKD was associated with a decreased, increased, or unchanged prevalence of dental caries. A recent systematic review with a meta-analysis of 14 studies has shown no significant differences in the number of decayed (mean difference −0.18; 95% CI −1.52–1.17; $P > .05$) and filled (mean difference −0.47; 95% CI −2.84–3.78; $P > .05$) teeth or the DMFT score (mean difference −3.17; 95% CI −0.83–7.18; $P > .05$) between patients with CKD and those undergoing in-center HD compared to control individuals without renal disease; however, the large heterogeneity in the studies makes interpretation of their results challenging.[204]
- *Patients undergoing in-center HD*. Although these patients displayed significantly greater amounts of dental biofilm and calculus[173] and a prevalence of cariogenic bacteria (*Streptococcus mutans*, *Lactobacillus salivarius*, *L. fermentum*, *L. vaginalis*, *Scardovia wiggsiae*, and *Actinomyces. naeslundii*) in dental biofilm,[205] the prevalence of dental caries was similar to that in control individuals without renal disease.[173]
- *Patients receiving KT*. These patients had a higher but statistically nonsignificant prevalence of dental caries (DMFS or DMFT score) compared to control individuals without renal disease (5.3% vs. 1.4%).[40,206] However, these patients had a significantly higher DMFT score compared to patients with other organ transplants (liver and lungs).[159]

Figure 16-7 Dental caries (ICD-10-CM Diagnosis Code K02 – multiple codes).

Etiology and Pathogenesis

Caries resistance is associated with higher concentrations of ammonia due to the higher urease activity.[207,208] Increases in salivary urea resulted in elevated pH and increased amounts of dental calculus (this will be discussed in more detail in the Periodontitis section of this chapter). At the same time, this environment neutralizes the acidic environment associated with tooth demineralization and caries development.[209] In

addition, the similarities in the prevalence of dental caries in renal patients and control individuals without renal disease due to the high degree of heterogeneity of various studies implies that the differences could be masked by various other factors (e.g., differences in patient selection and their renal disease status, the presence or absence of other systemic conditions).

Significance

A two-year large multinational cohort study that included 4205 patients undergoing in-center HD has shown that complete edentulism (adjusted HR 1.29; 95% CI 1.10–1.51; $P < .001$) and DMF score ≥14 (adjusted HR 1.70; 95% CI 1.33–2.17; $P = .04$) were associated with higher all-cause mortality.[210] These observations suggest that the low prevalence of dental caries can serve as a plausible preventive determinant of clinical outcomes in these patients.

Edentulism (ICD-10-CM Code K08—Multiple Codes)

This is a loss of one or several teeth (partial edentulism) or all teeth (complete edentulism) due to various reasons, most commonly periodontitis and dental caries.

- *Patients with CKD (prior to undergoing in-center HD).* A recent systematic review with a meta-analysis showed that these patients lost significantly more teeth compared to control individuals without renal disease (mean difference 3.84; 95% CI 1.10–6.57; $P \leq .05$).[204] The increased tooth loss was significantly associated with the increased levels of cystatin C used as a surrogate estimate of decreased renal function (OR 7.70; 95% CI 1.24–47.84; $P = .03$), but not with age, CAL ≥4 mm, or body mass index (BMI);[211] however, a large CI should be noted.
- *Patients undergoing in-center HD.* A systematic review of observational studies showed that 21% of patients with CKD undergoing in-center HD were edentulous; however, no data on control individuals without renal disease were reported.[212] A smaller-scale study demonstrated that significantly more patients undergoing in-center HD were completely edentulous compared to control individuals without renal disease (13.6% vs. 2.2%), and dentate ones lost more teeth compared to control individuals without renal disease (14 vs. 10 teeth).[30]
- *Patients receiving KT.* No studies have been identified.

Etiology and Pathogenesis

Since several studies have shown that the prevalence of dental caries in patients with CKD (prior to undergoing in-center HD) and control individuals without renal disease was similar, dental biofilm–associated periodontitis is the most feasible etiology of edentulism in these patients. In addition, a severe periodontal breakdown could lead to tooth loss in rare cases of primary hyperoxaluria.

Significance

- *Masticatory dysfunction.* Tooth loss may result in compromised masticatory function of renal patients, which consequently leads to impaired quality of life. A large-scale NHANES III–based study of patients with CKD (prior to undergoing in-center HD) showed that the confounder-adjusted tooth loss was significantly associated with malnutrition in these patients.[213]
- *Esthetic concerns.* Tooth loss may result in esthetic concerns in renal patients.
- *Systemic dysfunction.* A study that involved patients with CKD (prior to undergoing in-center HD) and control individuals without renal disease (both cohorts presented with signs of carotid artery calcification) found that tooth loss was significantly more prevalent in patients with CKD. This study suggested that the combination of edentulism with calcification of the carotid artery might help in early diagnosis of renal diseases.[214] Also, a recent study showed that the association between the number of lost teeth and the incidence of death was statistically (but likely not clinically) significant (HR 0.95; 95% CI 0.92–0.98; $P = .002$);[215] which, however, could also be associated with the increased age of the participants.

Tooth Periapical Lesions (ICD-10-CM Diagnosis Code K04.90)

These are pathologic lesions associated with the apices of teeth and radiographically presented as radiolucencies. Periapical lesions can have odontogenic (periapical granulomas and radicular cysts) and, more rarely, nonodontogenic (periapical cemental osseous dysplasia) origin.

- *Patients with CKD (prior to undergoing in-center HD).* These patients had a significantly higher prevalence of apical periodontitis (OR 3.95; 95% CI 1.54–6.32; $P < .004$), but not the number of endodontically treated teeth (OR 2.54; 95% CI 0.9–5.32; $P > .05$), compared to control individuals without renal disease. The number of teeth with apical periodontitis significantly correlated with increased serum urea levels.[216]
- *Patients undergoing in-center HD.* Significantly more of these patients had periapical radiolucencies compared to patients with CKD (prior to undergoing in-center HD).[217]
- *Patients receiving KT.* A case of periapical radiolucency associated with odontogenic infection and no complications 7 years after its endodontic management was described in these patients.[218]

Etiology and Pathogenesis

A study that included patients with hypophosphatemic rickets due to the excessive loss of renal phosphate has shown that they have an increasing trend to develop endodontic infections, especially in the population >40 years.[219] Dental manifestations in patients with hypophosphatemic rickets

also include dental abscesses.[220] In patients with CKD (prior to and undergoing in-center HD), nonodontogenic periapical lesions could represent radiolucencies associated with brown tumor (see the section on Renal Osteodystrophy later in this chapter) and not odontogenic periapical lesions, especially if these teeth were vital and therefore did not require root canal therapy.[221]

Other Tooth Conditions

A large-scale study has shown that 47% and 2.7% of patients undergoing in-center HD presented with dental erosion and enamel hypoplasia, respectively.[33] A smaller-scale study has demonstrated that 3.7% of HD patients had enamel hypoplasia.[36] A recent systematic review with a meta-analysis of five studies found no significant differences in the prevalence of developmental enamel defects (mean difference 0.73; 95% CI 0.33–1.64; $P > .05$) in patients with CKD (prior to in-center HD) and those undergoing in-center HD compared to control individuals without renal disease;[204] however, the large heterogeneity in this study makes interpretation of its results challenging. These conditions were primarily associated with extrinsic factors associated with decreased SFR and various electrolyte imbalances ($P \leq .05$), including significantly decreased salivary (but not serum) Ca^{2+}, increased salivary and serum phosphorus, and markedly increased parathyroid hormone (PTH) levels ($P \leq .01$ for all comparisons).[222] Tooth hypercementosis has also been reported.[223]

Several studies have also shown that patients with CKD had an increased prevalence of pulpal stones compared to control individuals without renal disease.[224,225] A recent systematic review with a meta-analysis of seven studies has demonstrated a significant association between pulpal and kidney stones (OR 1.97; 95% CI 1.21–3.18]; $P < .05$),[226] which became even more pronounced in patients with ≥3 teeth with pulpal stones (OR 5.78; 95% CI 2.013–16.592; $P < .05$). Studies suggest that pulpal stones may predict undiagnosed kidney stones, and since kidney stones were significantly associated with the development of CKD (HR 1.46; 95% CI 1.2–1.77; $P < .05$), pulpal stones may have a diagnostic value for CKD as well.[227]

(2) Bone Conditions

Renal Osteodystrophy (ICD-10-CM Diagnosis Code N25.0)

CKD-mineral and bone disorder (CKD-MBD) is a systemic mineral and bone condition associated with CKD and presented with abnormalities in appendicular skeleton and craniofacial bones.[228] Among these conditions, a spectrum of pathologic alterations of bone morphology in patients with renal disease is classified under the term "renal osteodystrophy" (RO). Studies have shown that 70% of patients undergoing in-center HD for more than 3 years had signs of RO, evidenced by generalized calcification and bone resorption.[229] A systematic review of 205 publications has demonstrated that the average age of RO patients was 30 years, with women being affected 1.7 times more often than men[230] and with the highest prevalence in African Americans and lowest prevalence in those of Hispanic origin.[231]

Based on the rate of bone turnover and levels of circulating PTH, four types of RO can be distinguished: osteitis fibrosa (also called hyperparathyroidism bone disease, osteitis fibrosa cystica, leontiasis ossea, and von Recklinghausen's disease), osteomalacia, adynamic bone disease, and mixed disease.[232,233] In a cohort of patients with ESRD, 50% of them presented with osteitis fibrosa, 27% with adynamic bone disease, 7% with osteomalacia, and 15% with mixed disease; patients with adynamic bone disease were significantly older compared to those with osteitis fibrosa and mixed disease (56 vs. 41 vs. 39 years).[233]

Clinically, RO is characterized by painless or painful swelling masses of the jaw, causing facial deformity,[234] which is observed in the mandible (41%), maxilla (29%), and both jaws (30%).[230] This makes jaw hypertrophy the most common observation in RO, affecting up to 78% of patients.[230] Up to 62% of patients diagnosed with CKD-MBD had the severe form of RO called brown tumor;[235] in these patients, jaws were affected in 62% of cases,[236] with a higher prevalence in the mandible than maxilla (54 vs. 46%),[235] thus making them the most frequent skeletal location. Despite its name, the brown tumor does not have any neoplastic characteristics, but rather reflects the expanding masses within the jaw.[237] The higher prevalence of brown tumor in the mandible is thought to be due to circulating PTH stimulating osteoclastic activity in cortical bone, which makes brown tumor one of the earliest diagnostic signs of hyperparathyroidism.[237] Due to early diagnosis and improved therapy, the incidence of brown tumors is low;[229] however, it is three times more prevalent in women than in men and is more common in the third and fourth decades of life.[237] Other forms of RO are also rare, with the continuously decreasing prevalence due to the improved early diagnosis using biochemical parameters and the withdrawal from aluminum-containing dialysis fluids.[238]

Jaw hypertrophy can be accompanied by severe periodontitis,[239] increased tooth mobility, pathologic tooth migration, diastemas (spaces between teeth),[234] increased palatal size, and flattening of the nasal bridge due to the widening of the nares;[240] however, the gingival covering of the expansive bone mass was normal.[239] Clicking of the

temporomandibular joint associated with pain around it and surrounding tissues has also been reported.[241,242] Other clinical features may include delayed tooth eruption, hypoplastic enamel, and dental erosion.[234] Various functional changes (e.g., masticatory dysfunction, nasal obstruction, epiphora, and diplopia) have also been reported.[237,243] Whether RO-associated periodontal breakdown is related to inflammation-associated periodontitis is unclear, as the periodontal status of these patients was not described in detail. According to the 2017 classification of periodontal diseases and conditions by the American Academy of Periodontology and European Federation of Periodontology, periodontal changes secondary to hyperparathyroidism should be classified under the category of "systemic diseases or conditions affecting periodontal supporting tissues" and not under the general "periodontitis" category.[244]

Radiographic Features

Radiographic changes are among the earliest signs of RO, which become more pronounced with disease progression.[234] In the most common type of RO, osteitis fibrosa, they have a diagnostic value in 47%[231] and include the partial or complete loss of lamina dura of the tooth sockets (creating a characteristic "floating teeth" appearance[245]), loss of cortical bone in maxillary sinus walls and mandibular canal, generalized diffuse bone porosity, and widening of the periodontal ligament (PDL) space (suggesting an increased osteoclastic activity).[234,237,246–249] In contrast to control individuals without renal disease who presented with heterogeneous and dense trabecular bone, the bone pattern in patients with CKD had a "ground-glass" appearance due to a finely meshed pattern of bone resorption[237,250–253] and a "salt and pepper" pattern of the skull bones on cone-beam computed tomography (CBCT).[254–256] Well-demarcated unifocal or multifocal bony lesions can be observed in patients with brown tumor.[231,237,243] Multiple periapical lesions around the root apices (sometimes coalescent into a single multilocular radiolucent lesion) could also be seen, but contrary to periapical lesions of odontogenic origin, tooth vitality was not affected.[241,246,248]

Etiology and Pathogenesis

The development and progression of RO are associated with impaired hydroxylation of 1-hydroxycholecalciferol to the active form of vitamin D (1,25-dihydroxycholecalciferol, or calcitriol) and impaired Ca^{2+} balance (due to its decreased retention in renal tubules, reduced absorption in the gastrointestinal tract, and secondary hyperparathyroidism leading to increased Ca^{2+} release from bone to blood).[229,257,258]

Significance

- *Bone fracture*. The decreased bone resistance in patients with RO may predispose them to a higher fracture risk;[233,259,260] however, bone healing following tooth extraction appears to be unaffected.[261]
- *Functional impairment*. Due to the expansive growth of the bone in patients with osteitis fibrosa, patients may have difficulty in swallowing and chewing and this may lead to airway obstruction, which can predictably be addressed by surgical therapy.[223,262]
- *Cardiovascular and anemia-related conditions*. Patients with RO can have compromised erythropoiesis and poorer response to EPO therapy, which have been associated with the mean serum PTH, the extent of the peritrabecular and marrow fibrosis, and the percentages of eroded bone surfaces.[263] As mentioned in the section on renal replacement therapy in end-stage renal disease, failure in production of EPO by the kidney is an underlying mechanism of anemia progression in renal disease patients.[258] Also, PTH levels represent the main biochemical marker of RO and have been shown to be associated with the development of cardiovascular diseases.[264]

Primary Hyperoxaluria (ICD-10-CM Diagnosis Code R82.992)

This is a rare, inherited, autosomal recessive disorder of glyoxylate metabolism characterized by an accumulation of oxalate due to its excessive production and impaired excretion (systemic oxalosis).[265–268] It is commonly observed in patients with CKD stages 4 and 5,[265] and although during CKD and early dialysis treatment the disease appears to be rather mild and not to affect the patient's health substantially, it becomes much more severe after as short as 2 years of dialysis, likely due to the inefficiency of dialysis treatment to reduce oxalate load.[265]

Clinical Signs

The disease is characterized by the presence of needle- or star-like crystals in virtually all tissues (systemic oxalosis), including alveolar bone, periodontium, dental pulp, and salivary glands. The degree to which the disease affects quality of life and life expectancy depends on the extent and rate of oxalate deposition in the tissues.[266] The reported dental cases include patients in their 20–30s, suggesting a rapid progression of dental conditions.[269–271] Oral findings include poor oral hygiene, vital teeth,[271] generalized gingival inflammation, external root resorption due to increased osteoclastic activity, increased tooth mobility due to severe periodontal breakdown and alveolar bone loss, and masticatory dysfunction.[269–271]

Radiographic Findings

Radiographically, diffuse deposition of radiopaque oxalate crystals within various soft (oral mucosa, PDL, dental pulp) and hard tissues (dentin, alveolar bone, and cementum) was observed.[269,270,272] Widened PDL[273] and well-demarcated bony lesions resembling cysts[269] could also be observed.

Etiology and Pathogenesis

The oxalate crystal deposition can be alleviated by the increased permeability of blood vessels in periodontitis, thus leading to a greater extent of periodontal breakdown.[274] However, it is unclear whether periodontal changes are associated with the deposit of crystals alone or aggravated by the inflammatory events of periodontitis. Since the 2017 classification of periodontal and peri-implant conditions does not list primary hyperoxaluria among the systemic conditions affecting the periodontium,[275,276] these conditions might be classified as periodontal abscesses associated with foreign bodies (oxalate crystals).

Significance

- *Local effects*. Hyperoxaluria-associated adverse effects could contribute to increased tooth mobility, tooth loss, and subsequent compromised chewing. However, the long-term outcomes of dental management of oral lesions, especially in patients after KT and liver transplantation, have not been reported.[274]
- *Systemic effects*. In addition to functional impairment of multiple tissues and organs, deposition of crystals in bone leads to an inflammatory reaction, activation of bone remodeling, and hyperparathyroidism.[265] Progressive renal fibrosis induced by chronic inflammation leads to the deterioration of glomerular filtration, causing systemic oxalosis, primarily in the bones, causing pain, spontaneous fractures, and EPO-resistant anemia, and radiographically presented with "bone-within-bone" and diffuse demineralization.[277]

Other Bone Conditions

A few cases of ossifying fibroma have been reported in patients undergoing in-center HD with poorly controlled secondary hyperparathyroidism, radiographically presenting with osteolytic bone and displaced roots of the teeth.[278,279] Also, aneurysmal bone cyst in a patient undergoing in-center HD and presenting with hyperparathyroidism has been described.[280] A more advanced stage of bisphosphonate-related osteonecrosis of the jaw is significantly associated with eGFR[281] and a poorer degree of response to therapy, especially in older individuals.[282] Also, a case of extensive osteonecrosis of both maxilla and mandible (not related to bisphosphonate use) of a patient who received KT (15 years after transplantation) has been recently described.[283]

DENTAL CONSIDERATIONS AND MULTIDISCIPLINARY MANAGEMENT

As already discussed, patients with renal disease present with various oral manifestations and pathologic lesions of soft and hard tissues and teeth. At the same time, the presence of oral lesions even in individuals without renal disease is associated with a statistically significant reduction in mean GFR compared to the respective controls without oral lesions (49.7 vs. 109.5 mL/min).[74] These findings suggest that observation of oral lesions can serve as an early indicator of reduced GFR flow and a predictor of future renal diseases; however, long-term follow-up studies are needed to determine whether patients with oral signs and reduced GFR eventually develop renal disease. Due to the compromised systemic condition of patients with renal diseases, dental professionals must establish close multidisciplinary collaboration with the patient's nephrologist team to ensure the patient's safety, minimize the risk of complications, and provide the best possible care. At the same time, nephrologists need to understand the importance of dental care in the systemic health of their patients and ensure that all acute or chronic loci of dental infections are eliminated prior to renal treatment, which is especially relevant for patients receiving KT.[284] Limited evidence suggests that the efficiency of this collaboration, however, appears to be inadequate. An older questionnaire study showed that 81% of dentists were aware of the kidney status of their patients with CKD and only 71% of patients had complete medical records;[29] nevertheless, whether the use of modern electronic health records has improved this statistic remains unexplored. At the same time, only ~30% of Brazilian nephrologists referred their patients for dental consultations,[285] although whether or not these data can be extrapolated to other countries is still uninvestigated. The importance of these gaps in patient management should not be overlooked.

Those who are not nephrologists frequently encounter issues with antibiotic dosing and electrolyte abnormalities in patients undergoing HD. Excellent volume control is necessary for certain tests or procedures so that patients can lie in the supine position for the duration of the test or procedure. Most dialysis units can accommodate longer or extra treatments before procedures that optimize acid–base and volume status prior to major procedures requiring general anesthesia.

Based on the available literature evidence, we have summarized the current knowledge on the dental management of patients with renal conditions.

Up to 70% of KT candidates require dental therapy prior to transplant surgery.[286] The multidisciplinary dental management of patients receiving KT is similar to that for patients with CKD and those undergoing in-center HD. However, patients receiving KT commonly present with more compromised immune conditions, which require special consideration. Ongoing dental infections (dental caries or periodontal breakdown) in these patients can contribute to fever, cough, and jaw pain, which are alleviated after addressing the respective dental conditions.[287] Therefore, the United Network of Organ Sharing has published guidelines for patients anticipating organ transplants (including patients with renal diseases) that outline the process of preparation for transplantation and include a "dental exam clearance" communication form, which should be completed by a dentist and returned to the transplantation team before a patient can be "listed" for transplantation. Since most US kidney pre-transplant patients have Medicare, their dental treatment preceding transplantation may not be covered (except for selective tooth extractions).[288] This poses a higher risk of delaying KT procedures. Therefore, nephrologists should establish close communication with dentists regarding the schedule for KT and the patient's dental needs.

Hematologic Conditions

The anemia and hypertension commonly seen in patients with renal disease as well as various anticoagulants used in HD therapy and vascular access maintenance[258] pose a significant risk of increased bleeding. Up to 50% of patients with CKD and those undergoing in-center HD had an increased tendency for systemic preoperative bleeding[289] and a significantly higher perioperative risk of blood transfusion.[290] A case report study of patients undergoing in-center HD who displayed medication-induced gingival overgrowth reported extensive (1650 mL) bleeding during gingivectomy and extensive tooth extraction (19 teeth), even despite normal blood tests (bleeding time and upper limits of PTT and PT).[291]

The mechanisms of the increased bleeding in patients with CKD prior to undergoing in-center HD commonly include an impaired coagulation cascade and fibrinolytic system, platelet dysfunction, vasodilation with increased fragility of the blood vessel wall, impaired platelet–vessel wall interaction, and inflammation (see Table 16-8).[127,258,289] In select patients undergoing in-center HD (typically three 3-5-hour courses of dialysis weekly), increased bleeding can be associated with the use of anticoagulants (commonly heparin, but danaparoid, lepirudin, and argatroban can also be used as alternatives[292]) prior to each procedure.[258] Older studies have proposed performing dental procedures before dialysis, since any medications given by a dentist and their metabolites will be removed during subsequent dialysis.[293] Currently, it is recommended that dental procedures be performed on alternate days to dialysis to avoid anticoagulant-induced bleeding and the adverse effects of uremic metabolites, which may otherwise put the patient at hemorrhagic and/or cardiovascular risk, and to avoid conflicts in the dialysis and dental appointment schedule.[258,294,295] Heparin dose in hemodialysis is very low and it is safe to treat patients after 6 hours from a coagulation point of view; however, logistically it may be better to do more invasive procedures after dialysis day. Caution needs to be exercised when doing invasive procedures in patients who are taking direct oral anticoagulants. These include antithrombotic agents such as acetylsalicylic acid and clopidogrel, anticoagulants (unfractionated heparin, low molecular weight heparin, fondaparinux), direct thrombin inhibitors (such as dabigatran), and direct factor Xa inhibitors (such as rivaroxaban or apixaban). Patients with advanced CKD (stages 4 and 5) and ESRD may experience higher bleeding risk than the general population, and this needs to be addressed when planning invasive dental procedures.

Patients undergoing PD use their peritoneum as a filter, and routine use of anticoagulation is not required during PD; hence, clotting of blood in the extracorporeal system is not a potential complication.

Nevertheless, dentists who plan invasive dental procedures and expect greater than minor bleeding should still

Table 16-8 Mechanisms of increased bleeding in patients with renal disease.

- Impaired coagulation cascade and fibrinolytic system
- Platelet dysfunction (disturbance of the platelet α-granules; impaired intracellular calcium flux; impaired synthesis and/or release of thromboxane A_2 and a subsequent reduction in platelet adhesion and aggregation; deregulated metabolism of arachidonic acid and prostaglandins; intake of medications affecting platelet function)
- Vasodilation with increased fragility of the blood vessel wall
- Impaired platelet–vessel wall interaction (due to the decreased expression of platelet glycoprotein Ib, and impaired binding of von Willebrand factor and fibrinogen to activated platelets)
- Inflammation (indirectly, due to increased tissue fragility)

Part 7: renal disorders. *Br Dent J*. 2003;195(4):181–184; Lutz J, Menke J, Sollinger D, et al. Haemostasis in chronic kidney disease. *Nephrol Dial Transplant*. 2014;29(1):29–40.

communicate with nephrologists to discuss the possible risk of excessive bleeding. In addition, they should be ready to use various local hemostatic agents (e.g., oxidized regenerated cellulose, Gelfoam with activated thrombin, tranexamic acid [Cyklokapron, 500 mg/5mL], and cellulose sponges),[291,296] especially in patients with thrombocytopenia and platelet dysfunction (see Table 16-9). Appropriate flap management and suturing techniques were required to minimize the risk of excessive bleeding[297] and provide optimal healing of intraoral soft tissues.[298]

In an emergency, various systemic aids, including heparin antagonist protamine sulfate and desmopressin, antifibrinolytic drugs (tranexamic acid, epsilon aminocaproic acid), fresh frozen plasma, and platelet transfusion can also be performed in the appropriate settings (see Table 16-10).[291,296]

If a patient receives warfarin to maintain shunt patency, International Normalized Ratio (INR) values prior to the procedure need to be obtained. Minor invasive procedures, such as isolated tooth extraction, can be safely performed with INR <3.5, whereas higher INR values require a nephrologist consultation.[305] For a comprehensive review of bleeding disorders and their dental management, refer to the Bleeding and Clotting Disorders chapter of this textbook.

Medications

A non-nephrologist frequently encounters issues with antibiotic dosing and electrolyte abnormalities in patients undergoing dialysis. Excellent volume control is necessary for certain tests or procedures so that patients can lie in a supine position for the duration of the test or procedure. Most dialysis units can accommodate longer or extra treatment before the procedure to optimize acid–base and volume status prior to major procedures requiring general anesthesia. Hyperkalemia, hyperphosphatemia, and hypocalcemia were the most commonly encountered electrolyte abnormalities in patients undergoing in-center HD. Drugs that prolong the QT interval should be carefully prescribed in patients with ESRD (a noninclusive list is shown in

Table 16-9 Local hemostatic agents used during invasive dental procedures.

Name	Mode of Action	Mode of Delivery
Oxidized regenerated cellulose	Stimulates denaturation of blood proteins, activates platelet aggregation, and induces blood clot formation[299,300]	Local application to the wound area
Gelfoam with activated thrombin	Gelfoam acts as a spongy carrier that can be soaked with thrombin that induces the formation of fibrin from fibrinogen[301]	Local application to the wound area
Cyklokapron (tranexamic acid)	Antifibrinolytic; reduces the binding of plasminogen to fibrin[302]	• Oral rinse (15 mL) 4×/day for 10 days • Soaking a piece of gauze and biting on it for 15–20 min
Sutures	Mechanically approximate wound tissue margins	Placed during the surgical invasion

Table 16-10 Systemic hemostatic agents used during invasive dental procedures.

Name	Mode of Action	Effects
Protamine sulfate	Heparin antagonist	If emergency treatment has to be performed on a heparinized patient, protamine sulfate can be used to antagonize the anticoagulant effect of heparin[294,295]
Desmopressin	Stimulates the release of von Willebrand factor from endothelial cells (effects last for up to 4 hours[258,297,303])	If prolonged bleeding time and low platelet aggregation tests are observed, 0.3 μg/kg of desmopressin can be administered subcutaneously or intravenously.[304] Preferably perform the procedures in one visit to avoid the use of another dose of desmopressin

Table 16-11 The use of drugs prolonging QT interval in patients with renal disease.

Category	Drugs
Antiarrhythmics	Amiodarone, disopyramide, dofetilide, ibutilide, procainamide, quinidine, sotolol
Antidepressants	Amitryptyline, fluoxetine, sertraline, venlafaxine
Antimicrobials	Azithromycin, clarithromycin, erythromycin, levofloxacin (fluoroquinolones), fluconazole (azole antifungals), pentamidine
Antipsychotics	Chlorpromazine, clozapine, haloperidol, quetiapine, risperidone, ziprasidone
Miscellaneous	Methadone, ranolazine, sumatriptan, zolmetriptan

Table 16-11). Communication with dialysis units and nephrologists is key to delivering optimal care to medically complex patients undergoing in-center HD.

As a general rule, clinicians should avoid prescribing any medications that are nephrotoxic or become nephrotoxic due to accumulation and prolonged plasma levels in patients with renal disease (see the detailed examples that follow).[258,284] In these patients, other mechanisms of impaired pharmacokinetics of the drugs may include hypoalbuminemia (which limits the amount of proteins available to bind the drugs) and elevated urea levels (inhibiting the binding of proteins to plasma albumin), leading to the decreased availability of bound drugs and increased levels of free drugs. As a result, the doses and duration of various medications must be adjusted depending on the stage of renal disease. Therefore, it is essential to understand the pharmacokinetics of various drugs in patients with renal disease, taking into consideration their compromised health and increased risks for the development of infections.

Antibiotics

Bacteremia is a common sequela of impaired renal function, often leading to the development of infective endocarditis (IE),[306,307] Even while undergoing in-center HD, patients have a significantly higher risk of IE (1.4% vs. 0.3% at 1 year, 2.2% vs. 0.6% at 3 years, and 3.9 vs. 0.9% at 5 years),[308] which is a frequent cause of all-cause mortality of these patients.[309] Antibiotics were commonly used in the management of impaired renal function to prevent or minimize the risk of adverse complications associated with bacteremia.[310] Since many of them were excreted by the kidneys,[310] assessment of the functional activities of the kidneys is essential for choosing the optimal dose (see Table 16-12). Several papers provide guidelines on the choice and dose of antibiotics depending on eGFR (see Table 16-13).[258,284,304,311–313]

To minimize the possible risk of IE after invasive dental procedures, US dentists use prophylaxis antibiotics according to the American Heart Association (AHA) and American College of Cardiology guidelines.[314] Clinicians in Europe follow similar recommendations outlined by the European Society of Cardiology.[315] However, since these guidelines do not address the need for prophylactic antibiotics prior to dental procedures in patients with renal disease and those who have received KT, some dentists have raised concern about this need. It has been argued that cessation of antibiotic prophylaxis, as recommended by the UK National Institute for Health and Care Excellence, has resulted in an increased incidence of IE.[316] Although antibiotic prophylaxis appears to be safe and cost-effective,[298,316,317] 81% of antibiotic prophylaxis prescriptions prior to dental procedures were made to patients not at high cardiac risk, thus not following the AHA guidelines.[318] In patients receiving KT, antibiotic prophylaxis is recommended,[284,319] and some authors suggest it for at least 2 years after KT.[258] However, a retrospective study of patients receiving KT has shown that antibiotic prophylaxis prior to extraction procedures had no effect on the outcome of the procedure, and no difference in post-healing events were found compared to patients receiving no antibiotic prophylaxis.[261] Therefore, best practice remains discussion with the patient's nephrologist to evaluate the indication for antibiotic prophylaxis in each individual case.[294]

Nonsteroidal Anti-inflammatory Drugs

NSAIDs are commonly used to minimize inflammatory changes and reduce pain after invasive dental procedures. Extensive overviews of their use in dental patients with renal disease are available.[311,320] In a healthy, well-hydrated patient, the use of NSAIDs does not pose an increased nephrotoxic effect. However, in patients with impaired renal function, NSAIDs, especially those used for an extensive period of time or at high doses, can exert nephrotoxic effects, including the induction of hyperkalemia and hypertension, retention of sodium and fluids, and production of acidosis, and therefore they deteriorate already compromised renal function and contribute to the progression of CKD.[312,321,322]

Patients undergoing in-center HD with reasonable residual renal function (urine output >200–300 mL/24 hrs) may want to avoid long-term NSAIDs to preserve renal function. It is generally recommended to avoid NSAIDs, especially in patients with GFR <10 mL/min.[296,311] In patients with eGFR 10–50 mL/min, aspirin can be used no more often than every 6 hours; however, it is recommended to avoid it due to increased platelet dysfunction, impaired renal blood flow, commonly observed gastrointestinal ulcers, increase in gastrointestinal bleeding, and deterioration in renal function.[294,312] For postoperative

Table 16-12 Antibiotics.

Antibiotic	Can It Be Used in Renal Patients? (Y/N)	Recommended Dose
Tetracycline	Y	250–500 mg every 6 hrs
Doxycycline	Y	No dose adjustment necessary
Minocycline	Y	Do not exceed 200 mg/day
Doxycycline and minocycline	Y (excreted via bile)	
Erythromycin (and other macrolides)	• Y (in non-renal-transplant patients) • N (in patients receiving KT and taking CsA since it reduces CsA metabolism and leads to increased toxicity)	• No dose adjustment necessary (stages 1–4) • 50%–75% of the normal dose (maximum 1.5 mg/day) for stage 5 and dialysis • N/A
Amoxicillin (and other penicillins, except potassium penicillins)	Y	• 500 mg (stages 1–4) every 12 hrs • 250 mg (stage 5) every 12 hrs • 250 mg every 24 hrs—dose after dialysis (HD) • Avoid high doses (>500 mg every 12 hrs) due to the possibility of seizures
Clindamycin	Y	No dose adjustment necessary (oral, 600–1800 mg/day in 2–4 divided doses)
Metronidazole	Y	• For CKD stages 1–4, no dose adjustment necessary (500 mg every 8–12 hrs) • For CKD stage 5 and dialysis, dose adjustment is necessary (500 mg every 12 hrs, dialyzable, dose after HD on dialysis days)
Aminoglycosides	N	• IV/IM • Nephrotoxic (AKI and AKI on CKD) • If no alternative, can use regular dose every 48–72 hrs with therapeutic drug level monitoring
Cephalosporins	Y	0.5 mg IV 1 hr prior to procedure[298]

AKI, acute kidney injury; CKD, chronic kidney disease; CsA, cyclosporine A; HD, hemodialysis; IM, intramuscular; IV, intravenous; KT, kidney transplant; N, no; N/A, not applicable; Y, yes.

Table 16-13 Antibiotic doses in patients with various estimated Glomerular Filtration Rates (eGFRs).

eGFR	Antibiotics
10–50 mL/min	Regular dose of antibiotic of choice (e.g., amoxicillin, clindamycin, metronidazole, erythromycin) • Amoxicillin: 500 mg 21 tabs (3×/day for 7 days) • Metronidazole: regular dose every 12 hrs
<10 mL/min	Reduced doses of antibiotics: • Amoxicillin: 250 mg 21 tabs (2–3×/day for 7 days) • Clindamycin: no dose adjustment • Erythromycin: 50–75% of a regular dose (maximum of 1500 mg/day) Metronidazole: regular dose every 12 hrs
Dialysis (hemodialysis and peritoneal dialysis)	Same as with eGFR <10 mL/min

pain management, acetaminophen is generally more recommended, since it does not cause bleeding and is tolerated better (every 6 hours if GFR 10–50 mL/min and every 8 hours if GFR <10 mL/min).[294,311] However, chronic administration of acetaminophen should be avoided, since it can form phenacetin with nephrotoxic effects.[312] NSAIDs with weaker effects on renal prostaglandins (e.g., nabumetone, etodolac, and sulindac)[320] and nonacetylated salicylates (e.g., diflunisal, salsalate, magnesium choline salicylate, or salicyl salicylate)[311] can also be considered in patients with ESRD.

Benzodiazepines and Opioid Drugs (Narcotics)

Many long-lasting benzodiazepines (e.g., diazepam, clorazepate, and flurazepam) are excreted renally and produce toxic active metabolites with long half-lives that accumulate in patients with renal impairment (see Table 16-14).[311,312]

A recent review study has summarized various aspects of opioid use in older patients with CKD and suggested that opioids should only be used when absolutely necessary.[323] Buprenorphine, fentanyl, ketamine, and hydromorphone form inactive metabolites and therefore are the safest opioids to use (Table 16-15). In contrast, hydrocodone, oxycodone, and methadone form active metabolites, which may accumulate due to reduced renal function and induce toxicity (Table 16-15). Due to greatly reduced clearance with renal impairment and possible enhancement of drug effects, codeine, morphine, and meperidine should also not be used in nondialysis renal patients (Table 16-15).[295,297,311,312,323] However, even safe and short-lasting opioids delivered repeatedly can substantially prolong the elimination of the drug and its metabolites. Also, due to the anemia commonly seen in patients with renal disease, narcotics should be used with caution due to their respiratory depressant effects.[61]

Table 16-14 Metabolites formed by benzodiazepines.

Benzodiazepines	Effects
Chloral hydrate	Reduced excretion of its active metabolite 2,2,2-trichloroethanol leads to its accumulation owing to a long half-life (>10 hours) and excessive and prolonged sedation; avoid its use if GFR <50 mL/min
Meprobamate	Eliminated via renal route almost entirely unchanged; unmetabolized meprobamate (10%–12% of total concentration) accumulates with repeated dosing due to long half-life (>10 hours), resulting in excessive sedation; double the dosing interval when GFR is 10–50 mL/min and triple it when GFR <10 mL/min
Chlordiazepoxide, diazepam, clorazepate, flurazepam	Active metabolites with long half-lives; avoid multiple doses (as multiple dosing greatly increases the half-life and prolongs sedation); reduce doses by 33%–50% if GFR >30 mL/min

Oral Sedatives

Patients with renal disease may require long-term glucocorticoid therapy, which can result in an adrenal crisis during stressful events (such as dental treatment).[258,294] Therefore, these patients should be treated in a quiet, stress-free environment, as exogenous steroids can reduce

Table 16-15 Opioid drugs (Narcotics).

Opioid Drug	Effects
Buprenorphine, fentanyl, ketamine, hydromorphone	Do not form active metabolites (relatively safe to use)
Hydrocodone, oxycodone, methadone	Form active metabolites (should not be used in patients prior to undergoing in-center HD; should be used judiciously in patients undergoing in-center HD and those who have received KT)
Codeine	Forms an active metabolite, morphine-6-glucuronide
Meperidine	Forms an active metabolite, normeperidine (neurotoxic central nervous system stimulant and convulsant)
Propoxyphene	Forms an active metabolite, norpropoxyphene, which accumulates due to its long half-life (>36 hours) and causes cardiotoxic and seizure activity. Avoid its use in GFR <10 mL/min
Tramadol	Forms an active metabolite, O-desmethyltramadol, which accumulates and causes seizures and respiratory depression)

GFR, glomerular filtration rate; HD, hemodialysis; KT, kidney transplant.Sources: Alamo S, Esteve C, Pérez M. the adrenal function to produce cortisol in response to stress, thus posing an increased risk for hypotension.[324] When this is not possible, oral sedatives may provide an excellent level of sedation and patient comfort. Similar to various other medications, sedatives are affected by compromised renal function. A comprehensive review of the use of oral sedatives in renal patients has been published.[311] Chlordiazepoxide, diazepam, clorazepate, and flurazepam produce active metabolites; therefore their dose should be reduced by 33%–50% if GFR >30 mL/min, and multiple doses should be avoided (as multiple dosing greatly increases the half-life and prolongs sedation). Chloral hydrate can be accumulated in the form of its active metabolite, 2,2,2-trichloroethanol, resulting in excessive sedation; therefore chloral hydrate should be avoided in GFR <50 mL/min. Meprobamate is eliminated via the renal route almost entirely unchanged; unmetabolized meprobamate accumulates with repeated dosing due to its long half-life (>10 hours), resulting in excessive sedation; its dosing interval should be doubled in GFR 10–50 mL/min and tripled in GFR <10 mL/min.

Intravenous Sedation

A large cohort study that involved patients undergoing in-center HD and conscious sedation by nephrologists has shown that midazolam alone was used in 95% of cases (mean dose of 3.4 mg); fentanyl alone in 1% of cases (mean dose 79 μg); and their combination in 4% of cases (mean doses 3.3 mg and 60 μg for midazolam and fentanyl, respectively). The study has concluded that both drugs were safe to use even in high-risk patients, although in decreased doses.[325] Another study has shown that compared to diazepam, midazolam was preferable because of the lower risk of thrombophlebitis.[326]

Local Anesthetics

Local anesthetics (administered during infiltration or nerve block anesthesia) have a hepatic route of elimination, and therefore they can be safely used in patients with renal disease at a regular dose (300–500 mg to 14 cartridges).[258,284,297,311,312] Due to an increased prevalence of hypertension, epinephrine-containing anesthetics should be used judiciously.[312]

Cardiovascular Considerations

Hypertension is a common etiologic factor, and at the same time a consequence of renal disease, which should be monitored pre- and postoperatively.[258,295] In addition, some medications, such as NSAIDs, can produce hypertension.[295] Due to the elevated blood potassium levels, renal patients may also present with increased neuromuscular excitability, potentially leading to life-threatening ventricular arrhythmias and cardiac arrest.[327] It is important to remember to protect dialysis access during dental procedures[61,304,312] by avoiding the arm with vascular access for the measurement of blood pressure (as well as delivering IV medications or drawing blood),[295,297,312] as its accidental damage can cause torrential hemorrhage.[258] Patients should be kept in comfortable positions in the dental chair and allowed to take breaks as needed to minimize the risk of access obstruction.[61] These patients should be treated sitting upright to minimize the risk of pulmonary edema and congestive heart failure.[258] A recent study has shown that patients undergoing in-center HD might have a higher prevalence of carotid artery calcifications identified in dental panoramic radiographs compared to patients with ESRD and CKD (26 vs. 22 vs. 16%).[328] Therefore, a dentist may be the first healthcare specialist to observe these signs and refer the patient to a nephrologist or another medical specialist.

Box 16-1 Protocol for Dental Management of Patients with Chronic Kidney Disease and Those Undergoing In-Center Hemodialysis[208,329–331]

Prior to Dental Treatment

- Implementation of a multidisciplinary, patient-centered dental plan tailored to their individual needs upon communication with the nephrologist. This communication should include (a) any systemic concerns (e.g., stage of renal disease, most recent blood tests, presence of systemic comorbidities, risk of excessive bleeding); (b) choice/dose/duration of current medications and medications suggested (and contraindicated) prior to, during, and after dental procedures (including the need for antibiotic prophylaxis); and (c) proposed duration and timing of treatment, anticipated results, time frame of healing, and post-therapeutic complications that could possibly develop.
- Implementation of a stress reduction protocol that includes morning dental appointments, a quiet calm environment to minimize the risk of stressful changes, and possible conscious sedation.
- Comprehensive intra- and extraoral examination, including hard tissue charting, periodontal examination, and intraoral pathology screening. Full-mouth radiographs and/or panoramic radiograph should be obtained to properly evaluate tooth hard tissue conditions and possible alveolar bone changes.

- A patient-centered oral hygiene care plan, including patient education, demonstration of stained biofilm, calculation of plaque, and evaluation of brushing and interdental flossing efficiency, should be developed and implemented. Daily use of antibacterial mouth rinses with essential oils or 0.12% chlorhexidine is recommended to minimize the risk of a fungal infection or in patients who are unable to follow a recommended oral hygiene protocol. Evaluate the need for topical fluoride therapy in patients with high caries risk, but remember that systemic delivery of fluoride for caries prophylaxis should be minimized due to its nephrotoxicity for patients with compromised renal function.[319] Identify local risk factors for the development or progression of oral infections (such as dentures). In patients with xerostomia, chewing gum or artificial saliva can be used to alleviate xerostomia symptoms.[52,332,333] Salivary substitutes should be alcohol free, and contain xylitol and carboxymethylcellulose (or hydroxyethyl cellulose). Adjust the frequency of professional cleaning appointments, if needed.
- In patients presenting with halitosis, mechanical removal of dental biofilm, tongue coating, and bacteria,[62,65,334] mouthwashes (containing cetylpyridinium chloride, zinc, triclosan, H_2O_2, and 0.12% chlorhexidine),[335-337] and patient education on proper oral hygiene[338] should be used. In cases of pseudo-halitosis, a referral to a psychologist may be necessary.
- In patients presenting with a reduced salivary flow rate, the following approaches should be considered: (a) patient education emphasizing the importance of exercising oral hygiene and smoking cessation; (b) management of systemic diseases and medications associated with their treatment; (c) preventive measures to reduce oral diseases, and pharmacologic treatment with sialagogues (e.g., pilocarpine, cevimeline, sugar-free chewing gums); and (d) blood tests and biopsy of minor salivary glands to identify systemic contribution.[31] Although pilocarpine appears to be a medication of choice for patients with xerostomia,[339] it should be used with caution in patients receiving beta-blockers.[31] Although various saliva stimulants are available and beneficial,[332] there is no strong evidence to support their particular choice.[340] It is also important to remember that artificial saliva substitution agents do not exert the protective properties of natural saliva.[31]
- If an invasive dental procedure is planned, a dentist should anticipate excessive bleeding during the procedure. Obtain a complete blood count (white blood cell count, absolute neutrophil count, platelet count) and coagulation tests prior to any invasive dental treatment and ensure the availability of local and systemic hemostatic agents in the dental office. Although tooth extractions are not contraindicated in patients with renal disease, they can present with weakened jawbones due to renal osteodystrophy. In addition, postextraction healing events may differ from those in control individuals without renal disease.[250] For patients considering dental implants, general guidelines have been described recently,[341] and implant placement appears to be safe to consider.[342]
- If a patient is hypertensive, a dentist should consider the proper choice of local anesthesia agent or sedation (oral or intravenous [IV]) prior to the procedure. Ensure you use the correct arm to deliver IV medications and take blood pressure measurements.

During Dental Treatment

- The dentist should follow medication recommendations (including antibiotic prophylaxis) received from the patient's nephrologist. If the patient is on warfarin, International Normalized Ratio values should be obtained <1 hour prior to the procedure.
- In patients prior to undergoing in-center dialysis who need to have IV sedation or drug administration, the cephalic vein should not be used, since the arteriovenous fistula established through this vein is the first choice for permanent dialysis access.[343] Therefore it should be preserved in case the patient needs to be placed on dialysis in the future.[344] In hemodialysis patients with limited peripheral IV access, IV antibiotic prophylaxis at the end of the dialysis session and prior to the dental appointment may be needed and should be discussed with the nephrologist.[344] Patients who receive antibiotic prophylaxis and schedule multiple dental appointments should allow for an interval of 1–2 weeks between these appointments, and may need to use antibiotics from a different class to avoid resistance to it.
- If a patient presents with signs of chronic or active infection (e.g., dental caries, periodontal disease, abscesses, endodontic infection), these need to be addressed as soon as possible.
- If a flap needs to be raised, conservative flap management and hemostatic agents are encouraged.

After Dental Treatment

- Follow the post-therapeutic schedule appropriate for the dental procedure performed.
- Reinforcement of patient education on home oral hygiene and smoking cessation (if the patient is a smoker) should be undertaken. Patients should be advised to have professional dental cleanings.
- Ensure you have an updated list of medications and medical procedures performed during this period.
- Communicate with the nephrologist regarding the post-therapeutic outcomes, especially if there are complications or side effects of the medications used.

Box 16-2 Protocol for Dental Management of Patients Who Have Received Kidney Transplant[284,294,329,331,345–348]

Prior to Transplantation

This period is characterized by a high risk of the development of oral infections due to the concurrent immunocompromised status of these patients. Therefore, the goal of dental treatment is to perform aggressive elimination of the existing infectious foci *prior to* transplantation, and ensure that the patient has reached an acceptable oral hygiene and dental status for transplant candidacy.

Initial Patient Visit

- Whenever possible, the patient needs to be treated in a quiet environment, especially if they are receiving long-term glucocorticoid therapy. In these cases, it is also important to remember that the use of glucocorticoids can be associated with hypertension and hyperglycemia, which should be considered by the dentist.
- Obtain and review the most recent medical history, including the presence and status of systemic comorbidities (cardiovascular conditions, diabetes, hepatitis, etc.). Update the list of medications and be familiar with the side effects of these medications and their combination. Ensure the use of protective equipment and universal precautions.
- Although cancer screening is a mandatory part of dental examinations and standard of care, patients who have received a kidney transplant may have an increased prevalence of intraoral malignancies due to their immunocompromised conditions. Therefore, dentists should be especially thorough in performing oral cancer screening of these patients.
- Update the dental history and full mouth series (FMS), if needed.
- If the dentist is not aware that the patient requires antibiotic prophylaxis prior to a dental visit, perform a noninvasive (without periodontal probing) dental examination.
- Reinforcement of oral hygiene via patient education, motivation for home care (toothbrushing, using interdental floss or brushes, use of antibacterial mouth rinses), and professional visits.
- Discuss the findings with the patient and propose a treatment plan.

Consultation with the Patient's Nephrologist

- Is the proposed dental treatment feasible considering the patient's renal and other systemic conditions?
- What is the desired time frame for dental procedures considering the expected date of the transplantation surgery?
- Does the patient need to have antibiotic prophylaxis prior to the dental procedures?
- Are medications proposed during the dental treatment recommended or not? If yes, do these medications require dose adjustment?
- If the patient receives prolonged corticosteroid therapy, are supplemental doses of corticosteroids recommended prior to the dental procedure to avoid an adrenal crisis?
- If the patient presents with signs of medication-induced gingival enlargements, can alternative medications be used?

Dental Treatment

- Perform comprehensive hard tissue, periodontal evaluation, and oral pathology screening.
- Initiate the proposed dental treatment after receiving approval from the patient's nephrologist.
- The dentist should address all dental concerns, including but not limited to treatment of active (progressive) periodontal disease, operative treatment of dental caries, extraction of hopeless or impacted teeth, endodontic treatment, elimination of all sources of active infection (fistulas, abscesses, pericoronitis) or necrotic tissue, adjustment of existing or fabrication of new dental dentures, and removal of orthodontic appliances. Consider the use of 0.12% chlorhexidine irrigation throughout the dental visit and its prescription to reduce the risk of dental caries and biofilm-induced gingival inflammation due to poor oral hygiene.[284]
- During prophylaxis (dental cleaning), a limited number of teeth may be instrumented during the same appointment.
- No implant therapy or periodontal procedures that require a long healing period (such as maxillary sinus elevation and guided tissue regeneration using particulate bone graft material) should be performed at this point.
- Reinforce patient education on oral hygiene and home care. Perform smoking cessation counseling, if needed.

- In the case of intraoral fungal infections, it is important to remember that antifungal medications can interact with immunosuppressive medications, inhibit their metabolism, and increase their blood concentration.[349] Therefore, their use requires close monitoring and a possible dose reduction of immunosuppressive medications.[304] In addition, some antifungal medications (e.g., clotrimazole and terbinafine) are poorly (if at all) absorbed by the oral mucosa,[304] especially in patients with xerostomia,[31] and thus cannot enter the systemic circulation. Therefore their choice should be justified depending on both systemic and intraoral patient conditions.

Months 0–6 after Transplantation

During this period, patients receive intense immunosuppressive therapy.

- Only emergency dental procedures, in the hospital environment and after the nephrologist is informed and has consented to this treatment, should be performed.
- Follow the recommended steps described for pretransplantation patients (see above).

Months 6+ after Transplantation

During this period, graft healing is expected to stabilize.

No Transplant Rejection

- The patient should be observed to reveal any intraoral lesions secondary to the transplant procedure or medications (yeast infection, gingival overgrowth, and possible malignancies). Any updates on the patient's dental status should be reported to a nephrologist.
- Selective dental procedures can be performed. Dental implants appear to be safe and predictable to perform.[350]
- All new emergency cases should be addressed as soon as possible. Report their occurrence to the patient's nephrologist.
- Follow the recommended steps described for pretransplantation patients (see above).

Transplant Rejection

Only emergency dental treatment should be done, preferably in the hospital environment.

CONCLUSIONS

Patients with compromised renal conditions present with a wide variety of oral manifestations and lesions, which are often challenging to recognize and interpret for medical professionals. Therefore, nephrologists should consider referring patients to an oral healthcare professional for comprehensive evaluation and treatment. Considering the increased prevalence of renal disease in the United States and worldwide, it is expected that oral healthcare professionals will see increasing numbers of these patients. Therefore, the ability to observe, differentiate, and diagnose oral conditions can be important in the early diagnosis of renal disease and evaluation of their progression. Not only will the proper management of oral conditions improve the quality of dental conditions and quality of life of the patient, it also will contribute to improved outcomes of renal treatment. It is important to note that patients with renal disease can be treated safely and appropriately in ambulatory dental settings as long as proper communication with the patient's primary care provider and/or nephrologist has been undertaken prior to, during, and after the course of renal therapy.

Limitations to the Current Literature Evidence

- As mentioned throughout the chapter, literature evidence is lacking for the presence and severity of various oral symptoms and signs in patients with renal disease.
- The vast majority of studies represent case reports, case series, and studies that are retrospective in nature, with their inherent study design limitations. In addition, since a majority of studies are case-control studies, the only estimates we have are odds ratios (OR) and not relative risk (RR). This poses a risk of overestimating the extent of the association or intervention effect and erroneously presenting the results as clinically substantial and justified.
- Several studies evaluated dental conditions without having a dentist as an author. In these and other studies, only limited periodontal evaluation was performed.
- Several studies showed the presence/absence and prevalence of oral symptoms and signs only in patients with renal disease, without comparison with control individuals without renal disease. Therefore, it is challenging to interpret these findings and assess the impact of renal conditions on oral symptoms and signs.

- Several studies did not conduct multiple regression analysis to adjust for confounding factors (such as systemic comorbidities, duration of HD, ethnicity, etc.)
- Only a few studies evaluated the effects of renal therapy on the prevalence and severity of oral symptoms and signs. Similarly, only a few studies have examined the impact of dental therapy on renal function.
- We question the statistical analysis in several studies (e.g., demonstrating statistical significance with lower or upper limits of the 95% CI being ~1.0). In other instances, OR were statistically significant, but their clinical significance is inconclusive due to a small OR value (up to 1.5), which was not addressed in the studies.

Alessandro Villa, DDS, PhD, MPH

HEMATOPOIESIS

Hematopoiesis is the process of production of blood cells and platelets, which continues throughout life. This lifelong supply is derived from a rare population of multipotent hematopoietic stem cells (HSCs). Hematopoiesis has long been thought of as a hierarchal linear process where multi-, oligo-, and unipotent progenitors develop into mature hematopoietic cells. In the older model, long-term hematopoietic stem cells (LT-HSCs) located in the adult bone marrow are pluripotent, can self-replicate, and are the progenitors from which all blood cell lineages arise. They are usually quiescent, but they become activated when exposed to a stress stimulus. Short-term HSCs (ST-HSCs) are derived from LT-HSCs, can rapidly restore the hematopoietic system, and differentiate into multipotent progenitors (MMPs) with no detectible self-renewal ability. MMPs further differentiate into lineage-committed oligopotent progenitors: the common lymphoid progenitor (CLP) that only possesses lymphoid-restricted ability, and the common myeloid progenitor (CMP), which further differentiates into megakaryocyte–erythrocyte progenitor (MEP) and granulocyte–monocyte progenitor (GMP). MEPs give rise to megakaryocytes that mature to platelets, erythroid cells that mature to red blood cells (RBCs), and GMPs that give rise to eosinophils, neutrophils, basophils, and macrophages. CLPs give rise to B lymphocytes, T lymphocytes, and natural killer and dendritic cells.[1]

It is now acknowledged through single-cell transcriptome, epigenetic, and transplantation analysis, along with barcoding and in vitro clonal functional assays, that the process of lineage commitment is not strictly unidirectional, but more plastic and flexible, and lacks boundaries at the different hierarchical levels.[2] In the revised hierarchical roadmap, the MMPs are divided into four subgroups (MMP1, MMP2, MMP3, and MMP4/LMPP). LT-HSCs, intermediate-term HSCS (IT-HSCs), and ST-HSC/MMP1s give rise to MMP2, MMP3, and MMP4/lymphoid-primed multipotent progenitors (LMPPs). MMP2 and MMP3 mainly give rise to CMPs and MMP4/LMPP predominantly generate lymphoid lineages. The CMPs produce mature hematopoietic cells similar to the MEPs and GMPs of the old model, and the

Burket's Oral Medicine, Thirteenth Edition. Edited by Michael Glick, Martin S. Greenberg, Peter B. Lockhart, and Stephen J. Challacombe.

CLPs yield mature lymphocytes. Megakaryocyte differentiation can bypass the states of MMPs, CMPs, and MEPs coming directly from the HSCs (Figure 17-1).[1]

Hematopoiesis is continuous, adaptive, and capable of responding to metabolic, infectious, and inflammatory challenges. Perturbations of the system lead to disease. Regulation of hematopoiesis is complex and only partially understood. It entails signaling through external factors such as cytokines and intracellular factors such as transcriptional signaling factors and microRNAs.[3] While LT-HSCs undergo several intermediate steps to produce mature blood cells, megakaryocyte lineage segregation occurs early during differentiation. The primary cytokines governing erythrocyte, platelet, and granulocyte production have been identified and are erythropoietin, thrombopoietin, and granulocyte colony-stimulation factor (G-CSF), respectively. Additional factors positively regulating erythropoiesis include insulin, insulin-like growth factor, activin, and angiotensin II. Factors negatively regulating erythropoiesis include transforming growth factor beta- and alpha-related ligand, growth and differentiation factor 11, inflammatory cytokines such as c-interferon, tumor necrosis factor (TNF) alpha, and tumor necrosis factor-related apoptosis-inducing ligand.[4]

The healthy human produces approximately 10^9 RBCs, 10^8 white blood cells, and 4 billion platelets every hour. Different cell types have different normal lifespans (e.g., 120 days for erythrocytes, 5–10 days for platelets, 6–8 hours for neutrophils, day to years for lymphocytes). Senescent or otherwise damaged erythrocytes are recognized and removed by the reticuloendothelial system. At least half of senescent RBCs are destroyed in the spleen by splenic macrophages and the remaining RBCs are destroyed in the liver, bone marrow, or other sites of the mononuclear phagocyte system. Aging platelets are also sequestered in the spleen and are subject to phagocytosis by macrophages. The death and removal of neutrophils and lymphocytes are less well understood.

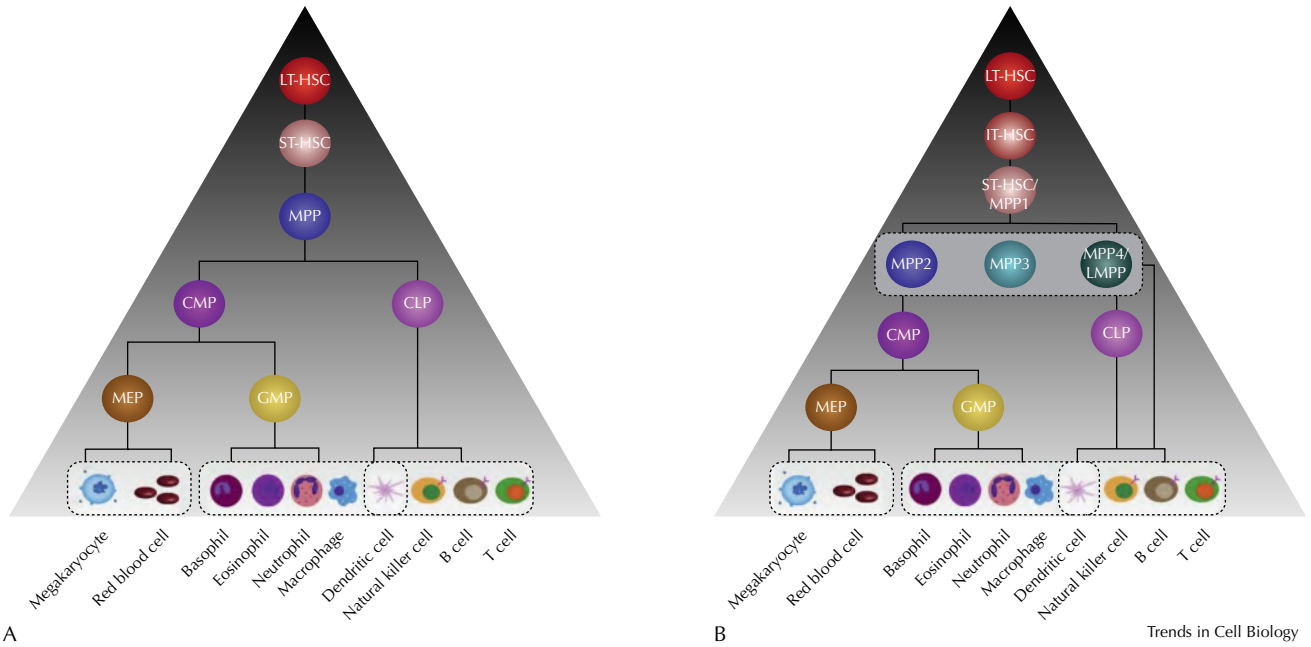

Figure 17-1 Classical and revised roadmap of hematopoietic hierarchy. (a) In the classical hierarchy roadmap, LT-HSCs and ST-HSCs are both multipotent, but sit at different hierarchical levels owing to their distinct self-renewal abilities. The HSCs give rise to the MPPs with an accompanying reduction of self-renewal ability. Next there emerges a myeloid/lymphoid lineage segregation downstream of MPP. CLPs can produce lymphocytes. CMPs diverge into MEPs and GMPs. MEPs yield megakaryocytes and erythrocytes. GMPs generate granulocytes, macrophages, and dendritic cells. (B) In the revised hierarchy roadmap, LT-HSCs, IT-HSCs, and ST-HSCs/MPP1 cells are all multipotent, but differ in their self-renewal ability. In the branching trees, the HSCs differentiate into MPPs, which consist of MPP2, MPP3, and MPP4/LMPP subpopulations. MPP2 and MPP3 cells mainly give rise to CMPs, whereas MPP4/LMPP cells predominantly generate lymphoid lineages. Next, CMPs can produce mature hematopoietic cells via MEP and GMP stages. CLPs can yield mature lymphocytes, which also can derive from MPP4/LMPP cells directly. CLP, common lymphoid progenitor; CMP, common myeloid progenitor; GMP, granulocyte/macrophage progenitor; IT-HSC, intermediate-term hematopoietic stem cell; LMPP, lymphoid-primed multipotent progenitor; LT-HSC, long-term hematopoietic stem call; MEP, megakaryocyte/erythrocyte progenitor; MPP, multipotent progenitor; ST-HSC, short-term hematopoietic stem cell. *Source:* Zhang Y, Gao S, Xia J, Liu F. Hematopoietic Hierarchy – An Updated Roadmap. *Trends Cell Biol.* 2018;28(12):976–986. doi:10.1016/j.tcb.2018.06.001. © 2018, Elsevier.

RBCs are made up mostly of hemoglobin, a metalloprotein composed of heme (the iron-containing portion that binds oxygen) and globin (amino acid chains that form a protein) groups. Normal hemoglobin types include adult hemoglobin A (HgbA; about 95%–98%) containing two alpha globulin chains and two beta globulin chains; $HgbA_2$ (2%–3%) containing two alpha and two delta chains; and fetal hemoglobin (HgbF, up to 2%). HgbF has two alpha and two gamma chains. HgbF is the primary hemoglobin produced by the fetus during gestation. Its production usually falls to a low level shortly after birth.

Hemoglobinopathies occur when point mutations or deletions in the globin genes cause changes in the amino acids that make up the globin protein, resulting in abnormal forms of hemoglobin. The structure of hemoglobin may be abnormal in its behavior, production rate, and/or stability. Several hundred hemoglobin variants have been documented; however, only a few are common and clinically significant. The majority of these are beta chain variants that are inherited in an autosomal recessive fashion. Since a person inherits one copy of each beta-globin gene from each parent, if one normal beta gene and one abnormal beta gene are inherited, the person is said to be a carrier or heterozygous for the abnormal hemoglobin. The abnormal gene can be passed on to offspring, but does not cause symptoms or disease in the carrier. If two abnormal beta genes of the same type are inherited, the person is considered to have the disease and is homozygous for the abnormal hemoglobin.

The initial laboratory test to assess hematopoietic health is a complete blood count (CBC) with differential (see Table 17-1). When necessary, more specific testing to include a peripheral blood smear, bone marrow biopsy, molecular/cytogenetic analysis, and functional assessments may be ordered to further assess the patient.

RED BLOOD CELL DISORDERS

Erythrocytosis

Erythrocytosis is suspected when elevated hemoglobin (Hb) levels (>185 mg/dL for males, >165 mg/dL for females) or elevated packed RBCs (hematocrit [HCT]; >52% for males, >48% for females) is seen. As Hb and HCT are surrogate indicators of true red cell mass, absolute or true erythrocytosis is confirmed when the red cell mass exceeds 125% of the predicted value for body mass using specialized nuclear medicine tests (e.g., radioisotope RBC studies).[5] Once an absolute erythrocytosis has been confirmed, it is desirable to identify the underlying etiology, which may be classified as either primary or secondary. Apparent erythrocytosis occurs in the presence of elevated venous HCT but RBC mass below 125% of predicted value. Relative erythrocytosis is when the RBC mass is in the normal reference range, but the plasma volume is decreased. This generally occurs with significant dehydration (e.g., from diuretics, persistent diarrhea, excessive use of alcohol, or burns).

Primary erythrocytosis is a condition in which the erythropoietic compartment of the bone marrow leads to increased red cell production. The predominant form of primary erythrocytosis is polycythemia vera (PV), discussed in detail below. Other causes of erythrocytosis include primary familial and congenital polycythemia, a rare primary form of erythrocytosis caused by mutations of the erythropoietin (EPO) receptor gene resulting in increased RBC mass and low EPO levels, tumors such as cerebellar hemangiomas or parathyroid adenomas causing increased EPO secretions, and rare genetic mutations to oxygen-sensing pathways resulting in dysregulation of EPO synthesis.[6]

Secondary erythrocytosis is characterized by increased red cell production in response to something external to the

Table 17-1 Red blood cell indices.

Test Name	Normal Range (SI units)	Increased	Decreased
Red Blood Cell (RBC)	Adult male: 4.5–9.0 x $10^6/\mu$ Adult female: 4.5–5.1 x $10^6/\mu$	Polycythemia; erythrocytosis; fluid loss due to dehydration, diuretics, diarrhea, burns	Anemia
RBC Indices			
Mean corpuscular volume	Adult: 80–93 μm^2	Vitamin B_{12} and folate deficiency	Iron deficiency anemia; thalassemia
Mean corpuscular hemoglobin	27.5–33.2 pg	Hyperchromia	Hypochromic anemia
Mean corpuscular hemoglobin concentration	33.4%–35.5% (concentration fraction 0.334–0.355)	Hyperchromia	Hypochromic anemia
Hemoglobin	Adult male: 13–14.2 g/dL Adult female: 11.6–12.3 g/dL	Same as RBC results	Same as RBC results
Hematocrit	Adult male: 41.5%–50.4% Adult female: 35.9%–44.6%	Same as RBC results	Same as RBC results

bone marrow that causes tissue hypoxia, inappropriately increased erythropoietin production, or increased sensitivity to erythropoietin. Common causes of hypoxia include chronic lung disease, right to left cardiopulmonary vascular shunts, CO_2 poisoning, high-altitude habitat, smoking, and renal artery stenosis. Less common causes include EPO receptor mutations, Chuvash polycythemia (in which a mutation in the *VHL* gene affects the hypoxia-sensing pathway), right to left arteriovenous shunts in the lungs, and proline hydroxylase 2 and hypoxia-inducible factor 2 alpha (*HIF-2α*) mutations. Secondary erythrocytosis may be congenital (high oxygen-affinity Hb, EPO receptor-mediated dysfunction, 2,3-bisphosphogycerate mutase deficiency), or acquired. Acquired erythrocytosis may be due to central EPO-mediated hypoxia driven, local EPO-mediated hypoxia driven (end-stage renal disease [ESRD], renal cysts), or pathologic EPO production (tumors or drugs).[7] The term idiopathic erythrocytosis (IE) is reserved for cases in which all primary and secondary causes of increased red cell mass have been ruled out. As a consequence of increased recognition of primary and secondary causes of erythrocytosis, patients classified as having IE are on the decline.[6]

PV is a myeloproliferative neoplasm, a panmyelopathy with an estimated incidence of 1.9–2.3 cases per 100,000 persons/year and a slight male predominance. It is often caused by more than one genetic event in a single hematopoietic progenitor that results in clonal myeloid of pluripotent stem cell (expansion of red cell production). PV is characterized by an acquired Janus kinase 2 (*JAK2*) V617F mutation. JAK/STAT signaling plays a role in cellular proliferation and cell survival. The *JAK2* V617F mutation accounts for 95%–97% of PV cases, while a similar mutation of *JAK2* in exon 12 accounts for 3% of PV cases. The *JAK2* V617F mutation is associated with dysregulation of tyrosine kinase receptor binding, resulting in increased RBC, platelet, and granulocyte production; mutation of *JAK2* exon 12 results in increased RBCs only.[8] PV shares several features with two other forms of myeloproliferative neoplasia: essential thrombocytosis (ET) and primary myelofibrosis (PMF). Collectively, these three conditions exhibit relatively normal cellular maturation, phenotypic and genotypic mimicry, *JAK2* gene mutations, and a tendency to evolve into each other or develop myelofibrosis. There is growing evidence from studies in patients with sporadic PV as well as familial myeloproliferative neoplasms that the *JAK2* V617F mutation is not the PV-originating somatic mutation, but rather represents a late secondary change occurring in a clone initiated by as yet unidentified genetic change(s).[9]

The diagnostic criteria for PV were updated by the World Health Organization in 2016 and consist of both major and minor criteria. Major criteria are (1) Hb >16.5 g/dL in men, >16.0 g/dL in women, or HCT >49% in men, >48% in women, or increased red cell mass >25% above mean normal predicted value; (2) bone marrow biopsy showing hypercellularity for age with trilineage growth (panmyelosis), including prominent erythroid, granulocytic, and megakaryocytic proliferation with pleomorphic, mature megakaryocytes (differences in size); (3) presence of *JAK2* V617F or *JAK2* exon 12 mutation. Minor criterion: subnormal serum erythropoietin level. The presence of all three major criteria or the first two major plus the minor criterion is required for the diagnosis (see Table 17-2).[10]

Clinical and Oral Manifestations

PV is usually asymptomatic and often only discovered incidentally. Its clinical course is measured in decades. It can be acquired at any age, but is rarely seen in children and increases exponentially in those aged >60 years.[11] PV should be suspected in patients with elevated hemoglobin or HCT levels, splenomegaly, or portal venous thrombosis. When symptoms occur, they may include pruritis, vertigo, gastrointestinal (GI) pain, headache, paresthesias, burning pain in the feet and hands, fatigue, weakness, visual disturbances, tinnitus, and facial plethora. Pruritis following a bath or shower is often the predominant complaint and has been suggested to be due to mast cell degranulation.[12]

Major complications of PV (e.g., stroke, venous thromboembolism) are attributable to blood hyperviscosity and the qualitative and quantitative platelet alterations observed in the disease. Other complications include ocular migraine, transient ischemic attacks, thrombosis, leukocytosis, hyperuricemia, and splenomegaly. PV is an indolent disease with a lifespan that can exceed 40 years.[11]

PV can manifest intraorally with erythema (red-purple color) of mucosa, glossitis, and erythematous, edematous gingiva.[13] Spontaneous gingival bleeding can occur because the principal sites for hemorrhage, although rare, are reported to be the skin, mucous membranes, and gastrointestinal tract.

Treatment

Contemporary PV therapy is focused on reducing vascular risks and tailored to the thrombotic risk stratification of the

Table 17-2 Polycythemia vera diagnostic criteria.

Major Criteria	Minor Criterion
Hb >16.5 g/dL in men >16.0 g/dL in women	Subnormal serum erythropoietin level
Bone marrow biopsy: panmyelosis, prominent erythroid, granulocytic, and megakaryocytic proliferation with pleomorphic, mature megakaryocytes	
JAK2 V617F or *JAK2* exon 12 mutation	

patient. Low-risk PV patients or intermediate-risk PV patients with a high HCT level are treated with phlebotomies to reduce the HCT (<0.45% for males and <42% for females) plus low-dose aspirin, if no contraindications are present. Poorly compliant patients or those who manifest progressive myeloproliferation warrant myelosuppressive therapy. Hydroxyurea is the primary drug of choice, with anagrelide or peginterferon-alpha as alternatives. All of these agents have potential side effects. Hydroxyurea is a ribonucleotide reductase inhibitor and an effective agent in managing PV and is the drug of choice. It is important to remember that there is risk for leukemic transformation, so it is usually not recommended in young patients. Current nonmyelotoxic therapy is ruxolitinib, which targets *JAK2* kinase.[11] Busulfan has been shown to induce durable hematologic response in patients unable to tolerate hydroxyurea.[14] Radioactive phosphorus (^{32}P) has been used in the past, with a success rate of 80%–90%; however, its association with an increased incidence of acute leukemic transformation severely restricts its usefulness to patients >75 years of age.

Oral Health Considerations

There are no established guidelines addressing the delivery of dental care for the PV patient. The delivery of routine dental care for the well-controlled PV patient likely incurs minimal risk. Low-dose aspirin is rarely associated with hemorrhagic complications from dental extractions. Poorly controlled patients are at an increased risk for both thrombotic and hemorrhagic complications due to blood hyperviscosity and concurrent qualitative and quantitative platelet alterations.[15,16] It is important to know that inappropriately high HCT can lead to spuriously high prothrombin time values.[11]

Anemia

Anemia is defined as a reduction in the quantity of the oxygen-carrying pigment (Hb) in the blood. The normal range for hemoglobin is 13–14.2 g/dL for men and 11.6–12.3 g/dL for women.[17] Data from large population studies suggest that hemoglobin levels for African Americans tend to be 0.8–0.7 g/dL lower, perhaps owing to the high frequency of alpha-thalassemia in this population. Another important factor is the trend of hemoglobin. For example, a patient with previous hemoglobin values at the higher end of the normal range, who presents with a hemoglobin concentration at the lower end of the normal range, can now be considered anemic.[17]

The signs and symptoms of anemia occur as a consequence of the hypoxia and compensatory physiologic responses. Typical symptoms include fatigue and dizziness. The classic sign of anemia is pallor, which may be observed in the conjunctivae, face, nail beds, tongue, and palmar creases. Analysis of National Health and Nutrition Examination Survey (NHANES) data from 2003 to 2012 shows that 5.6% (95% confidence interval [CI]: 5.1–6.1%) of the US population had anemia.[18] In the elderly, anemia is associated with decreased physical performance of daily activities, cognitive impairment, depression, diminished quality of life, greater hospital admissions, and impaired survival.[19]

The initial laboratory tests used to assess suspected anemia are the CBC and the blood smear. The blood smear is used to morphologically characterize the red cells (e.g., macrocytic, normocytic, microcytic, normocytic, hypocytic). Once discovered, it is essential to determine the underlying cause of the anemia. There are several broad causes of anemias, which can be due to impaired production of the RBC (EPO deficiencies, hypoproliferation, impaired maturation of the RBC, impaired heme or globin production), accelerated destruction, consumption or loss of RBCs due to morphologic changes (sickle cell, cell membrane defects, enzymopathies), reduced protein stability, and factors extrinsic to the RBC.

Anemias Due to Impaired Production

Erythropoietin Deficiency

EPO is a hormone secreted by the liver in fetal development and then primarily by peritubular fibroblasts in the renal cortex of the kidneys in response to hypoxia or low O_2 tension (hemorrhage, hemolysis, etc.). It circulates in the plasma and binds to receptors on erythroid progenitor cells in the bone marrow to promote proliferation and differentiation of erythroid precursors to increase RBC production in a dose-dependent manner. EPO mRNA is also detectable in liver, spleen, bone marrow, lung, and the brain, where it may play a paracrine role. Renal function impairment (i.e., chronic kidney disease) leads to insufficient EPO production in the kidney, either from direct damage to the EPO-producing cells of the kidney or from suppression of EPO production by inflammatory cytokines in a patient with inflammatory disorders such as rheumatoid arthritis, cancer, or acquired immunodeficiency syndrome (AIDS).[20]

Impaired Hemoglobin Production

Hb, the protein in the RBC responsible for transporting oxygen, is made up of four subgroups, each containing a heme group with an iron atom. If there is no iron within the heme group (due to insufficient iron or inefficient delivery of iron), a defect in the synthesis of the heme group and resulting ability to bind, or lack of globin production (thalassemia), the RBC is smaller than normal. The term for this is microcytic anemia. To understand microcytic anemias, it is crucial to understand iron metabolism and homeostasis. The lifespan of a normal RBC is

~120 days, when senescent erythrocytes are removed from circulation by macrophages of the spleen. Most of the iron contained in the Hb is stored in macrophages or transported to the blood plasma bound to transferrin back to the myeloid tissue and used in the production of Hb for the new RBC. Hepcidin is a regulatory hormone produced by hepatocytes and functions to decrease plasma stores of iron. It does this by acting on enterocytes of the small intestine to inhibit the iron-exporting activity of ferroportin, thereby promoting cellular storage of iron and lowering plasma iron concentration. Plasma iron levels are maintained at a range of 10–30 μM and whole-body stores of 0.3–1 g. The following section describes microcytic anemias.

Iron Deficiency Anemia

Iron deficiency anemia (IDA) is the most common type of anemia worldwide. It is defined as a reduction in total body iron to an extent that iron stores are fully exhausted, and some degree of tissue iron deficiency is present in the presence of anemia. Iron deficiency affects approximately 40% of preschool children, 30% of menstruating females, and 38% of pregnant women. The most common cause of iron deficiency in children is malnutrition; in adult males, postmenopausal women, and the elderly, the cause is bleeding (cancers, GI bleed); and in women of childbearing age, menstruation, pregnancy, and, minimally, lactation. First, menstrual iron loss exceeds dietary intake. Second, dietary intake is insufficient to meet the demands of fetal development in the gravid or lactating female. Pathologic causes of IDA are more commonly observed in older adults and include gastritis, peptic ulcer disease, ulcerative colitis, GI carcinoma, achlorhydria, and celiac disease.

Iron resistance are disorders of the GI tract such as partial or total gastrectomy, *Helicobacter pylori* infection, celiac disease, and gluten sensitivity, another common cause of IDA. IDA affects up to 45% of people, particularly women, who have undergone gastric bypass, as the procedure removes active iron absorption from the gut and caloric intake is severely restricted.[21]

Plummer–Vinson syndrome, also called Paterson–Kelly syndrome, is rare and characterized by the classic triad of dysphagia, IDA, and upper esophageal webs or strictures.[22,23] It usually affects middle-aged white women in the fourth to seventh decades of life, but has also been described in children and adolescents. The dysphagia may be intermittent or progressive over the years, is usually painless and limited to solids, and may be associated with weight loss. Symptoms resulting from anemia (weakness, pallor, fatigue, tachycardia) dominate the clinical picture. Other potential findings include glossitis, glossopyrosis, glossodynia, angular cheilitis, koilonychia, fragility, thinning of nails, and brittle hair. Radiologic examination of the pharynx shows the presence of webs.[24] The etiopathogenesis is unknown, but it is postulated that iron deficiency adversely affects iron-dependent enzymes in the epithelium of the upper GI tract, increasing free radical stress, DNA damage, and malignant transformation.[22]

Iron deficiency anemias can often be treated effectively with iron supplementation. In cases of significant obstruction of the esophageal lumen by esophageal webs/strictures with persistent dysphagia in Plummer–Vinson anemia, rupture and mechanical dilation of the web may be required. Since Plummer–Vinson syndrome is associated with an increased risk of squamous cell carcinoma of the pharynx and the esophagus, these patients are monitored closely.[22]

Anemia of Inflammation/Chronic Disease

Anemia of inflammation (AI), also known as anemia of chronic disease (ACD), is the second most prevalent anemia and the most common type of anemia seen in hospitalized or chronically ill patients. It affects up to 77% of the elderly. The most common associated diseases include infections, cancer, autoimmune diseases, chronic kidney disease, and rejection after solid organ transplant.[25]

The body needs 20 mg of iron per day. Only 1–2 mg is absorbed from the intestine; the rest is obtained from recycling senescent RBCs or iron stores in hepatocytes and macrophages, as it is not excreted from the body. One of the main processes that are associated with anemias of inflammation are those that affect iron metabolism via hepcidin. Hepcidin is the main iron-regulatory hormone responsible for controlling the actions of ferroportin, a major iron export protein located on cell surfaces (enterocytes, macrophages, and hepatocytes) that release iron into the plasma. Hepcidin directly binds to ferroportin to decrease its functional activity. During iron overload, hepcidin synthesis increases and functions to shut down iron absorption by enterocytes, decrease recycling by macrophages, and increase storage into the hepatocytes.

Inflammation (acute, chronic, autoimmune conditions, and malignancy) acts as a potent stimulus for hepcidin production through JAK-STAT signaling through proinflammatory cytokines (interleukin (IL)-6, IL-1, TNF-alpha). Increased hepcidin results in increased stored iron into marrow, splenic, and hepatic macrophages and lowered serum iron levels, but not a true iron deficiency and otherwise known as a disorder of iron distribution. Increased cytokines produced in systemic inflammation also push hematopoiesis more toward myeloid production instead of erythroid production and activate erythrophagocytosis by macrophages, shortening the lifespan of erythrocytes by approximately 25%.[26] IL-6 is one of the most important cytokines involved in AI/ACD. It does this by inhibiting TNF-alpha and inducing transcription of ferritin, which increases retention of iron and storage within

reticuloendothelial cells, and inhibits erythropoiesis and hemoglobin synthesis.[25–28]

Sideroblastic Anemia

Sideroblastic anemias are inherited or acquired bone marrow disorders. Heme is assembled from iron and protoporphyrin IX in mitochondria by ferrochelatase. Iron within the mitochondria is also required to generate iron–sulfur clusters that regulate cellular iron uptake, heme synthesis, and iron storage. In sideroblastic anemia, there is pathologic iron accumulation in the mitochondria of erythroid precursors, which appear as coarse granules occurring in a perinuclear distribution that stains with Prussian blue. Iron metabolism is altered, leading to ineffective erythropoiesis to generate a systemic iron overload state that suppresses hepcidin to increase intestinal absorption of iron. Treatment consists of repeated transfusions for severe anemia, which adds to iron burden and then iron depletion preformed via phlebotomy or iron chelation. Pharmacotherapeutics include deferoxamine (Desferal), deferasirox (Exjade), and deferiprone (Ferriprox).[29,30]

Diagnosis

It is often difficult to serologically differentiate between IDA and ACD. IDA has three stages: the first stage exhibits iron depletion with decreased iron stores without decrease in serum iron levels or Hb concentration and low serum ferritin; the second phase exhibits abnormal iron serologies (reduced transferrin saturation, increased total iron-binding capacity, and increased zinc protoporphyrin); and in the third phase there is Hb concentration of less than the lower limit of the normal range.[17]

ACD presents as a normocytic/normochromic anemia that changes with time to become hypochromic and microcytic. Less than 25% of cases will present as microcytic hypochromic anemia. There is decreased serum iron, total iron-binding capacity, and transferrin saturation and an increase in serum ferritin and bone marrow iron stores. Table 17-3 shows the differences between ACD and IDA.[26] To complicate matters, the two conditions can coexist.

Diagnosis of ACD is made in the presence of systemic inflammation, iron restriction not caused by systemic iron deficiency (low serum iron, low transferrin saturation, and low ferritin), and symptoms such as fatigue, exercise intolerance, and dyspnea. Indeed, a patient with an inflammatory condition such as inflammatory bowel disease (IBD) may manifest both IDA and ACD. However, patients with ACD have normal transferrin receptor levels and high hepcidin levels, while patients with IDA have high transferrin receptor levels and normal or low hepcidin levels. Iron stores are usually adequate, but there is impaired iron delivery and EPO production is usually suppressed. When the diagnosis remains ambiguous, further testing including a bone marrow biopsy may be necessary.[17]

Sideroblastic anemias can be congenital or acquired. The distinction between the two may not be apparent until adulthood. The clinical laboratory findings include microcytosis, hypochromia, increased red cell distribution width, and absence of evidence for common causes of microcytic anemia such as iron deficiency and thalassemia. Definitive diagnosis is based on showing a genetic defect by mutational analysis.

Clinical and Oral Manifestations

The most important clinical symptom of anemia is chronic fatigue. Outward signs may be subtle and may include pallor of the conjunctivae, lips, and oral mucosa; brittle nails with spooning, cracking, and splitting of nail beds; and palmar creases. This has traditionally been used by physicians in the diagnosis of anemia. Among 50 prospectively examined patients, a statistically significant correlation was noted

Table 17-3 Differences in laboratory measures in iron deficiency anemia and anemia of inflammation.

Laboratory Measure	Iron Deficiency Anemia	Anemia of Inflammation
MCV	Low	Normal
MCH	Low	Normal
Reticulocyte hemoglobin	Low	Normal
% Hypochromic erythrocytes	High	Low
Serum transferrin	High	Low
Serum transferrin receptor	High	Normal
Serum ferritin	Low	High
Serum hepcidin	Low	High

MCH, mean corpuscular hemoglobin; MCV, mean corpuscular volume.

between hemoglobin concentration and the following: color tint of the lower eyelid conjunctiva, nail-bed rubor, nail-bed blanching, and palmar crease rubor.[31] Other findings may include palpitations, shortness of breath, numbness and tingling in fingers and toes, and bone pain.

Glossitis and stomatitis are recognized oral manifestations of anemia. In a study of 12 patients, oral signs and symptoms of anemia included angular cheilitis (58%), glossitis with different degrees of atrophy of fungiform and filiform papillae (42%), pale oral mucosa (33%), oral candidiasis (25%), recurrent aphthous stomatitis (8%), erythematous mucositis (8%), and burning mouth (8%) for several months to 1 year's duration.[32] IDA or ACI should be suspected in every case of glossitis, glossodynia, angular cheilitis, erythematous mucositis, oral candidiasis, recurrent oral ulcers, and burning mouth when no other obvious causes are identified.[33–35] These findings are believed to be caused by impaired cellular immunity, deficient bactericidal activity of polymorphonuclear leukocytes, inadequate antibody response, and epithelial abnormalities attributed to lack of iron.[36] Clinically evident atrophic changes of the tongue, giving a smooth red tongue appearance, in patients with IDA have been associated with a significant reduction in the mean epithelial thickness of the buccal mucosa as determined histologically.[37]

Treatment

Treatment is usually focused on treating the underlying disease (infection, autoimmune disorder, cancer), but most AI disorders and malignancies are chronic conditions. Otherwise, the goal is to improve the oxygen-carrying capacity of blood. This is achieved through iron supplementation, blood transfusions, erythropoiesis-stimulating agents, and downregulating the production of TNF-alpha and IL-6. Novel agents include hepcidin antagonists (monoclonal antibodies, siRNA, antisense oligonucleotides, hepcidin-binding proteins, and aptamers) are in development. Vitamin D deficiency has also been associated with increased prevalence of ACD, so vitamin D supplementation is also a consideration.[27,28]

For IDA, oral iron supplementation is safe, cost-effective, and convenient. The goal is to increase serum hemoglobin by 1–2 g/dL every 2 weeks, and ultimately restore iron stores in in about 3–4 months. Ferrous sulfate and ferrous gluconate have good bioavailability and contain 20% and 12% of elemental iron for absorption, respectively.[38] The recommended dose for both is 325 mg three times per day. Foods and medications that inhibit iron absorption include tea, coffee, phosphate-containing carbonated beverages, antacids, proton pump inhibitors, and H_2-blockers. Adverse effects of oral iron therapy are dose related, can adversely affect compliance, and include nausea, epigastric discomfort, and constipation. For such cases a lower dosage regimen should be attempted.

When oral iron supplementation is ineffective due to poor patient compliance or intolerance, intravenous iron therapy is indicated. Other possible indications for intravenous iron therapy are high iron requirements due to chronic uncorrectable bleeding or chronic hemodialysis; iron malabsorption secondary to a GI condition; IBD with ineffective erythropoiesis, poor iron absorption, and intolerance to oral iron supplementation; and the need for rapid restitution of iron stores (e.g., preoperative).[39] Intravenous iron products are made up of nanoparticles of iron oxyhydroxide gel in colloidal suspension, held within a stabilizing carbohydrate shell.[38] Available products include high molecular weight iron dextran, low molecular weight iron dextran, iron sucrose, ferric gluconate, and ferumoxytol. Serious and potentially life-threatening hypersensitivity reactions may occur, with the highest risk associated with high molecular weight preparations.

Thalassemia

Thalassemias are a group of inherited disorders of hemoglobin synthesis leading to reduced-production of globin chains. Gene clusters on chromosomes 16 and 11 code for alpha- and beta-like globins, respectively. Hemoglobin A, the major hemoglobin component of adult RBCs, is made up of two alpha and two beta chains (Hb A $\alpha_2\ \beta_2$). Defects can occur in either the alpha or beta-hemoglobin chain and these defects yield difficulties in transportation of oxygen. There are over 100 genetic forms of alpha-thalassemias, with phenotypes ranging from asymptomatic to lethal. Clinically relevant forms of alpha-thalassemia usually involve α^0-thalassemia, either coinherited with α^+-thalassemia and resulting in hemoglobin H (HbH) disease, or inherited from both parents and resulting in hemoglobin Bart's hydrops fetalis, which is lethal in utero or soon after birth.[40] Deletion of or mutations in three alpha-chain genes lead to HbH disease, which presents with more prominent anemia.[41] Worldwide, an estimated 5% of the population carry an alpha-thalassemia variant trait.[40] In the United States, the incidence of alpha-thalassemia is 1 in 1,000,000 and the incidence of beta-thalassemia is 1 in 100,000.[42] Historically, alpha-thalassemia is thought to be highly protective against severe malaria, therefore more prevalent in persons of African and Southeast Asian descent, and beta-thalassemia is most common in persons of Mediterranean, African, and Southeast Asian descent. However, human migration greatly blurred these distinctions.[43]

In beta-thalassemia, insufficient beta-globin synthesis results in excess alpha-hemoglobin production. There have been over 200 mutations in the beta-globin gene that cause

disease. Beta-thalassemia has been categorized as minor, major, and intermedia based on alpha-globin or beta-globin chain imbalance, clinical signs, and the severity of anemia. Beta-thalassemia minor trait or carrier manifests as microcytic anemia and is clinically asymptomatic. Beta-thalassemia major presents with severe anemia in infants and is transfusion dependent. Both beta-thalassemia major and beta-thalassemia intermedia result from homozygous or compound heterozygous inheritance of a mutated beta-globin gene. Beta-thalassemia intermedia can also result from increased production of alpha-globin gains.[44]

Clinical and Oral Manifestations

Clinical signs and symptoms of thalassemia are dependent on the severity of the disease and range from none to life-threatening. With regard to alpha-thalassemia, Bart's hydrops fetalis is lethal in utero or shortly after birth due to severe hypoxia. If transfusions are administered intrauterine and after delivery, life expectancy can be extended to 5 years. HbH presents with variable phenotypes with varying severities, ranging from moderate anemia and splenomegaly to a more severe course with episodes of intercurrent infection, severe anemia, and need for transfusions. Other manifestations include jaundice, growth retardation in children, infections, leg ulcers, gall stones, folic acid deficiency, and drug-induced hemolysis.

Patients with beta-thalassemia trait are usually asymptomatic, but may have mild anemia. Patients with beta-thalassemia major develop signs and symptoms as infants, including failure to thrive, pallor, weakness, jaundice, protruding abdomen with enlarged spleen and liver, dark urine, abnormal facial bones, and growth retardation. Compensatory hypertrophy of erythroid marrow with extramedullary erythropoiesis may lead to deformities of the long bones and typical craniofacial changes (see below). Beta-thalassemia intermedia patients manifest variable signs and symptoms of anemia that are milder and occur later in life; however, they are prone to experiencing thrombotic events, especially if splenectomized. Such events include deep vein thrombosis, stroke, portal vein thrombosis, and pulmonary embolism.

Significant oral manifestations related to thalassemia appear to occur more frequently in the beta-thalassemia group and are reflective of the underlying extramedullary erythropoiesis observed in the more severe phenotypes.[45] Characteristic craniofacial deformities include a class II skeletal base relationship with a short mandible, reduced posterior facial height, increased anterior facial proportions, and "chipmunk facies."[46] Other reported potential findings include spike-shaped and short roots, taurodontism, attenuated lamina dura, enlarged bone marrow spaces, small maxillary sinuses, absence of inferior alveolar canal, retained primary teeth, and thin cortex of the mandible.[47] Dental arch morphologic changes include a narrower maxilla, high arched palate, and smaller incisor widths for the maxillary and mandibular arches.[48,49] Consistent with general growth retardation, the dental development of 31 of 39 patients with Cooley's anemia was delayed by a mean of 1.11 years and 0.81 years for boy and girls, respectively.[49]

Individuals with thalassemia appear to experience similar rates of gingivitis and periodontitis to healthy controls.[50,51] An increased caries risk has been reported, which may be attributable to such factors as disease-induced immunologic dysfunction, decreased access to care, and insufficient patient oral hygiene.[50,52] While the parotid salivary flow rates in Cooley's anemia are similar to controls, quantitative changes consisting of reduced levels of phosphorus, immunoglobulin (Ig) A, and urea have been reported.[53,54] Increased oral cavity levels of *Streptococcus mutans* and *Candida* have also been reported.[53,55]

Diagnosis

Thalassemia is diagnosed using a battery of laboratory tests, including a CBC, qualitative and quantitative hemoglobin analysis, and DNA testing. Screening programs are considered for populations where thalassemias are most prevalent.[40] People with thalassemia have microcytic anemia, lowered hemoglobin, and defects in alpha or beta chains of hemoglobin. The clinical signs and symptoms of severe thalassemia usually become apparent within the first 2 years of life.

Treatment

The prognosis for thalassemia patients has improved dramatically over the past decades, but medical management remains complex and multidisciplined. Appropriate genetic counseling and screening should be afforded all patients with thalassemia trait.[40] Patients with alpha- or beta-thalassemia trait generally require no special medical management.

Mild HbH patients may require intermittent transfusion therapy, mainly during intercurrent illness. More severely affected HbH patients may require chronic transfusions, iron chelation therapy, and eventual splenectomy. Management strategies for patients with beta-thalassemia (Cooley's anemia) usually entail periodic lifelong blood transfusions to maintain the hemoglobin level above 90–105 g/L, to prevent growth impairment, organ damage, and bone deformities. Transfusions are given sporadically to patients under acute stress as well. The need for transfusions to manage beta-thalassemia patients is more episodic and dictated by the severity and potential progression of the disease. Splenectomies are traditionally performed as an alternative or adjunct to transfusion.[44]

Regularly transfused patients require iron chelation to resolve the inevitable iron accumulation that leads to dysfunction, primarily involving the heart, liver, and endocrine system. In the United States, there are three Food and Drug Administration (FDA)-approved iron chelators: deferoxamine (Desferal), deferasirox (Exjade), deferiprone (L1) and Ferriprox-L1 (Ferriprox). The most commonly used agent is the oral dispersible agent deferasirox, likely due to its good oral bioavailability and convenient once-a-day dosing. Common side effects include dose-related GI symptoms (e.g., nausea, vomiting, diarrhea, abdominal pain) and mild skin rash. The most serious side effects with deferasirox are potential kidney damage and renal tubular acidosis.[44]

Hemopoietic stem cell transplantation is the only curative treatment for thalassemia. Disease-free survival exceeds 80% with human leukocyte antigen (HLA)-matched sibling donors. Cord blood transplantation may be successful, but there is a 5%–10% mortality from transplant conditioning, graft-versus-host disease, and graft failure. Clinical guidelines are available.[44,56] Future therapeutic strategies involving normal gene transfer via suitable vectors, molecular targeting (i.e., BCL11A) using CRISPR/Cas9, ligand traps (sotatercept and luspatercept) for stimulation of late-stage erythropoiesis, *JAK2* inhibition (in patients who develop myeloproliferative disorders), and agents to stimulate hepcidin production are being investigated.[44]

Infections are major complications and constitute the second most common cause of mortality and a main cause of morbidity in patients with thalassemia. Predisposing factors for infections in thalassemic patients include severe anemia, iron overload, splenectomy, and a range of immune abnormalities.

Oral Health Considerations

There are no contraindications for providing routine dental care for thalassemia patients under proper medical management. Splenectomized patients are more susceptible to developing postsplenectomy sepsis from encapsulated bacteria (e.g., *Streptococcus Pneumoniae, Haemophilus Influenzae*, and *Neisseria Meningitidis*). Prevention of postsplenectomy sepsis includes immunization against the abovementioned bacteria, and early antibiotic treatment for fever and malaise. Additionally, patients with beta-thalassemia intermedia may be on an antithrombotic agent, so one should caution about prolonged bleeding.[57]

Impaired Maturation (Macrocytosis)

The term macrocytosis refers to a blood condition in which RBCs are larger than normal and is reported in terms of mean corpuscular volume (MCV). MCV, the average volume of RBCs, is calculated as HCT × 1,000 divided by RBC (millions/μL). Normal MCV values range from 80 to 100 femtoliters (fL), depending on gender, age, and reference laboratory. Macrocytosis is identified by reviewing peripheral blood smears and/or by automated RBC indices, and is diagnosed when MCV is >100 fL. It is a relatively common finding with a reported incidence ranging from 2% to 4% and about 60% of those who have anemia. Potential causes include alcoholism and B_{12} or folate deficiency. Medications that interfere with DNA synthesis, such as methotrexate, trimethoprim-sulfamethoxazole, nucleic acid analogs (5-fluorouracil, zidovudine), and others (hydroxyurea, pentamidine, phenytoin, pyrimethamine, sulfasalazine, triamterene), may result in macrocytosis. Measures to address the underlying cause often result in normalization of the MCV. Other causes of macrocytosis are variants of associated conditions such as Down syndrome and pregnancy.[58]

B_{12} and Folate Deficiency Anemia

Vitamin B_{12} and folate are cofactors necessary for the enzyme methionine synthase used in the conversion of homocysteine to methionine. As a byproduct of this reaction, methyl-tetrahydrofuran (THF) is converted to THF, which is converted to intermediates used in the synthesis of pyrimidine bases of DNA. In B_{12} deficiency, homocysteine cannot be converted to methionine, and thus methyl-THF cannot be converted to THF and pyrimidine bases cannot be formed, slowing down DNA synthesis and affecting rapidly proliferating cell lines, resulting in a megaloblastic anemia, among other problems.[59] From a hematologic perspective, lack of either B_{12} or folate results in an essentially identical megaloblastic anemia.

B_{12} deficiencies or pernicious anemia can be due to insufficient B_{12} absorption associated with an autoimmune-related atrophy of the gastric mucosa, which reduces the number of parietal cells that produce intrinsic factor (IF). IF is a protein produced by the parietal cells of the fundic mucosa of the stomach that binds B_{12} to allow it to be absorbed through the GI tract. Decreases in IF may be due to gastric disease or surgery (complete or partial gastrectomy or gastric reduction), intake of drugs that affect gastric acid secretion resulting in increased stomach pH and inability for B_{12} to be released from the food matrix, and/or reduced B_{12} consumption (vegetarian/vegan diet, chronic alcoholism). More than 90% of patients with pernicious anemia have serum antibodies against gastric parietal cells and about 50% have antibodies against intrinsic factor.[60] The predominant causes of folate deficiency involve scenarios of inadequate intake, such as malnutrition and alcoholism. The increased physiologic folate and B_{12} requirement associated with pregnancy or lactation and conditions of chronic hemolysis

or hemorrhage may lead to an anemic state. Secretion of intrinsic factor decreases as the stomach acid pH becomes more alkaline, therefore long-term use of proton pump inhibitors may result in pernicious anemia. Vitamin B_{12} deficiency prevalence varies by age range (3% ages 20–39, 4% ages 40–59, 6% ≥60 years), with marginal depletion occurring frequently (>20%) among those 60 years or older.[61]

Clinical and Oral Manifestations

Fatigue, decreased mental concentration, glossitis, and weakness are characteristic of folate or B_{12} deficiency. B_{12} deficiency may present as neurologic symptoms such as clumsiness, unsteady gait, and paresthesia. Prolonged severe B_{12} deficiency, as may be seen in pernicious anemia, may lead to demyelination of the dorsal columns of the spinal cord, resulting in more advanced signs and symptoms such as peripheral neuropathy and ataxia. Severe deficiency shows evidence of bone marrow suppression.[62] Unfortunately, these advanced signs and symptoms are often not reversed with replacement therapy.

Oral signs of folate and B_{12} deficiency are similar to those observed with IDA or ACI and include a beefy red tongue with smooth or patchy areas of erythema. Symptoms include soreness or a burning sensation affecting the tongue, lips, buccal mucosa, and other mucosal sites. Paresthesia and taste alterations have been reported.[63]

Diagnosis

The diagnostic process begins by establishing the presence of vitamin B_{12} (cobalamin) or folate deficiency in the presence of clinical signs. The primary laboratory investigations include total B_{12}, holotranscobalamin, metabolites, methylmalonic acid (MMA), and homocysteine.[64] Serum cobalamin and folate levels are assessed in tandem. To determine differences between pernicious anemia and other causes of low cobalamin, anti-IF antibody assay is the preferred test. Newer assays measure holotranscobalamin II (the proportion of transcobalamin II conjugated to vitamin B_{12}). If tested after oral administration of cobalamin, it can be used to assess intestinal uptake and diagnose vitamin B_{12} malabsorption.[62]

Use of the Schilling test (which measures cyanocobalamin absorption by increasing urine radioactivity after an oral dose of radioactive cyanocobalamin) for detection of pernicious anemia has been supplanted for the most part by serologic testing for parietal cell and intrinsic factor antibodies.[65]

Treatment

Treatment strategies for folate or B_{12} deficiency are dictated by the underlying cause and B_{12} repletion. Protocols entail parenteral B_{12} administration of 1000 μg cyano-B_{12} or hydroxy-B_{12} intramuscular injections daily or every other day, followed by weekly injections for up to 8 weeks, then every 3–4 weeks. Oral administration (high-dose cyano-B_{12} 2000 μg oral tablets daily until remission, then 1000–2000 μg daily) is an effective alternative to injections to manage deficiency. Even when intrinsic factor is not present to aid in the absorption of vitamin B_{12}, as in pernicious anemia or in other diseases that affect the usual absorption sites in the terminal ileum, oral therapy is still effective. However, prescribed folate supplementation may still be necessary in scenarios of alcoholism and malnutrition.

Accelerated Destruction, Consumption, or Loss

The normal RBC lifespan is 110–120 days in the circulation. Hemolytic diseases result in anemia, if the bone marrow is not able to replenish adequately, the prematurely destroyed RBCs. The hemolytic anemias are classified as either inherited or acquired. Inherited forms include sickle cell disease (SCD), thalassemias (described above), hereditary spherocytosis, hereditary elliptocytosis, glucose-6-phasphate dehydrogenase (G6PD) deficiency, and pyruvate kinase deficiency. Acquired forms of hemolytic anemias are immune hemolytic anemia, mechanical hemolytic anemias, paroxysmal nocturnal hemoglobinuria (PNH), and exposure to certain infections, toxins, or snake venom.

With acute hemolytic disease, the signs and symptoms depend on the mechanism that leads to red cell destruction. The release of free hemoglobin occurring in intravascular hemolysis may present as acute flank pain, free hemoglobin in the plasma and urine, and renal failure. In patients with chronic or progressive anemias, symptoms depend on the patient's age and adequacy of blood supply to critical organs. With moderate anemia, symptoms may include fatigue, loss of stamina, breathlessness, tachycardia, and, less commonly, jaundice and hemoglobinuria. Physical findings include jaundice of skin and mucosae, splenomegaly, and other findings associated with specific hemolytic anemias.

A careful history and physical examination provide important clues to the diagnosis of hemolytic anemias. Once a patient presents with clinical signs and symptoms of anemia, laboratory testing should be supported by a complete drug and toxin exposure history and family history. Laboratory tests in the anemic patient may be used initially to demonstrate the presence of hemolysis and define its cause. An elevated reticulocyte count is the most useful indicator of hemolysis, reflecting erythroid hyperplasia of the bone marrow. Assessment of RBC morphology, findings on the peripheral blood smear, and, rarely, bone marrow biopsy may provide additional clues to support the specific diagnosis.

Sickle Cell Disease

SCD, formerly known as sickle cell anemia (SCA), is an umbrella term that defines a group of inherited diseases (including SCA, HbSC- and HbS-beta-thalassemia) characterized by mutations in the gene encoding hemoglobin subunit beta, resulting in a glutamic acid-to-valine substitution in the sixth position on the beta-hemoglobin chain. The resulting mutant protein generated from the sickle beta-globin subunit is sickle Hb (HbS). When the Hb is not bound to oxygen, HbS can polymerize and cause the erythrocytes to assume a crescent or sickled shape.[66] The sickled erythrocytes form distorted rigid sickle cells, which lose their ability to effectively transport oxygen to the microcirculation and are prone to hemolysis. The sickled cells also cause recurrent vaso-occlusive episodes, leading to end-organ ischemia and necrosis affecting nearly every organ in the body.

SCD is an inherited autosomal codominant trait. It affects an estimated 100,000 people in the United States and the global annual incidence of SCD exceeds 300,000.[67] About 100,000 individuals in the United States have the disease and most are African American. Globally, there are over 300 million carriers of SCD. The life expectancy of adults with SCD in high-income and middle-income countries yields a median survival of 67 years. In lower-income regions, life expectancy is reduced by about 30 years and patients have a poor quality of life. Treatments remain costly, limiting access to care to those of higher socioeconomic standing.

While vaso-occlusive events clinically characterize SCD, the etiopathogenesis of SCD is far more complex and involves ongoing hemolysis; increased RBC dehydration and adherence to endothelium; vascular instability due to nitric oxide deficiency; inflammation, hypercoagulability, increased neutrophil adhesiveness, and platelet activation. Patients with SCD may have other hemoglobin genotypes including compound heterozygosity for the HbS gene and other Hb variants such as HbC, HbE, and HbD or variants of HbS-beta-thalassemia.[67] Fetal hemoglobin (HbF) is excluded from the HbS polymer. It usually peaks by mid-gestation and drops to about 1% by the age of 6 months. In SCD, it is maintained in adults at higher levels.

Endothelial activation, induced directly or indirectly by the proinflammatory behavior of sickle erythrocytes, is the most likely initiating step toward vaso-occlusion. Stressors that can lead to vaso-occlusion typically include viral and bacterial infection, hypoxia, dehydration, iron overload, and cell and fluid phase–related causes. Microvascular occlusion arises predominantly in localized areas of marrow, leading to necrosis. Inflammatory mediators activate nociceptive afferent nerve fibers, evoking the pain response. Commonly affected areas are the long bones, ribs, sternum, spine, and pelvis, often with multiple-site involvement.

Clinical and Oral Manifestations

Nearly every organ is affected in SCD.[67] Damaged erythrocytes cause vaso-occlusion, which lead to acute complications including vascular–endothelial dysfunction, functional nitric oxide deficiency, inflammation, oxidative stress and reperfusion injury, hypercoagulability, increased neutrophil adhesiveness, and platelet activation, ultimately leading to ischemic damage to tissues.[68] This damage results in severe pain and/or organ failure.

Pain is characteristic of SCD and the most common reason for hospitalization. Pain management is personalized and guided by pain severity. Home management with analgesics and hydration is first-line therapy. If that is insufficient, rapid administration of opioids is recommended. The most frequently affect sites are the lower back, knee/shin area, and hips. One study describes four phases of the pain event: prodromal, consisting of mild localized pain without hematologic aberrations; initial/infarctive, consisting of acute pain lasting 2–3 days; a postinfarctive phase; and a recovery phase. Laboratory findings include elevated reticulocytes, lactate dehydrogenase, and C-reactive protein (CRP). The resolving phase occurs when the pain intensity is decreased, usually as a result of appropriate care.[69]

Acute chest syndrome is the second most frequent cause of hospitalization and the leading cause of death in patients with SCD. It is associated with >10% fatality or association with neurologic events. It can be defined as a *new* infiltrate in at least one segment of the lung, along with fever and respiratory symptoms. Splenic dysfunction plays a key role in increased susceptibility to bacterial infections. The impaired immune function associated with SCD places children at risk of developing life-threatening infections, especially from *Streptococcus pneumonia* and *Haemophilus influenzae*.[70,71] Long-term penicillin prophylaxis and vaccinations are recommended; however, concerns of penicillin resistance may lead to changes.[66] Children with vascular velocity >200 cm/s are at risk for central nervous system (CNS) injury (stroke). Prevention consists of chronic transfusion therapy and/or hydroxycarbamide. Pulmonary and renal complications as well as depression are other comorbidities.

Numerous nonpathognomonic oral findings have been described in SCD and include mucosal pallor (70%), delayed eruption (23%), mandibular pain (20%), osteomyelitis (5%), and discolored and depapillated tongue.[72] Radiographic changes have been noted in 70%–100% of patients.[73] In radiographic assessment of SCD patients, higher prevalence of external resorption; number of teeth with pulp

calcification; partial and total loss of lamina dura; changes in trabecular structure of maxilla and mandible; and hypercementosis was found when compared to controls.[74]

Diagnosis

Premarital, antenatal, and neonatal screening programs have been established in some high-income countries, including parts of the Middle East and the United States, and areas with a high prevalence of the disease.[67] Screening consists of DNA-based testing for prenatal diagnosis, and after-birth diagnosis by hemoglobin electrophoresis, thin layer isoelectric focusing, solubility testing, and examination of peripheral blood smear.

Treatment

Advances in medical therapies have dramatically improved the lifespan of SCD patients due to supportive care and hydroxyurea. General measures to provide palliation and reduce the myriad of SCD complications require a multidisciplinary approach and comprehensive patient education. Hydroxyurea has been used to prevent acute pain and acute chest syndrome. Preventive measures include penicillin prophylaxis in children, Doppler screening for stroke prevention, and regular blood transfusions. Clinical trials using small-molecule therapies are underway. A New Drug Application has been submitted to the FDA for L-glutamine to reduce the frequency of acute pain. Hematopoietic stem cell transplantation (HSCT) is curative, but the costs associated with it are prohibitive, particularly in lower-income populations.[67] There are currently several ongoing trials with emerging treatment approaches including L-glutamine powder, rivipansel, hydroxycarbamine, prasugrel, vepoloxamer, L-arginine, N-acetylcysteine, and magnesium sulfate.

Penicillin prophylaxis for children with SCD under the age of 5 years reduces infection-related morbidity and mortality, as does appropriate vaccination against pneumonia and influenza. Vaccination with both the 13-valent pneumococcal-conjugated vaccine (PCV13) and pneumococcal polysaccharide vaccine PPSV23 can prevent infections by most serotypes. Acute chest syndrome is the leading cause of death. Therapy is intensive and expansive, and possible interventions include transfusion, supplemental oxygen, continued respiratory therapy, antibiotics, bronchodilators, pain management, fluid management, corticosteroids, and mechanical ventilation.

Oral Health Considerations

Measures to reduce oral disease burden and infection in the SCD patient are clearly indicated. Long-term penicillin prophylaxis in SCD children under age 6 years inhibits the acquisition of *Streptococci mutans*, resulting in significantly lower caries rates in these children.[75] However, within 4 years of cessation of prophylaxis, the levels of mutans streptococci reached that of matched controls. While SCD is not associated with increased periodontal disease per se,[76] cases of periodontal infections[77] and mandibular osteomyelitis[78] precipitating a sickle cell crisis have been reported.

Given the wide variability in disease severity, it is essential that a comprehensive history and medical consultation be obtained to determine the patient's status. During non-crisis periods, there are no contraindications concerning the delivery of routine dental care under local anesthesia with inhalational sedation.[79,80] The avoidance of using a local anesthetic agent without a vasoconstrictor is unwarranted. The need for providing antibiotic prophylaxis before rendering dental care is controversial and no clear consensus or guidance exists.[80,81] Most patients can be treated safely in an outpatient setting.[82] For patients deemed high risk, dental therapy may be considered in a hospital setting where appropriate medical support is readily available.

Cell Membrane Defects

Another mechanism for an absolute decrease in the number of circulating RBCs is through increased hemolysis due to membrane defects. This results in morphologic changes of the RBC, leading to cell weakness, fragility, and/or rigidity. These conditions include hereditary spherocytosis (HS), hereditary elliptocytosis (HE), pyropoikilosis (a subtype of HE resulting in severe hemolytic anemia), stomatocytosis, and paroxysmal nocturnal hemoglobinuria (PNH).[83,84]

HS is the most common inherited red cell membrane disorder. It occurs in 1 of every 2000–3000 individuals and is most frequently seen in Europe and North America. There is a loss of surface area on reticulocytes and RBCs due to disruption of the vertical linkages between the phospholipid bilayer and the membrane skeleton as a consequence of mutations in genes encoding for various red cell membrane proteins, including ankyrin, band 3, protein 4.2, spectrin, and RhAg 0C. HE is a red cell membrane disorder characterized by mutations in genes coding for skeletal proteins involved with horizontal protein connections, including SPTA1 and SPTB and protein 4.1R, causing the morphologic changes. It affects 3–5 per 10,000 individuals.

Stomatocytosis is a rare red cell disorder divided into two entities, xerocytosis and dehydrated hereditary stomatocytosis (DHSt) and overhydrated hereditary stomatocytosis (OHS), in which there are alterations in intracellular cation content and cell volume alterations resulting in osmotic deformities of the RBCs.[84]

For all of the red cell membrane diseases, the clinical manifestations are variable and the diagnosis is made based on clinical signs (pallor, jaundice, splenomegaly) and examination of the blood smear. Treatments include splenectomy, transfusions, and clinical trials of senicapoc and PIEZO1 channel inhibitors for hydration disorders.

Paroxysmal Nocturnal Hemoglobinuria

PNH is a rare acquired condition characterized by episodes of hemolysis, bone marrow failure, thrombosis, and smooth muscle dystonia. It affects 1–1.5 cases per million worldwide.[85] Patients with PNH are deficient in proteins that bind to the cell surface through a glycosylphosphatidylinositol (GPI) anchor due to mutations in the phosphatidylinositol glycan anchor biosynthesis class A gene (*PIGA*) gene. Several of these proteins (CD55, CD59) are complement-regulatory proteins, and treatment with a humanized monoclonal antibody that inhibits terminal complement activation such as eculizumab can ameliorate hemolysis and symptoms. Many cells contain GPI anchors, but since erythrocytes lack a nucleus, they are more susceptible to lysis. Clonal expansion of HSCs harboring somatic mutations in the X-linked gene renders lineage cells vulnerable to complement-mediated intravascular and extravascular hemolysis. Intravascular hemolysis leads to release of free hemoglobin, a potent scavenger of nitric oxide. The subsequent lack of tissue nitric oxide is believed to underlie many of the clinical manifestations of PNH, including fatigue, pain, esophageal spasm, erectile dysfunction, and possibly platelet activation. Patients with classic PNH are at increased risk for thrombosis and other complications of intravascular hemolysis. Without therapy, the median survival rate is 10–20 years.[86] Allogeneic bone marrow transplantation is the only curative therapy available for PNH, with reported success rates of 50%–70%. The human monoclonal antibody eculizumab blocks terminal complement activation at C5 and markedly reduces the risk of intravascular thrombosis, decreases or eliminates the need for transfusions, improves quality of life, and offers a more favorable prognosis.[85,86]

Glucose-6-Phosphate Dehydrogenase Deficiency

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is inherited as an X-linked hemolytic anemia caused by mutations in the *G6PD* gene and more than 400 mutational variants have been defined.[87] Affected individuals are at risk for developing hemolytic anemia. The World Health Organization classifies the different variants according to the magnitude of enzyme deficiency and severity of hemolysis: class I is <1% of enzyme activity, class II is <10%, class III is 10%–60%, class IV is 60%–90%, and class V is >110%.[88] G6PD deficiency is the most common enzyme deficiency in the world and is estimated to affect 330–400 million people worldwide. The two most commonly observed variants are classes II and III. The geographic areas of highest prevalence correlate well with areas where malaria is endemic, such as Africa, Mediterranean Europe, Southeast Asia, and Latin America. It is widely believed that G6PD deficiency confers some level of protection against *Plasmodium falciparum* malaria.

The *G6PD* enzyme acts via the hexose monophosphate shunt to catalyze the oxidation of glucose-6-phosphate to 6-phosphogluconate, while concomitantly reducing the oxidized form of nicotinamide adenine dinucleotide phosphate ($NADP^+$) to nicotinamide adenine dinucleotide phosphate (NADPH). NADPH, a required cofactor in many biosynthetic reactions, maintains glutathione in its reduced form. Reduced glutathione acts as a scavenger for dangerous oxidative metabolites in the cell. While other cells may produce NADPH via alternate pathways, the RBC relies exclusively on G6PD activity. Hemolysis typically occurs when the RBCs undergo excessive oxidative stress, usually due to an external trigger such as drug exposure, fava bean ingestion, or infection. Other potential triggering factors include diabetes mellitus, myocardial infarction, and strenuous exercise.[89,90]

Clinical Manifestations

The vast majority of individuals with G6PD deficiency remain clinically asymptomatic throughout their lives. If hemolysis occurs in an affected patient, characteristic signs and symptoms include fatigue, flank pain, anemia, and jaundice. Patients with the most severe class I variant of the disease (also known as congenital nonspherocytic hemolytic anemia) typically experience chronic anemia, more severe hemolytic episodes requiring transfusion, reticulocytosis, gallstones, and splenomegaly.

About one-third of male newborns who manifest neonatal jaundice within the first 1–4 days of life are G6PD deficient.[91] The icterus of neonatal jaundice is not due to hemolysis, but to the inability of the liver to adequately conjugate bilirubin. If not treated appropriately, it can lead to serious neurologic consequences.[90]

Infection is a common trigger of hemolysis in at-risk patients as well as medications used to treat infections. While the mechanism of triggering hemolysis is unknown, it is postulated that leukocytes release oxidative stressors during phagocytosis. Drug-induced hemolysis typically occurs within 24–72 hours of exposure and dark urine due to hemoglobinuria is common as anemia progresses for about a week, followed by recovery over the next 8–10 days.

Ingestion of fava beans is a recognized trigger. Fava beans contain high concentrations of vicine and convicine, which are transferred to the intestinal epithelium and into the blood to produce reactive oxygen species (ROSs). The reduction of NADPH in G6PD-deficient red cells is unable to reverse glutathione depletion and RBCs sustain severe oxidative damage when exposed to ROSs and promote hemolysis.[89] Patients with class II variant G6PD deficiency are at greatest risk. Fava bean–related hemolysis occurs within the first 24 hours of ingestion, is usually severe, and often leads to acute renal failure.

Diagnosis

Two point-of-care tests have been developed for G6PD activity.[92,93] A definitive diagnosis of G6PD deficiency entails assessment of enzyme activity, by quantitative spectrophotometric analysis of the rate of NADPH production from NADP. Quantifying the specific percentage of activity is necessary to determine the severity.

Treatment

Most cases of acute hemolysis are short-lived and resolve without complication. Severe cases of hemolysis may require transfusion, the provision of fluids to prevent hemodynamic shock, and possibly hemodialysis due to acute renal failure. Neonatal jaundice is usually treated with phototherapy and, when severe, exchange blood transfusion. Once the diagnosis of G6PD deficiency is established, measures to reduce exposure to oxidative stressors are warranted. Infections should be promptly treated and immunizations kept up to date. Patients susceptible to fava bean–induced hemolysis should avoid their ingestion. Patients with G6PD deficiency can tolerate the delivery of all necessary dental care.

Aplastic Anemia

Aplastic anemia (AA) represents bone marrow failure with loss of HSCs (empty marrow) and pancytopenia. AA may be secondary to direct bone marrow damage, inherited syndromes, or an immune-mediated process. AA is a rare disorder with the majority of cases occurring in Asia, manifesting mostly during the first three decades of life. Marrow failure can be secondary to direct injury from radiotherapy, chemotherapy, intermediate metabolites of some common drugs, and benzene (a workplace toxin mainly used in developing countries).[94] Other cases are associated with viral infections, transfusion-associated graft-versus-host disease, hepatitis, pregnancy, and genetic and clonal diseases. Marrow damage results from loss-of-function germline mutations, usually inherited. The most frequently mutated genes include *ASXL1*, *BCOR*, *BCORL1*, *DMNT3A*, and *PIGA*; common karyotypic abnormalities include 6pUPD (acquired uniparental disomy with loss of heterozygosity in the short arm of chromosome 6) and abnormalities of chromosomes 7 and/or 13.

In inherited bone marrow failure syndromes, mutations have been identified in more than 30 genes that encode for subunits of three multiprotein complexes, providing powerful genetic evidence for the role of these complexes in bone marrow failure. Examples include Fanconi anemia (replication-dependent removal of interstrand DNA cross-links), dyskeratosis congenita (telomere maintenance and repair), or stem and progenitor cell differentiation and self-renewal pathways, as in GATA27. Marrow failure has been also observed in syndromes affecting immune regulation, such as in DADA and CTLA48.[95]

Clinically, patients may present with fatigue, pallor, petechiae, ecchymoses (due to thrombocytopenia), and infections (due to neutropenia). Some patients may develop hemolytic anemia or thrombosis as well. A diagnosis of AA is made with a bone marrow aspiration and biopsy that shows hypocellular/aplastic bone marrow, with normal residual hematopoietic cells, and no infiltration with malignant cells or fibrosis. Lab work shows pancytopenia with relatively normal lymphocyte count, decreased reticulocytes of the bone marrow replaced by fat from chemical or physical damage, and increased erythrocyte mean cell volume. The peripheral blood smear reveals macrocytic or normocytic red cells with reticulocytopenia, decreased neutrophils and platelets, and the absence of abnormal circulating white blood cell forms.[96]

AA is classified in different forms depending on the severity. Severe AA patients present with bone marrow cellularity <25% (or 25%–50% if <30% of residual hematopoietic cells) and at least two of the following: (1) peripheral blood absolute neutrophil count (ANC) <500/μL (<0.5×10^9/L); (2) peripheral blood platelet count <20,000/μL; or (3) peripheral blood reticulocyte count <20,000/μL. Very severe AA cases follow the same criteria for SAA and present with an ANC <200/μL.

Nonsevere AA patients manifest with hypocellular bone marrow (as for severe AA) and a peripheral blood cytopenia not fulfilling criteria for severe AA or very severe AA.[96]

Management of AA depends on the severity of the disease and the underlying cause. Approximately 75% of patients initially respond well to immunosuppression, but relapse occurs in about 30%–40% of cases. Cytopenia is managed with sequential transfusion and antibiotics. In some rare cases patients may require therapy with growth factors. Individuals with severe AA who are younger than 20 years of age, and those aged 20–50 with no significant past medical history, are recommended to undergo allogeneic stem cell transplant. For patients over the age of 50, the decision to use immunosuppressive therapy versus supportive care alone depends on the patient's past medical history and comorbidities. If the patient can tolerate immunosuppressive therapy, eltrombopag

for 6 months plus horse antithymocyte globulin and cyclosporin A is the treatment of choice. These patients are monitored on a regular basis for hematologic response.[97–99] The most serious fatal complication of AA is infection and patients with severe AA are at increased risk for fungal, viral, and bacterial infections. While no standard guidelines are available to manage these patients, prophylactic antibiotic therapy (when deemed clinically appropriate), use of antivirals, and antifungals in this patient population is imperative.

Oral Health Considerations

The goal of dental therapy is to establish and maintain optimal oral hygiene, thus reducing the risk of infections. Patients with AA can generally tolerate routine care and the need for prophylactic antibiotic prophylaxis in this AA cohort remains controversial. Patients with severe AA are at high risk for hemorrhage and infection, both oral sourced and nosocomial. These patients should be managed in a hospital setting to ensure appropriate perioperative management and follow-up. Severely neutropenic patients (neutrophil count <500/μL) may require prophylactic antibiotics. Invasive dental procedures should be done in conjunction with the patient's hematologist.

WHITE BLOOD CELL DISORDERS

White blood cells (WBCs) are composed of granulocytes (neutrophils, eosinophils, and basophils) and agranulocytes (T and B lymphocytes, monocytes, and macrophages). Granulocytes are distinguished by their appearance under Wright's stain. The most abundant granulocyte is the neutrophil, which has neutrally staining cytoplasmic granules. The granules in granulocytes contain hydrolases, elastase, myeloperoxidase, cathepsin G, cationic proteins, bactericidal/permeability-increasing protein, and defensins, with broad antimicrobial activity against bacteria, fungi, and certain enveloped viruses. WBC disorders can be either quantitative or qualitative in nature. Table 17-4 outlines alterations in the WBC and differential cell counts that occur in various disorders. This section provides an overview of the most common WBC disorders encountered in a hospital-based oral medicine practice.

Granulocytosis/Neutrophilia

Neutrophilia is a term that refers to an increase of peripheral blood neutrophils, usually >7700 neutrophils/μL (in adults). Neutrophilia is frequently used interchangeably with granulocytosis, although the latter also includes an increased basophil or eosinophil count. Elevated WBC counts typically reflect a normal response to infection or inflammation and usually represent an increase in the number of neutrophils. In acute infections, leukocyte counts typically are 15,000–25,000/μL. Less often, leukocytosis is the sign of a primary bone marrow abnormality related to leukemia or a myeloproliferative disorder. Causes of neutrophilia change depending on the individual and the clinical setting. For example, young patients are more likely to have inherited diseases compared to adults. In addition, 2.5% of the population present with physiologic fluctuating neutrophil counts.[100,101] Cigarette smoking is a common cause of modest neutrophilia and the underlying mechanism remains unknown.[102,103] Mild neutrophilia has also been associated with stressful events such as surgical procedures, seizures, and exercise.[104] In general, neutrophil production may be reactive (e.g., following an infection), autonomous (e.g., secondary to a malignancy), or idiopathic.[105,106]

Reactive Neutrophilia

Inflammation

Acute and chronic inflammation may result in neutrophilia. Examples include Kawasaki disease, rheumatoid arthritis in adult patients, inflammatory bowel diseases (e.g., Crohn's disease, ulcerative colitis), and Sweet syndrome. The diagnosis is made based on the clinical findings and by exclusion. CRP and erythrocyte sedimentation rate (ESR) are usually elevated, but unspecific.

Infection

Infection is a common cause of neutrophilia.[107] A total WBC count greater than 25,000/μL is usually indicative of an acute infectious process. Bacterial infections are associated with a left shift and the blood smear may exhibit Döhle bodies, cytoplasmic vacuoles in neutrophils, and toxic granulations. In younger patients, neutrophilia may be involved also in several viral infections (e.g., Varicella zoster virus [VZV], herpes simplex virus [HSV]), mononucleosis, and advanced tuberculosis.

Medication

Medications may lead to an increased neutrophil count by (1) stimulating bone marrow myelopoiesis; (2) releasing granulocytes from the bone marrow (e.g., glucocorticoids); (3) an allergic reaction to a specific drug; and (4) demarginating neutrophils within the vasculature.

Autonomous Neutrophilia

Asplenia

Neutrophilia is also observed in patients with asplenia secondary to splenectomy, auto infarction in SCD, or other conditions.[108,109]

Myeloproliferative Neoplasms

Myeloproliferative neoplasms may be associated with an increased neutrophil count in both patients with a malignant disorder (such as chronic myeloid leukemia) or a benign condition (such as PV, or essential thrombocythemia). Neutrophilia secondary to a malignancy often presents with

Table 17-4 Key laboratory tests for white cell disorders.

Test Name	Normal Range (SI Units)	Increased	Decreased	Oral Findings
White blood cell (WBC)	4400–11,000/μL	Infections Inflammation Cancer Leukemia	Hematologic neoplasia Early leukemia Drug-induced cyclic neutropenia Viral infection Severe bacterial infections Bone marrow failure Congenital marrow aplasia	Enlarged gingiva, oral ulcerations, infection due to immune suppression from disease or therapy
Differential WBC				
Polymorphonuclear neutrophils	41%–78%	See Table 17-5	See Table 17-5	
Band neutrophils	0%–6%	Immature neutrophils; indicates rapid production of cell line often seen in infection		
Lymphocytes	23%–44%	Viral infections, mononucleosis, infectious lymphocytosis, hypoadrenalism, hypothyroidism	Immunodeficiencies, adrenal-corticosteroid exposure, severe debilitating illness, defects in lymphatic circulation	
Monocytes	0%–7%	Chronic infections (tuberculosis), bacterial endocarditis, granulomatous disease		
Eosinophils	0%–4%	Parasitic diseases, certain allergic diseases, chronic skin diseases, various miscellaneous diseases (sarcoidosis, Hodgkin disease, metastatic cancer)		
Basophils	0%–2%	Chronic hypersensitivity states, no specific allergen, myeloproliferative disorders		

anemia of chronic disease/inflammation. Leukocytosis to values in excess of 50,000 cells/μL, which is not associated with leukemia, is termed a leukemoid reaction.

Genetic and Inherited Conditions

Neutrophilia secondary to an inherited or genetic cause (e.g., leukocyte adhesion deficiency, hereditary chronic neutrophilia, Down syndrome) is usually more common during childhood and in neonates. Inheritance should be suspected when other family members present hematologic or somatic abnormalities. A bone marrow examination may be necessary to confirm the diagnosis.[110,111]

Evaluation and Diagnosis

The evaluation of a patient with neutrophilia starts with the clinical history and physical examination, including a CBC and differential. In patients with a suspicious hematologic disease, a peripheral blood smear examination is necessary. Nonspecific markers of inflammation (e.g., CRP, ESR), serum chemistries, and coagulation studies may be helpful to assess possible secondary complications.

Neutropenia

Neutropenia refers to an ANC <1500/μL. Exceptions are made for newborns who have a slightly elevated ANC during the first few days post partum and certain ethnic groups (such as Yemenite Jews, West Indians, Arab Jordanians, and black people of South African extraction) who have a physiologically lower WBC and ANC. The ANC is defined as the number of WBCs that are neutrophils {(WBC [cells/μL] x percent [PMNs + bands]) ÷ 100}.

Neutropenia can be categorized into mild, moderate, or severe. In mild neutropenia the ANC ranges between 1000 and 1500/μL, moderate between 500 and 1000/μL, and severe <500/μL. The risk of infection typically increases

Table 17-5 Neutrophil disorders.

Quantitative Disorders	
Neutrophilia	**Neutropenia**
Primary	*Primary*
Hereditary	Cyclic neutropenia
Idiopathic inflammation	Familial benign myeloka thexis
Cancer	Severe chronic glycogen storage disease
Leukemia	Failure to release
Colchicine sulfonamides	*Secondary (Immunodeficiencies)*
Down syndrome	X-linked hyperimmunoglobulin M
Chronic myelogenous	X-linked agammaglobunemia
Polycythemia vera	*Acquired Anemia of Inflammation*
Leukocyte adhesion deficiency	Drug-induced
Secondary	Clozapine
Infections	Antithyroid
Smoking	Sulfasalazines
Chronic inflammation	Others
Stress	*Destruction*
Exercise	Hypersplenism
Steroids	Felty's syndrome
Lithium	Systemic lupus erythematosus
Marrow stimulation	*Nutritional*
Solid tumor	B_{12} and folate deficiencies
Heat stroke	Copper deficiency
Asplenia	
Sweet syndrome	
Qualitative Disorders	
Adhesion	Granule Disorders
Leukocyte adhesion deficiency (types 1, 2 and 3)	Myeloperoxidase deficiency
	Chediak–Higashi syndrome
Phagocyte Activation	Chronic granulomatous disease
Hyper-immunoglobulin E (Job syndrome)	Neutrophil-specific granule deficiency
Chronic granulomatous disease	Impaired chemotaxis
Chediak–Higashi syndrome	Shwachman–Diamond syndrome

when the ANC is <1000/μL. Agranulocytosis is a condition in which the ANC is <100/μL. Neutropenia can be either acquired or congenital, transient or chronic.

Transient Neutropenia

Transient neutropenia is usually associated with a viral infection. Epstein–Barr virus (EBV)-associated infectious mononucleosis is a common cause of transient neutropenia. Other causes include bacterial infections, autoimmune conditions, and medications, as outlined in detail in Table 17-6.[112] Medications cause neutropenia and/or agranulocytosis by direct toxicity on marrow granulocytic precursors or by an immune-mediated destruction of circulating neutrophils by drug-related antibodies. Specifically, medications (or their metabolites) bind to the membrane of the neutrophils, which causes production of T cells or antibodies against the neutrophil membrane. Monitoring the WBC count and differential periodically may be helpful to detect early signs of neutropenia and agranulocytosis secondary to certain drugs such as clozapine. If a patient is diagnosed with drug-induced neutropenia, the offending agent should be discontinued if possible and in the presence of fever and/or positive blood, urine, or sputum, broad-spectrum intravenous antibiotics should be initiated. Bone marrow aspiration and biopsy may be considered as well.

In the presence of an active infection, administration of granulocyte colony-stimulating factor (G-CSF) subcutaneously is recommended (dose of 5 μg/kg per day) in individuals

Table 17-6 Causes of transient neutropenia.

Infection	
Viral	Cytomegalovirus, Epstein–Barr virus, human immunodeficiency virus, influenza, parvovirus B19, hepatitis
Bacterial	*Brucella*, paratyphoid, tuberculosis, tularemia, typhoid; *Anaplasma phagocytophilum* and other rickettsia
Protozoan	*Plasmodium vivax, P. falciparum*
Medications	
Anticonvulsant	Carbamazepine, valproate
Antimicrobial	Sulfonamides, penicillin, trimethoprim/sulfamethoxazole
Antipsychotic	Clozapine, olanzapine, phenothiazines
Antirheumatic	Gold, levamisole, penicillamine
Antithyroid	Methimazole, propylthiouracil
Other	Aminopyrine, azathioprine, cyclophosphamide, colchicine, deferiprone, ganciclovir, methotrexate, levamisole-adulterated cocaine, rituximab, quinine
Immune	
Neonatal isoimmune	
Autoimmune	Felty's syndrome, rheumatoid arthritis, lupus erythematosus, Wegener's granulomatosis

with severe medication-induced neutropenia and suspected reduced marrow reserve.

Congenital Neutropenia

Congenital neutropenia typically presents at birth and is caused by a primary bone marrow failure syndrome. There are three main types of congenital neutropenia: severe, cyclic, and Shwachman–Diamond syndrome (SDS). In addition to these conditions, there are now other known primary genetic defects that may cause important chronic neutropenia (e.g., WHIM syndrome, GATA2 deficiency/MonoMAC syndrome, glycogen storage disease type 1b, Chediak–Higashi syndrome, and congenital cobalamin deficiencies). Congenital neutropenia manifests with otitis media, oropharyngeal symptoms, cellulitis, respiratory infections, and dermatologic infections, usually due to staphylococci and streptococci. Oral ulcers with pain are common. When the GI tract is affected, patients may present with symptoms similar to those seen in Crohn's disease. Bone marrow aspiration may be helpful to differentiate the various forms of congenital neutropenia.[113]

Severe Congenital Neutropenia

Severe congenital neutropenia (SCN) is a rare, genetically transmitted disorder with dominant, recessive, or X-linked inheritance. Newborns usually present with an ANC <200/μL and high monocytes. The neutropenia in SCN is thought to be caused by an increased myeloid cell apoptosis. G-CSF administration is the treatment of choice and hematopoietic cell transplantation is theoretically curative.[114]

Cyclic Neutropenia

Cyclic neutropenia is a rare, autosomal dominantly inherited condition due to mutations in the gene for neutrophil elastase (*ELANE*) on chromosome 19p13.3 (positive in 90%–100% of cases).[115] These patients usually present with a circulating neutrophil count that fluctuates with severe neutropenia, occurring every 21 days and lasting for 3–5 days. During these periods, patients report malaise, fever, gingivitis or periodontitis, aphthous-like ulcers, and pharyngitis, and are susceptible to bacterial infections. Symptoms usually improve when the ANC recovers to >500/μL. Blood tests during these episodes reveal low neutrophil counts. All children with confirmed cyclic neutropenia should be treated with G-CSF. Patients require monitoring for osteoporosis, regular dental care, and genetic counseling. Antibacterials may be needed in patients who are febrile during periods of neutropenia.

Shwachman–Diamond Syndrome

SDS is an autosomal recessive disorder that generally presents in newborns with bone marrow failure (including isolated neutropenia) and exocrine pancreatic dysfunction. As a result of the bone marrow dysfunction, patients with SDS are at a higher risk of developing myelodysplastic syndrome,

AA, and acute myeloid leukemia. SDS is also characterized by growth thrive, dental (enamel hypomaturation, hypocalcification, and hypoplasia), and skeletal abnormalities, and/or recurrent infections. The majority of patients present with mutations of the Shwachman–Bodian–Diamond syndrome (*SBDS*) gene. The diagnosis of SDS is made using clinical criteria (bone marrow failure and exocrine pancreatic insufficiency) or molecular findings (biallelic homozygous or compound heterozygous *SBDS* mutation). Laboratory testing includes CBC with differential, platelet count and tests of exocrine pancreatic function. No cure is available for SDS. Treatment is directed to the control of symptoms, with a multidisciplinary team including hematologists, gastroenterologists, geneticists, orthopedics, endocrinologists, immunologists, dentists, and others. G-CSF may be needed in cases of severe neutropenia and HSCT may be considered for those patients with severe pancytopenia.[116,117]

Chronic Idiopathic Neutropenia

Chronic idiopathic neutropenia is characterized by long episodes of neutropenia without a known cause. The ANC usually ranges from 500 to 1000/μL and is associated with monocytosis. Clinically, patients may be asymptomatic or develop gingivitis, periodontitis, early tooth loss, aphthous-like ulcers, and infections. Treatment to increase the neutrophil count is only for patients with severe recurrent infection-related complications.[118–120]

Agranulocytosis

Agranulocytosis is a rare disorder caused by medication use in 70% of cases. The majority of cases develop in the first 3–6 months after beginning the causing agent. Clinically, patients may present with oral ulceration and fever. Sepsis may occur in those cases with a sudden presentation. Agranulocytosis is not predictable and any patient on a medication known to cause agranulocytosis should be educated about this possible complication, and the drug discontinued as soon as the symptoms arise.[121,122]

Oral Health Considerations

In patients with significant neutropenia (ANC <1,000/μL) requiring urgent dental treatment, pre- and/or postoperative antibiotics may be initiated. A consult with the patient's managing physician concerning the risk of infection is indicated. In cases of severe neutropenia (ANC <500/μL), elective dental treatment should be postponed.

Leukemia

Leukemia is a clonal malignancy of any of the blood-forming cellular elements, consisting largely of immature precursors (blasts), preferentially involving the blood, bone marrow, or both. The disease course progresses over weeks to months, ultimately culminating in bone marrow failure. In 2019, the American Cancer Society estimated 61,780 new cases and 22,840 deaths attributable to leukemia, with a 62.7% 5-year survival rate. Leukemia was the 10th most common cancer to affect men of all races and represented 3.5% of all new cancer cases in the United States.[123] According to the most recent World Health Organization Classification of Tumors of Hematopoietic and Lymphoid Tissues, leukemia is classified based on clinical behavior (acute or chronic) and the primary hematopoietic cell line affected (myeloid or lymphoid) (Table 17-7). The four principal diagnostic categories are (1) acute myelogenous leukemia (AML); (2) acute lymphocytic leukemia (ALL); (3) chronic myelogenous leukemia (CML); and (4) chronic lymphocytic leukemia (CLL).[124]

Leukemic cells multiply at the expense of normal hematopoietic cell lines, resulting in marrow failure, altered blood cell counts, and, when untreated, death from infection, bleeding, or both. Leukemia is more common in adults than in children, with most chronic leukemia occurring in adults. Of acute leukemias, ALL is more common in children, whereas AML is more common in adults.

Leukemia is typically diagnosed via abnormal results on a full blood count. The peripheral granulocyte count is markedly elevated in chronic leukemia, but may be increased (with numerous blast forms), decreased, or normal in acute leukemia. Confirmation is determined with identification of abnormal hematopoietic cells in bone marrow. Additional techniques that may be used to further classify the type of leukemia include flow cytochemical staining (myeloperoxidase, Sudan black B), cytometric immunophenotyping, and genetic analysis.

Patients affected by leukemia may experience oral bleeding and are at a higher risk of infection. All patients should be instructed to maintain optimal oral hygiene by their oral healthcare professional. Precautions to be followed by dental providers are provided for each hematologic malignancy in the sections below.

Acute Lymphoblastic Leukemia

ALL, also known as acute lymphocytic leukemia or acute lymphoid leukemia, is the most common malignant disorder in children. ALL and lymphoblastic lymphoma (LBL) fall under the same classification and diagnosis. In the US, ALL/LBL is more frequent among Hispanic and Whites, compared to Blacks and Asians, with a peak incidence at 2–5 years of age and a male-to-female ratio of 55% to 45%.[123]

ALL/LBL is associated with genetic factors (such as Down syndrome), although the majority of patients have no known inherited cause. Radiation and exposure to specific chemicals have been linked with ALL in a small subset of children.[125] Large genome-wide association studies have shown

Table 17-7 World Health Organization (WHO) classification of myeloid neoplasms and acute leukemia.

Myeloproliferative Neoplasms (MPN)
Chronic myeloid leukemia (CML), *BCR-ABL1+*
Chronic neutrophilic leukemia (CNL)
Polycythemia vera (PV)
Primary myelofibrosis (PMF)
PMF, prefibrotic/early stage
PMF, overt fibrotic stage
Essential thrombocythemia (ET)
Chronic eosinophilic leukemia, not otherwise specified (NOS)
MPN, unclassifiable
Mastocytosis
Myeloid/Lymphoid Neoplasms with Eosinophilia and Rearrangement of *PDGFRA*, *PDGFRB*, or *FGFR1*, or with *PCM1-JAK2*
Myeloid/lymphoid neoplasms with *PDGFRA* rearrangement
Myeloid/lymphoid neoplasms with *PDGFRB* rearrangement
Myeloid/lymphoid neoplasms with *FGFR1* rearrangement
Myelodysplastic/Myeloproliferative Neoplasms (MDS/MPN)
Chronic myelomonocytic leukemia (CMML)
Atypical chronic myeloid leukemia (aCML), BCR-ABL1–
Juvenile myelomonocytic leukemia (JMML)
MDS/MPN with ring sideroblasts and thrombocytosis (MDS/MPN-RS-T)
MDS/MPN, unclassifiable
Myelodysplastic Syndromes (MDS)
MDS with single-lineage dysplasia
MDS with ring sideroblasts (MDS-RS)
MDS-RS and single-lineage dysplasia
MDS-RS and multilineage dysplasia
MDS with multilineage dysplasia
MDS with excess blasts
MDS with isolated del(5q)
MDS, unclassifiable
Myeloid Neoplasms with Germ Line Predisposition
Acute Myeloid Leukemia (AML) and Related Neoplasms
AML with recurrent genetic abnormalities
AML with t(8;21)(q22;q22.1);*RUNX1-RUNX1T1*
AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22);*CBFB-MYH11*
Acute promyelocytic leukemia (APL) with *PML-RARA*
AML with t(9;11)(p21.3;q23.3);*MLLT3-KMT2A*
AML with t(6;9)(p23;q34.1);*DEK-NUP214*
AML with inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2); *GATA2*, *MECOM*
AML (megakaryoblastic) with t(1;22) (p13.3;q13.3);*RBM15-MKL1*
AML with mutated *NPM1*
AML with biallelic mutations of *CEBPA*
AML with myelodysplasia-related changes
Therapy-related myeloid neoplasms
AML, NOS

(*Continued*)

Table 17-7 (Continued)

AML with minimal differentiation
AML without maturation
AML with maturation
Acute myelomonocytic leukemia
Acute monoblastic/monocytic leukemia
Pure erythroid leukemia
Acute megakaryoblastic leukemia
Acute basophilic leukemia
Acute panmyelosis with myelofibrosis
Myeloid sarcoma
Myeloid proliferations related to Down syndrome
Transient abnormal myelopoiesis (TAM)
Myeloid leukemia associated with Down syndrome
Blastic Plasmacytoid Dendritic Cell Neoplasm

Source: Arber DA, Orazi A, Hasserjian R, et al. The 2016 revision to the World Health Organization classification of myeloid neoplasms and acute leukemia. *Blood*. 2016;127(20):2391–2405. *Blood*. 2016;128(3):462–463. doi:10.1182/blood-2016-06-721662. © 2016, American Society of Hematology.

polymorphic variants of the *ARID5B*, *CEBPE*, *GATA3*, and *IKZF1* genes being associated with an increased risk of ALL. Rare germline mutations in *ETV6* and *PAX5* are related to familial ALL.

The clinical presentation of ALL/LBL is nonspecific. Patients may present with hepatomegaly (64%) and/or splenomegaly (61%). Lymphadenopathy is present in 50% of patients; fever, fatigue, and musculoskeletal pain are frequent at the time of diagnosis. Oral manifestations of ALL/LBL include gingival bleeding, ulcers, and gingival enlargement. ALL/LBL manifests with bleeding, bruising, and petechiae in the setting of thrombocytopenia (<100,000/μL). The WBC count may be low, normal, or high, although it is typically <10,000/μL in 50% and >50,000/μL in 20% of children. Children with persistent fever, pallor, bleeding/bruising, bone pain, hepatosplenomegaly, and/or lymphadenopathy should be evaluated for possible ALL/LBL.[125]

Laboratory tests include a CBC with differential, a review of the peripheral smear, and bone marrow biopsy. Morphology is variable, with small blasts, chunky chromatin, small nucleoli, and scant cytoplasm. T-lineage

lymphoblasts are positive for cytoplasmic or surface CD3, and negative for myeloperoxidase and B-cell antigens. B-lineage lymphoblasts are often positive for B-cell markers such as CD19, cytoplasmic CD22 and cytoplasmic CD79a; negative for CD3 and myeloperoxidase.

Treatment consists of induction, consolidation, and maintenance therapy. The goal of induction to eradicate all the leukemic cells (complete remission) from the blood and bone marrow. Induction therapy lasts 4–6 weeks and includes a therapy regimen with vincristine, corticosteroids, and asparaginase. Anthracycline may be added in high-risk patients. Response is measured with sequential bone marrow aspirates. The majority of t(9;22)/BCR-ABL1-negative ALL patients enter complete remission after completion of induction therapy. t(9;22)/BCR-ABL1-positive ALL children benefit from the administration of tyrosine kinase inhibitors (TKI; e.g., dasatinib or imatinib).[126,127]

Consolidation therapy is started after complete remission is achieved. Consolidation therapy is needed because a few leukemic lymphoblasts may still be present in the bone marrow despite evidence of complete remission. Consolidation therapy lasts 6–8 weeks and includes several different drug combinations (such as cytarabine, methotrexate, alkylating agents, or anthracyclines).

After completion of the consolidation therapy, children receive maintenance chemotherapy with daily oral 6-mercaptopurine and weekly methotrexate, with periodic vincristine, prednisone, and intrathecal therapy. Allogeneic hematopoietic cell transplantation remains an option for high-risk ALL/LBL patients such as t(9;22)/BCR-ABL1-positive ones (even when treated with a TKI), those with a poor initial response to treatment, and adults with MLL gene rearrangements (e.g., t[4;11]). Survivors are then monitored on a regular basis for long-term complications.[128] More recently, tisagenlecleucel, a CAR T cell immunotherapy, was FDA approved as standard of care for relapsed or refractory ALL up to age 25.[129]

Acute Myeloid Leukemia

AML is a hematopoietic neoplasm characterized by a clonal proliferation of precursor of the myeloid lineage that cannot differentiate into mature hematopoietic cells.[130,131] AML blasts have morphologic, cytochemical, and/or immunophenotypic characteristics of granulocytes, monocytes, megakaryocytes, erythrocytes, or their precursors.

AML represent the most common acute leukemia in adult patients, with a median age at diagnosis of 65 years and an incidence of 2–20 per 100,000 population. Acute promyelocytic leukemia (APL) is a specific subset of AML that has a much more favorable cure rate and an overall survival rate of 90%–95%, especially in those <60 years.[132] Risk factors for AML include genetic changes (such as familial mutations of *CEBPA*, *DDX41*, *RUNX1*; Fanconi anemia; Bloom's syndrome; and trisomy 21) and exposure to environmental factors, including ionizing radiation, chemotherapy, tobacco, and certain chemicals. Some cases of AML arise from myelodysplastic syndrome and other myeloproliferative neoplasms.[131]

Patients with AML usually present with signs and symptoms secondary to pancytopenia, fatigue, and generalized weakness. Infections, ecchymosis, and bleeding are common findings. The dentist should be familiar with the oral signs and symptoms associated with AML: patients may present with gingival enlargement, oral mucosal nodules, and ulcerations. APL is associated with an increased risk of bleeding with bruising, including gingival bleeding. Approximately 50% of patients with a diagnosis of AML demonstrate cytogenetic abnormalities. Most peripheral smears show large blasts, big nucleoli, a moderate amount of cytoplasm, and Auer rods. Flow cytometry of the marrow aspirate or peripheral blood express CD34, HLA- DR, CD117, CD13, and CD33. According to the World Health Organization classification system, blast forms must account for at least 20% of the total cellularity of the bone marrow.[130]

Treatment of AML varies depending on the risk profile associated with age (Table 17-8).[133] For medically fit older adults (>60 years), induction therapy is with cytarabine and daunorubicin ("7+3" therapy). Patients with adverse prognosis AML require CPX-351 or a hypomethylating agent. Subsequent treatment is guided by pretreatment determinants and response to initial therapy. In poorer-risk groups, when age, comorbidities, and donor availability permit, an

allogeneic stem cell transplant (SCT) is also a consideration. A proportion of these patients will be cured by chemotherapy alone; however, determining which patient is likely to relapse and hence benefit from allogeneic SCT in first remission is not easily defined. For medically frail patients, therapy is focused primarily on relief of symptoms, and improving quality of life.[134] For the APL patient, treatment is aimed at reversing coagulopathy, with aggressive plasma and platelet support, and a distinct treatment regimen of all-trans retinoic acid (ATRA), in combination with anthracycline-based chemotherapy and intensification during consolidation with intermediate- or high-dose cytarabine and addition of arsenic trioxide during both induction and consolidation.[131]

Chronic Lymphocytic Leukemia

Chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL) is a lymphoproliferative disorder characterized by an accumulation of monoclonal B lymphocytes due to a defect in apoptosis. It is associated primarily with cellular accumulation rather than proliferation and rarely transforms to an acute leukemia. CLL is considered to be identical to SLL (an indolent non-Hodgkin lymphoma); the term SLL is used when the disease is present mainly in the nodes, and CLL when the disease is in the blood.[135,136]

CLL is a disease of the elderly (median age at diagnosis 70 years) and patients often die of other causes before succumbing to CLL. CLL is associated with inexorable progression and concomitant immune deficiency. CLL is the most frequent adult leukemia in Western countries and represents 25%–30% of all leukemias in the United States. In 2019, there are likely to have been 20,720 new cases of CLL/SLL in the United States (7840 females), with 191,000 cases worldwide.[123] Staging is based on the extent of lymph node, liver, or spleen involvement and anemia, thrombocytopenia, or both. The Rai and Binet clinical staging systems are commonly used in the United States and Europe, respectively (Table 17-9).[137,138]

The majority of patients present with no symptoms and the CBC reveals absolute lymphocytosis. Some cases may have painful lymph nodes. A small subset of patients (5%–10%) present "B" symptoms of lymphoma, which include (1) weight loss ≥10% of body weight within the previous six months; (2) fevers for ≥2 weeks with no evidence of infection; (3) severe night sweats; and (4) fatigue.

A diagnosis of CLL is made when patients present with an absolute B lymphocyte count in the peripheral blood ≥5000/μL for at least 3 months. The peripheral blood smear shows lymphocytosis with small leukemic cells, mature-appearing lymphocytes with a darkly stained nucleus, partially condensed (clumped) chromatin, and indiscernible nucleoli. Flow cytometry demonstrates expression of the B cell–associated

Table 17-9 Rai and binet clinical staging.

Rai Staging System		
Risk Group	**Clinical Features**	**Median Life Expectancy (Years)**
Low risk (Rai stage 0/I)	Lymphocytosis without cytopenia, lymphadenopathy, or splenomegaly	13
Intermediate risk (Rai stage II)	Lymphocytosis, lymphadenopathy, and/or splenomegaly, but without cytopenia	8
High risk (Rai stage III/IV)	Lymphocytosis and cytopenia (a hemoglobinvlevel of ≤11 g per dL and/or a platelet count of ≤100,000 cells per μL)	2
Binet Staging System		
Low risk (Binet stage A)	<3 palpably enlarged sites without cytopenia	13
Intermediate risk (Binet stage B)	3+ palpably enlarged sites without cytopenia	8
High risk (Binet stage C)	Cytopenia (a hemoglobin level of ≤10 g per dL and/or a platelet count of ≤100,000 cells per μL)	2

Source: Kipps TJ, Stevenson FK, Wu CJ, et al. Chronic lymphocytic leukaemia. *Nat Rev Dis Prim*. 2017;3:16096. doi:10.1038/nrdp.2016.96. © 2016, Springer Nature.

antigens CD19, CD20, and CD23. The staining intensity of CD20 is usually low/dim. There is expression of CD5, an antigen expressed on T cells and subsets of mature B cells, as well as low levels of surface membrane immunoglobulin (i.e., SmIg weak). The immunoglobulin is most often IgM or both IgM and IgD, and typically only a single immunoglobulin light chain is expressed (i.e., either kappa or lambda but not both), confirming the clonal nature of these cells.[136,139]

Treatment for CLL is not necessary in all patients, since the survival rates for CLL are similar to those observed in the general population. Observation is usually indicated for patients with early-stage asymptomatic CLL. Treatment is recommended for "active disease" in patients with advanced-stage, high tumor burden, disease-related anemia or thrombocytopenia, or severe disease-related "B" symptoms.[139] Various combination regimens may be used, although fludarabine, a nucleoside analog, is the most frequently used first-line agent in CLL along with ibrutinib. Alemtuzumab is an FDA-approved monoclonal antibody directed at CD52 approved for CLL patients as first-line therapy and for patients with fludarabine-refractory CLL. Patients refractory to both fludarabine and alemtuzumab may be receiving ofatumumab, an anti-CD20 monoclonal antibody. Other FDA-approved agents include venetoclax (a selective inhibitor of the B-cell lymphoma 2 [Bcl-2] regulator protein) for patients with CLL with 17p deletion; and the combination of venetoclax and obinutuzumab for patients with previously untreated CLL.[140]

Patients with CLL are at a greater risk of developing infections, autoimmune disorders, or secondary malignancies. One of the most severe complications of CLL is the transformation to diffuse large B-cell lymphoma or Hodgkin lymphoma, which occurs in 2%–10% of CLL cases (Richter's transformation).

Oral Health Considerations

Oral manifestations at presentation of CLL are infrequent and generally involve bleeding or infection. CLL is a relatively indolent chronic hematologic malignant disease that often has a prognosis compatible with relatively normal dental treatment planning. Patients in late-stage disease, with severe thrombocytopenia (<50,000/μL), should be considered for platelet supplementation prior to dental surgery.

Chronic Myelogenous Leukemia

CML represents a hyperproliferation of the bone marrow due to a "partial" transformation of the HSCs. CML displays the t(9;22) chromosome translocation. This translocation results in the *Bcr-Abl1* fusion gene that produces Bcr-Abl tyrosine kinase, an abnormal protein that causes the excess WBCs typical of CML.[141] The prevalence of CML has been increasing in Western countries, with 1–2 new cases per 100,000 each year and a slight male predominance.[142]

CML has a chronic indolent phase (present in 85% of patients), an accelerated phase, and a blast crisis. During the chronic indolent phase, there is proliferation of a partially transformed hematopoietic stem cell, resulting in increased numbers of cells. In the accelerated phase neutrophil differentiation becomes increasingly impaired and leukocyte counts are more challenging to control with therapy. The constant proliferative drive promotes secondary genetic events that contribute to the development of the acute phase (blast crisis). Bone marrow aspiration and biopsy show granulocytic hyperplasia with a maturation pattern that reflects what is seen in the peripheral smear.[143]

The treatment of CML depends on the specific disease phase. TKIs are the first-line treatment for CML. Imatinib was the first agent approved for patients in the chronic phase. Imatinib competitively occupies the adenosine triphosphate-binding site required for BCR-ABL to phosphorylate its substrates; consequently, signal transduction is inhibited, and the leukemic cells die.[144,145] Second-generation TKIs (nilotinib, dasatinib, bosutinib) have demonstrated faster responses, but no improvement in overall survival. However, neither can inhibit BCR-ABL T315I. Several other TKIs are also in development, including bosutinib and ponatinib; the latter is the first TKI with activity against the T315I mutation. Other drugs that are active against T315I include omacetaxine mepesuccinate (homoharringtonine), a protein synthesis inhibitor that induces apoptosis through its effect on MCL1, a member of the BCL2 family of antiapoptotic proteins. The prognosis in the accelerated or blast phase is poor and allogeneic HCT is the treatment of choice. CML patients are monitored on a regular basis by quantitative polymerase chain reaction (Q-PCR) measurement in the peripheral blood of BCR-ABL1 transcripts.[146–148]

Lymphomas

Non-Hodgkin Lymphoma

Lymphomas are malignancies of normal lymphoid cells that originate in lymphoid tissues. Non-Hodgkin lymphoma (NHL) includes a group of malignant neoplasms variously derived from T-cell progenitors, B-cell progenitors, mature T cells, mature B cells, or natural killer cells (in sporadic cases). In the United States, NHL is one of the most prevalent cancers. In 2019, the American Cancer Society estimated 74,200 new cases (41,090 men).[123]

Clinically, NHL presents with various signs and symptoms depending on the type of lymphoma and region involved. Lymphomas are classified into aggressive and indolent[149] based on a combination of morphology, immunophenotype, genetic, molecular, and an expanded concept of clinical features such as age and tumor location, as defining criteria in several newly recognized categories (Table 17-10).

Table 17-10 World health organization classification of non-hodgkin lymphoma.

The Indolent Lymphomas
B-Cell Neoplasms
Small lymphocytic lymphoma/B-cell chronic lymphocytic leukemia
Lymphoplasmacytic lymphoma (± Waldenstrom's macroglobulinemia)
Plasma cell myeloma/plasmacytoma
Hairy cell leukemia
Follicular lymphoma (grade I and II)

T-Cell Neoplasms
Adult T-cell lymphoma/leukemia
Precursor T-lymphoblastic leukemia/lymphoma

Source: Modified from UpToDate, December 2019.

Examples of aggressive lymphomas include diffuse large B-cell lymphoma, Burkitt lymphoma, adult T-cell leukemia-lymphoma, precursor B- and T-lymphoblastic leukemia/lymphoma, and other peripheral T-cell lymphomas. Indolent lymphomas include chronic lymphocytic leukemia/small lymphocytic lymphoma, follicular lymphoma, and splenic marginal zone lymphoma. The aggressive types manifest with a rapid growing mass, "B" symptoms (such as profound night sweats, unexplained weight loss, and fever >100.4 °F), and/or elevated lactic acid dehydrogenase (LDH) and uric acid serum levels. Lymphomas that have indolent presentations present with slow-growing lymphadenopathy, splenomegaly, hepatomegaly, or cytopenias. Extranodal sites include the GI tract, skin, and bone. Rarely, kidney, bladder, adrenal glands, heart, lungs, breast, testes, and thyroid may be affected too.

NHL is known to be associated with autoimmune diseases including Sjögren's syndrome, rheumatoid arthritis, and systemic lupus erythematosus. Both viral and bacterial infections are also associated with several lymphomas. *Helicobacter pylori* infection has been associated with most gastric mucosa–associated lymphoid tissue (MALT) lymphoma, human T-cell leukemia/lymphoma virus with adult T-cell lymphoma, EBV with Burkitt lymphoma (see below) and nasal NK-T-cell lymphoma, *Chlamydia psittaci* and ocular adenexal lymphomas, *Borrelia burgdorferi* and *Chlamydia psittacosis* with marginal zone lymphomas, and hepatitis C with splenic or large-cell lymphomas.

Diagnosis is made with an excisional biopsy of an involved lymph node or tumor in another organ, although cutting-needle biopsy may be acceptable. Following the diagnosis, patients are staged through a careful history and clinical examination, and imaging with a combined positron emission tomography–computed tomography (PET-CT). A bone marrow biopsy is usually performed to identify bone marrow involvement in indolent lymphomas (e.g., follicular lymphoma). Currently, there are a variety of systems for predicting prognosis and making a treatment recommendation. The first of these systems was the International Prognostic Index (IPI; panel 2) which was developed for aggressive B-cell and T-cell lymphomas, but is predictive in fundamentally all other types of NHL.[150]

NHL is a radiosensitive tumor; thus, radiotherapy is used for all subtypes and stages. Patients with indolent lymphoma may be cured with radiotherapy; for those with aggressive disease, radiotherapy is used after or to consolidate chemotherapy and for palliative treatment. The optimal radiation dose in indolent and aggressive lymphoma remains unclear. Adults with NHL who were treated either with standard high-dose (HD) radiation (40–45 Gy in both indolent and aggressive NHL) or low-dose (LD) radiation (24 Gy in indolent NHL or 30 Gy in aggressive NHL) experienced the same efficacy with both radiation schemes. While safety was not statistically significantly reduced with the lower radiation dose, the lower dose might influence long-term outcomes positively. Chemotherapy of NHL differs between indolent or aggressive lymphoma. Additionally, the IPI influences the therapy option (such as watch and wait, chemotherapy, radiotherapy, or combined modality treatment). Treatment with CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) improves overall survival, is associated with reduced toxicity, and is the mainstay of the treatment of aggressive and indolent NHL.

Diffuse large B-cell lymphoma (DLBCL) accounts for approximately 40% of all NHL cases. Trials have demonstrated that the addition of a monoclonal antibody such as rituximab to CHOP (CHOP-R; typically administered every 3 weeks) is associated with increased overall survival. Recent studies have shown that doxorubicin, cyclophosphamide, vindesine, bleomycin, prednisone, and rituximab (ACVBP-R) are superior to CHOP-R in young patients with DLBCL (3-year progression-free survival of 87% compared to 73%). In addition, infusional chemotherapy regimens including etoposide, prednisone, vincristine, cyclophosphamide, doxorubicin, and rituximab (EPOCH-R) might be superior to CHOP-R. The FDA approved the use of CAR T-cell therapy for patients with relapsed or refractory DLBCL, high-grade B-cell lymphoma, and DLBCL that arises from follicular lymphoma.[151,152]

Double-hit lymphomas are at the interface between DLBCL and Burkitt lymphoma, although some diffuse large B-cell lymphomas fit into this category. They show mutations of both *MYC* and either *BCL6* or *BCL2*. These are typically seen in lymphoma patients that respond poorly to standard chemotherapy regimens, present with a lower incidence of complete remission, and frequently progress despite treatment. Patients often undergo autologous hemopoietic stem cell transplants when they are in complete remission, with controversial results. In general, patients who do not respond to an autologous transplant may occasionally benefit from an allogeneic hemopoietic stem cell transplant.

Follicular lymphoma (FL) accounts for 25% of all NHL and follows an indolent course, so patients are usually in advanced stages at diagnosis. For such patients, CHOP-R is standard therapy. Patients with indolent B-cell NHL also receive chemotherapy. In patients with advanced-stage indolent B-cell NHL and FL grade 3B, there is currently no standard therapy, but CHOP-R shows promising results as well. There is no evidence that HD radiation therapy improves overall survival in newly diagnosed or relapsed FL patients, but its prolongation of progression-free survival favors its use. For patients with relapsed FL, autologous and allogeneic haemopoietic stem cell transplantation may be curative. Several new treatment approaches are available for patients with relapsed FL, such as idelisilib and ibrutinib, lenalidomide, venetoclax, PD-1 or PDL-1 inhibitors.[153]

Cutaneous T-cell lymphomas (CTCL) are a clinically and histologically distinct group of T-lymphocyte malignancies that manifest primarily in the skin. They represent about 13% of all NHL. Mycosis fungoides and Sézary syndrome are the most prevalent subtypes of CTCL, which remains incurable by conventional therapies. Although initial response rates on mono- or poly-chemotherapeutic regimens are high, remissions are often short-lived and the prolongation of lifespan is questionable. Furthermore, there are considerable toxicities associated with these regimens. Therefore, therapies focus on the effect of allogeneic stem cell transplantation as the only potential cure and alternative to conventional therapy for advanced primary cutaneous T-cell lymphoma.[154]

Oral Considerations

Primary NHL of the oral region is rare and may present as a gingival or mucosal tissue swelling or mass. NHL may also manifest intrabony involvement characterized by osseous rarefaction around the roots of symptomatic teeth, mimicking toothache. In such a case, extraction of the associated tooth is followed by rapid growth of the tumor from the nonhealing extraction site. Nerve invasion can lead to paresthesia or anesthesia of related oral mucosal tissue. NHL may also present as a nonhealing mucosal ulceration with ill-defined borders, a benign-appearing gingival lesion, and a mucosal lesion resembling a vesiculobullous disease. Involvement of the oral mucosa in cutaneous T-cell lymphoma (mycosis fungoides) is uncommon and is usually associated with a poor prognosis.

Hodgkin Lymphoma

Hodgkin lymphoma (HL) is rare (0.5% of all cancers) and typically occurs in adolescents and young adults. In 2019, 8110 new cases of HL were expected. HL has a bimodal age distribution, between 15 and 30 years and in patients older than 55 years.[123] The incidence has been on the rise in industrialized countries. Two types of HL exist: classic HL and the rare nodular lymphocyte predominant HL (NLPHL). The classic type is then subdivided into nodular sclerosis (the most common), mixed-cellularity, lymphocyte-depleted, and lymphocyte-rich HL.[155]

The lymphocyte-depleted HL and mixed cellularity are more common in patients of lower socioeconomic status and are often associated with EBV, while the nodular sclerosis HL has been associated with a high standard of living. Risk factors for HL include immunodeficiency, solid organ or stem cell transplantation, and use of immunosuppressive drugs. Histologically, HL has Reed–Sternberg cells (multinucleated cells surrounded by inflammatory cells). Immunophenotyping helps with differentiating between classic HL and NLPHL. In the classic form the Reed–Sternberg cells typically express CD15 and CD30 and lack expression of B-cell markers, CD19, CD20, and CD79b, although infrequently B-cell antigens can be seen on a subset of cells.[155]

Children with HL may present with lymphadenopathy (cervical, supraclavicular, axillary, or, rarely, inguinal), fatigue, anorexia, weight loss, and mediastinal mass (observed in 75% of cases on a chest radiograph).[156] Pediatric patients usually receive chemotherapy with or without radiotherapy. Regimens include ABVE-PC (doxorubicin, bleomycin, vinblastine, etoposide-prednisone cyclophosphamide) or OEPA

(vincristine, etoposide, prednisone, doxorubicin) with COPDAC (cyclophosphamide, vincristine, prednisone, and dacarbazine) in intermediate/high-risk HL patients. When used, radiotherapy is administered at 15-25 Gy.[157]

HL patients are staged using the Ann Arbor staging system with Cotswold modification. More recently, the Lugano classification incorporated the use of fluorodeoxyglucose (FDG) PET-CT for staging (Table 17-11). HL is highly curable, and treatment depends on age and the severity of the disease. Patients with early-stage disease (stages I–II) are treated with combined modality strategies utilizing abbreviated courses of combination chemotherapy followed by involved-field radiation therapy (IFRT). For advanced stages (stages III–IV), ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) is the most widely used regimen in the United States, and escalated BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone) is used commonly in Europe, with improved progression-free survival when compared to ABVD, but with increased toxicity, including infection and infertility. Radiation therapy may be used for specific patients as consolidation. Stanford V (doxorubicin [Adriamycin], mechlorethamine [nitrogen mustard], vincristine, vinblastine, bleomycin, etoposide, prednisone) is another regimen available for advanced stages. Patients with a second relapse or progressive disease are candidates for high-dose chemotherapy and autologous hematopoietic cell transplantation. For patients who fail high doses of chemotherapy with autologous hematopoietic cell transplantation, brentuximab vedotin, an anti-CD-30 antibody conjugated to an antimicrotubule drug, is recommended. In 2016, the FDA approved nivolumab for the treatment of classical HL in patients who have relapsed or progressed after an auto transplant and brentuximab vedotin and pembrolizumab for refractory classic HL, or HL patients who have failed at least three prior treatments.[158,159]

Table 17-11 Lugano classification for staging of lymphomas.

Stage I—Involvement of a single lymph node region (e.g., cervical, axillary, inguinal, mediastinal) or lymphoid structure such as the spleen, thymus, or Waldeyer's ring.
Stage II—Involvement of two or more lymph node regions or lymph node structures on the same side of the diaphragm. Hilar nodes should be considered to be "lateralized" and, when involved on both sides, constitute stage II disease. For the purpose of defining the number of anatomic regions, all nodal disease within the mediastinum is considered to be a single lymph node region, and hilar involvement constitutes an additional site of involvement. The number of anatomic regions should be indicated by a subscript (e.g., II-3).
Stage III—Involvement of lymph node regions or lymphoid structures on both sides of the diaphragm. This may be subdivided stage III-1 or III-2: stage III-1 is used for patients with involvement of the spleen or splenic hilar, celiac, or portal nodes; and stage III-2 is used for patients with involvement of the paraaortic, iliac, inguinal, or mesenteric nodes.
Stage IV—Diffuse or disseminated involvement of one or more extranodal organs or tissue beyond that designated E, with or without associated lymph node involvement.
All cases are subclassified to indicate the absence (A) or presence (B) of the systemic symptoms of significant unexplained fever, night sweats, or unexplained weight loss exceeding 10% of body weight during the 6 months prior to diagnosis.
The designation "E" refers to extranodal contiguous extension (i.e., proximal or contiguous extranodal disease) that can be encompassed within an irradiation field appropriate for nodal disease of the same anatomic extent. More extensive extranodal disease is designated stage IV.
Bulky disease—a single nodal mass, in contrast to multiple smaller nodes, of 10 cm or ≥⅓ of the transthoracic diameter at any level of thoracic vertebrae as determined by CT; record the longest measurement by CT scan. The term "X" (used in the Ann Arbor staging system) is no longer necessary.
The subscript "RS" is used to designate the stage at the time of relapse.
Patients can be clinically or pathologically staged. Splenectomy, liver biopsy, lymph node biopsy, and/or bone marrow biopsy are mandatory for the establishment of pathologic stage. The pathologic stage at a given site is denoted by a subscript (e.g., M = bone marrow, H = liver, L = lung, O = bone, P = pleura, and D = skin).

Oral Health Considerations

The radiation fields for HL that involve bilateral cervical nodes have the potential to result in damage to the salivary glands. These include (1) involved-field RT when lymphoma involves the oral structures or Waldeyer's ring; (2) mantle; and (3) mini or modified mantle. Of these, the mantle field is the largest and involves radiation therapy to all supradiaphragmatic lymph node regions, including the following groups: bilateral cervical, supraclavicular, bilateral axillae, mediastinal, and bilateral lung hilar, treated contiguously. Mini or modified mantle typically refers to radiation therapy covering bilateral cervical, supraclavicular, and axillary lymph nodes. Because the parotid glands are usually not in the field of radiation, the risk of radiation-induced caries is minimal; however, topical fluoride varnish, gel, or 5000 ppm fluoride toothpaste can be used for caries prevention if the patient's mouth appears to be dry or the caries rate appears elevated. The risk of osteoradionecrosis is very low due to low radiation doses delivered and is limited to the inferior border and angle of the mandible. HL survivors who received mediastinal radiation 10–20 years earlier may develop late-onset heart disease characterized by heart valve pathology and accelerated atherosclerosis.

Burkitt Lymphoma

Early in the twentieth century, Sir Albert Cook, a missionary physician in Uganda, and other medical staff working in west, east, and central Africa noted the high frequency of

jaw tumors and childhood lymphomas. Years later, Denis Burkitt, a surgeon working in Africa, further described these jaw swellings, which have come to be known as Burkitt lymphoma (BL). Burkitt lymphoma is an aggressive B-cell NHL that manifests with fast-growing masses and/or a leukemia that can have substantial clinical and morphologic overlap with ALL/LBL.[160] A large majority of BL is characterized by the translocation involving chromosome 8 and/or MYC rearrangement, but in the 2016 World Health Organization revision, a Burkitt-like lymphoma with an alternative 11q aberration was included as a provisional entity. Three variants exist: endemic (African), sporadic (nonendemic), and immunodeficiency associated.[161]

Endemic BL is present in New Guinea and equatorial Africa with an incidence 50 times higher than in the United States, with 3–6 cases per 100,000 children each year. The sporadic form is observed in Western European countries and in the United States, representing 30% of all pediatric lymphomas and less than 1% of adult NHL in the United States. Most patients are males and Caucasian. The immunodeficiency-associated variant is linked with patients affected by HIV (usually those with a CD4 count >200 cells/μL). Chronic EBV infection is associated with virtually all cases of endemic BL and a few sporadic and immunodeficiency-associated BLs. The expression of the proto-oncogene MYC (located on chromosome 8q24) that encodes the MYC protein transcription factor plays a role in the development of BL. This transcription factor is responsible for modulation of the expression of target genes that regulate many cellular processes (such as cell growth and division, immortalization, Warburg metabolism, and apoptosis).

Patients present with fast-growing masses and demonstrate tumor lysis with different clinical manifestations depending on the BL form. Patient with endemic (African) BL usually have a facial bone or jaw tumor, which can spread to other sites such as breast, kidney, mesentery, ovary, testis, and meninges. The bone marrow is involved in 10% of cases at initial diagnosis, but becomes a frequent complication of refractory BL cases or recurrent BL. Other oral manifestations include tooth mobility and pain, intraoral swelling of the mandible and maxilla, and anterior open bite. Mobile teeth may be present even in the absence of clinically detectable jaw tumors. Radiographic features on panoramic images include resorption of alveolar bone; loss of lamina dura; enlargement of tooth follicles; destruction of the cortex around tooth crypts; displacement of teeth and tooth buds by the enlarging tumor, resulting in the impression of "teeth floating in air"; and sun-ray spicules as bone forms perpendicular to the mandible from subperiosteal growth.

The sporadic variant affects the abdomen with ascites and involvement of the stomach, cecum and/or mesentery, distal ileum, kidney, breast, testis, ovary, bone marrow, or CNS (15% of cases). Patients may report symptoms similar to those in acute appendicitis or intussusception. The bone marrow is involved in 30% of cases, while the jaw or facial bones are involved in 25% of patients with localized lymphadenopathy. Patients affected by immunodeficiency-related BL usually present with signs or symptoms associated with the immunodeficiency (e.g., immunodeficiency secondary to hematopoietic or solid organ transplantation, AIDS). The bone marrow, CNS, and lymph nodes are often involved.

A diagnosis of BL is made with a biopsy of the tissue involved (e.g., abdominal mass or other extranodal site), along with flow cytometry, chromosome analysis using Giemsa banding or FISH, and immunostains. The disease is staged according to a blood smear, CSF, bone marrow biopsy, and presence/absence of HIV infection. Histopathology consists of intermediate-sized B cells (12 μ) with high nuclear-to-cytoplasmic ratio. Nuclear contours are round to oval without cleaves or folds, a key feature in the distinction from diffuse large-cell lymphoma. Nucleoli are typically multiple, small to intermediate in size, and the nuclear chromatin is relatively immature, being finely granular. The characteristic starry sky is due to scattered tingible body–laden macrophages that contain apoptotic tumor cells. BL cells express surface IgM and B cell-lineage antigens (CD19, CD20, CD22, CD79a), as well as CD10, HLA-DR, and CD43, but the cells are generally negative for Bcl-2, CD5, and TdT.[162]

BL is aggressive, and once a diagnosis is made there is some urgency for an intensive chemotherapy regimen. Treatment can be divided into three broad group of patients. Patients with a localized tumor that was completely removed with a surgical procedure may be started on a short course of chemotherapy (<2 months). Commonly used drugs are cyclophosphamide, vincristine, prednisone, and doxorubicin. A regimen with dose-adjusted etoposide, prednisolone, vincristine, cyclophosphamide, doxorubicin, and regular- or double-dose rituximab (DA-EPOCH-R or -RR) is less toxic than standard BL drugs. Patients with a mass that cannot be surgically removed and does not involve the CNS, or more than 25% of the bone marrow, received chemotherapy for 4 months with the same agents used for the first group, with the addition of high-dose methotrexate and low-dose cytarabine. Rituximab is often included in the treatment and has been shown to improve the outcome for patients with a high LDH serum level. Several doses of chemotherapy into the spinal fluid are also administered as part of the treatment. Patients with CNS involvement, or at least 25% of bone marrow involvement, receive 6 months of chemotherapy with the addition of high-dose cytarabine and rituximab. Children with refractory or relapsed BL are difficult to treat successfully and should be encouraged to participate in clinical trials. Alternative agents are available for these patients and include ifosfamide, carboplatin, and etoposide

and rituximab followed by high-dose chemotherapy and either auto or all HSCT. New monoclonal antibodies (ofatumumab, blinatumomab, inotuzumab ozogamicin) and targeted agents against c-MYC may be effective for treatment of BL and are under investigation.[163–165]

Myelodysplastic Syndrome

The myelodysplastic syndromes (MDS) are a group of malignant hematopoietic stem cell disorders characterized by dysplastic and ineffective blood cell production and a variable risk of transformation to AML. Patients typically present with chronic cytopenia and are at risk of bleeding, infection, and symptomatic anemia.[166]

The incidence rate of MDS is approximately 4.9 per 100,000 people each year.[123] Most patients found to have MDS are older than 60 years with a male predominance; however, some children and young adults may develop MDS in the context of congenital mutations that lead to bone marrow failure syndromes or inherited predisposition to myeloid tumors. The pathogenesis of MDS remains unclear and involves the stepwise process of oncogenic mutations that may arise de novo or after exposure to environmental toxins (e.g., benzene), radiation, or certain chemotherapeutic agents (e.g., alkylating agents). Some cases have been linked to inherited genetic conditions (e.g., ataxia telangiectasia, Bloom syndrome, Fanconi anemia, trisomy 21) and other benign hematologic disorders (e.g., congenital neutropenia, paroxysmal and nocturnal hemoglobinuria). The most frequently mutated genes are *ASXL1*, *TP53*, *DNMT3A*, *TET2*, *RUNX1*, and genes that are components of the 3' RNA splicing machinery (e.g., *SF3B1*, *U2AF1*, *SRSF2*, and *ZRSR2*).[167] Some studies showed that a few cases of MDS respond to immunosuppressive therapy, suggesting that defects in the immune system may trigger myelosuppression and/or marrow hypocellularity, especially in younger patients.

Clinically, patients present with nonspecific signs and symptoms. Most patients are asymptomatic, and a diagnosis is made after incidental findings during a routine blood count. Others may report fatigue, weakness, dizziness, angina, or infections (secondary to neutropenia and granulocyte dysfunction).

Diagnosis is made through an evaluation of the bone marrow and peripheral blood smear, after careful clinical assessment, to document the requisite morphologic dysplastic cytologic changes of all hematopoietic cells. Blast forms account for <20% of the total nucleated cells of the bone marrow aspirate and peripheral smear. Minimal diagnostic criteria for MDS include (1) stable cytopenia; and (2) the exclusion of other potential diseases as a primary reason for dysplasia or cytopenia or both. In addition, the diagnosis requires ≥1 of 3 MDS-related decisive criteria: (1) dysplasia (≥10% in ≥1 of the three major bone marrow lineages); (2) a blast cell count of 5-%–9%; and (3) a specific MDS-associated karyotype, such as del(5q), del(20q), +8, or -7/del(7q).[168,169]

Management of MDS ranges from supportive care with transfusions or hematopoietic growth factors and administration of low-intensity cytarabine, to intensive chemotherapy. Three FDA agents approved for treatment of specific subtypes of MDS include azacytidine and decitabine for higher-risk patients or those with nonresponsive disease, and lenalidomide for patients with del(5q) cytogenetic abnormalities.[170] Although allogeneic HSCT is the only potentially curative therapy for MDS, mortality post transplantation is high, due to disease relapse and to transplant-related complications. Several prognostic models have been proposed to identify those patients at risk for relapse. Current prognostic models include patient-related factors, the disease, and molecular characteristics. *TP53* mutations were found to be the best predictor of survival after HSCT in patients with MDS, independent of age, Karnofsky performance-status score, and hematologic variables.

Multiple Myeloma

Plasma cell myeloma is a clonal plasma cell neoplasm that may present as a single lesion (solitary plasmacytoma) or multiple lesions (multiple myeloma or MM). This clone of plasma cells proliferates in the bone marrow and often results in extensive skeletal destruction with osteolytic lesions, osteopenia, and/or fractures.[171] MM represents 1.8% of all cancers in the United States, with a median age at diagnosis of 69 years. There were 32,110 estimated new cases in 2019, with a higher incidence in African Americans.[123]

Almost all MM cases are preceded by a premalignant plasma cell proliferative disorder known as monoclonal gammopathy of undetermined significance (MGUS). In MGUS, clonal cells are usually not detectable in bone marrow biopsies. Patients present with low levels of monoclonal protein present in serum (IgG <3 g/dL; IgA <1 g/dL) and serum monoclonal protein remain stable over long periods of time. These patients have no clinical manifestations of the disease and require careful observation. Long-term follow-up studies of patients with MGUS showed malignant transformation to MM at an annual rate of 1%–1.5%. In some patients, an intermediate asymptomatic but more advanced premalignant stage (smoldering multiple myeloma or SMM) can be recognized clinically. SMM is defined by the presence of a serum monoclonal protein (IgG or IgA) ≥3 g/dL and/or 10%–60% clonal bone marrow plasma cells, with no evidence of end-organ damage.[172]

MM is characterized by a plasma cell dyscrasia producing monoclonal immunoglobulins. This proliferation often results in extensive skeletal destruction (e.g., osteolytic lesions, hypercalcemia, anemia) and the excess production of monoclonal protein can result in renal failure, hyperviscosity syndrome, recurrent bacterial infections, and hematopoietic and immune dysfunction.[171] Risk factors for MM include chronic exposure to low-dose ionizing radiation, occupational exposure (e.g., chemical), genetic factors, and chronic antigenic stimulation (e.g., recurrent infections and drug allergies). Chromosome translocations involving the IgH locus and hyperdiploidy, with multiple trisomies of chromosomes 3, 5, 7, 9, 11, 15, 19, and 21, are considered primary events in MM patients, while del(17p) and amp(1q21) develop during disease progression. Hyperdiploidy is seen in approximately half of patients with MM and is associated with better progression-free survival and overall survival. Primary early chromosomal translocations occur at the immunoglobulin switch region on chromosome 14 (q32.33), which is most commonly juxtaposed to MAF (t[14;16] [q32.33;23]) and MMSET on chromosome 4p16.3. This process results in the deregulation of two adjacent genes, *MMSET* in all cases and *FGFR3* in 30% of cases. Secondary late-onset translocations and gene mutations that are implicated in disease progression include complex karyotypic abnormalities in *MYC*, the activation of *NRAS* and *KRAS*, mutations in *FGFR3* and *TP53*, and the inactivation of cyclin-dependent kinase inhibitors CDKN2A and CDKN2C. Other genetic abnormalities involve epigenetic dysregulation, such as alteration in microRNA expression and gene methylation modifications. Gene expression profiling allows for classification and risk classification of multiple myeloma.[173]

Most patients with MM present with signs and symptoms secondary to plasma cell infiltration into the bone or other organs, or to renal damage from excess light chains.[173] Two-thirds of patients develop anemia, 60% bone pain, 50% elevated creatinine, fatigue/generalized weakness in 30%, hypercalcemia in 28%, and weight loss in 24% of patients. Extramedullary plasmacytomas (EMP) are seen in approximately 7% of patients with MM at the time of diagnosis and are best diagnosed by PET/CT scan. EMP accounts for <1% of all head and neck malignancies, with the oral cavity being the rarest site affected. Oral EMPs may resemble other gingival nodules, with various signs and symptoms including spontaneous bleeding, pain, and paresthesia. Radiographic changes in patients with MM include typical "punched-out" lesions in the skull from the focal proliferation of plasma cells inside the bone marrow and jaw bone (mandible > maxilla) involvement, ranging from asymptomatic osteolytic lesions to pathologic fracture.

The initial diagnostic workup of patients with suspected MM includes whole-body low-dose CT or FDG-PET/CT skeletal survey, serum protein electrophoresis along with immunofixation, and a serum-free light chain assay. A 24-hour urine collection for electrophoresis and immunofixation is recommended if a diagnosis of MM is made. Further evaluation includes a bone marrow aspiration and biopsy, imaging, a CBC with differential, and a chemistry screen. The International Myeloma Working Group (IMWG) Updated Criteria for the Diagnosis of Multiple Myeloma require the presence of ≥10% clonal bone marrow plasma cells or biopsy-proven bony or EMP, plus one or more myeloma-defining events: (1) ≥ CRAB feature (CRAB: **C**alcium [hypercalcemia], **R**enal failure, **A**nemia, and **B**one lesions) or ≥ SLiM feature (SLiM: ≥**S**ixty percent [≥60%] clonal bone marrow plasma cells; serum-free **Li**ght chain ratio involved:uninvolved ≥100; >1 focal lesion (≥5 mm each) detected by **M**RI studies).[174,175]

Following diagnosis and risk stratification, patients undergo an evaluation to assess eligibility for autologous hematopoietic cell transplantation. Transplant patients receive induction therapy with a triplet regimen for 3–4 months prior to stem cell collection. Patients ineligible for HCT receive 8–12 cycles of novel agent-based three-drug regimens followed by maintenance therapy until progression unless there are significant adverse events. Though allo-HSCT showed good long-term disease control for certain MM patients, there were only some benefits from this approach because of significant transplant mortality rate and high relapse rates. Lenalidomide remains the preferred maintenance agent for both transplant-eligible and transplant-ineligible individuals. Management of focal bone lytic lesions may require radiation therapy, surgery, and use of analgesics. In cases of hypercalcemia, bisphosphonates, denosumab, and/or calcitonin are recommended to reduce calcium levels.[172]

Newer therapeutic agents including second-generation proteasome inhibitors (e.g., carfilzomib), third-generation immunomodulators (e.g., pomalidomide), monoclonal antibodies, and checkpoint inhibitors are emerging as promising and are currently under investigation.

Oral Health Considerations

Medication-related osteonecrosis of the jaw (MRONJ) is a serious complication of long-term intravenous antiresorptive therapy (e.g., bisphosphonate, denosumab). Another consideration for MM patients requiring invasive dental procedures is the risk of hemorrhage. Patients with MM and other disorders associated with high-titer serum paraproteins can manifest unique hemostatic disorders, predisposing the patient to hemorrhage, especially following surgical procedures. Predental surgical assessments should include radiographic

assessment for plasma cell tumors of the jaw and CBC and coagulation studies. Prevention of hemorrhage should be managed by consultation with the patient's hematologist regarding the status of treatment of the underlying disease and, depending on clinical circumstances, the need for additional therapies that might include plasmapheresis with appropriate factor replacement, desmopressin acetate (Stimate), fibrinolysis inhibitors ε-aminocaproic acid (Amicar) and tranexamic acid (Cyclokapron), and splenectomy.

Bleeding and Clotting Disorders

Joel J. Napeñas, DDS, FDS RCSEd
Lauren L. Patton, DDS, FDS RCSEd

Oral healthcare professionals are increasingly called upon to provide care to individuals whose bleeding and clotting mechanisms have been altered by acquired or inherited mechanisms. This engagement in care of the coagulopathy patient provides an opportunity for the dentist trained in the recognition of oral and systemic signs of altered hemostasis to assist in the screening and monitoring of the underlying condition.

Inherited coagulopathies, such as the hemophilias and von Willebrand disease (VWD), may be mild to severe in clinical presentation, are present life-long, are often diagnosed in infancy, and are predictable based on the hereditary pedigree. If it is not diagnosed in childhood, exposure to the first surgical procedure, which is often the removal of third molars, may reveal the underlying inherited bleeding disorder. Acquired coagulation disorders can result from drug actions or side effects of underlying systemic disease or their treatment. Over the past few decades, there have been expanding options for therapeutic anticoagulation for the prevention and management of thromboembolic disease. In addition to heparins and vitamin K antagonists (VKAs; e.g., warfarin), anticoagulants targeting enzymatic activity of

Burket's Oral Medicine, Thirteenth Edition. Edited by Michael Glick, Martin S. Greenberg, Peter B. Lockhart, and Stephen J. Challacombe.

thrombin and factor Xa (F Xa), often referred to as novel oral anticoagulants (NOACs) or direct oral anticoagulants (DOACs), have been developed and have become widely used. In addition to anticoagulants, antiplatelet therapy has become ubiquitous for the prevention of stroke or thromboembolic cardiac events (e.g., post coronary artery stenting, post myocardial infarction).

Moreover, systemic disease involving the liver and kidney, inherited or acquired platelet disorders, and myelosuppressive chemotherapy or treatment of hematologic malignancy add to the burden of altered hemostasis. Patients with liver disease may have impaired hemostasis due to thrombocytopenia and/or lack of coagulation factors, whereas renal failure may result in qualitative disorders in platelet function. Patients with hematologic malignancies may have thrombocytopenia as a result of overgrowth of malignant cells in the bone marrow that leaves no room for platelet precursors (megakaryocytes). In addition, cancer patients may have thrombocytopenia as a result of the cytotoxic effects of chemotherapeutic agents to treat their disease.

Invasive dental procedures resulting in bleeding can have serious consequences for the patient with a bleeding disorder, including severe hemorrhage or even death. Safe dental care may require consultation with the patient's medical provider, institution of systemic management, and dental treatment modifications.

EPIDEMIOLOGY

The World Health Organization's Global Burden of Disease (WHO-GBD) study indicates that diseases requiring medication to manage premature clotting are on the rise. By 2017, among all diseases, ischemic heart disease and stroke had risen to number 1 and 3 for leading causes of early death and number of years lived with disability at all ages.[1] In many countries, today the use of DOACs has surpassed the use of traditional VKAs.[2]

VWD is reported as the most common inherited coagulopathy, with a prevalence, including the multiple types and subtypes, of up to 1% of the population.[3] Hemophilia A (F VIII deficiency) is the most common congenitally missing coagulation factor deficiency, with a prevalence in the United States of 1:6500 live male births.[4] Hemophilia B or Christmas disease (F IX deficiency) occurs about a fifth as frequently as hemophilia A at 1:30,000 live male births.[5]

Systemic diseases that alter hemostasis are also increasing in prevalence. The American Cancer Society estimates that 1,806,590 individuals will be newly diagnosed with cancer in 2020, many being placed on myelosuppressive chemotherapy that creates thrombocytopenia; of these new cancer cases, 60,530 will be patients with leukemia who in addition may have malignancy-related thrombocytopenia.[6] Using WHO-GBD data, epidemiologists note that the rise of hepatitis C infection and other causes have increased cases of liver cirrhosis and increased years living with this disease. This places patients at risk for thrombocytopenia and coagulopathies from the inability of the liver to properly form clotting factors; liver cirrhosis accounted for 1.45 million deaths globally in 2013, a 63% increase from 0.89 million in 1990.[7] Systemic diseases with alteration of both coagulation and platelet number and/or function increase the complexity of hemostasis management during dental surgical procedures.

MECHANISMS OF HEMOSTASIS

Hemostasis is the process of blood clot formation at the site of vessel injury. Multiple processes occur in a rapid sequence that is localized and regulated. There is a careful balance between thrombin-stimulated clot formation and plasmin-induced clot lysis. Abnormal bleeding occurs when there is insufficient clot formation due to decreased thrombin (e.g., from F VIII deficiency) or increased clot lysis. Thrombosis that is nonphysiologic or functional clotting occurs when there is an excessive production of thrombin.

Hemostasis can be divided into four general phases:

- Endothelial injury and platelet plug formation—underway within 10–20 seconds of injury.
- Coagulation cascade and propagation of clotting—an initial hemostatic plug is formed in 1–3 minutes, and fibrin has been generated and added to stabilize the clot by 5–10 minutes.
- Termination of clotting by antithrombotic control mechanisms.
- Fibrinolysis and removal of the clot.

Endothelial Injury and Platelet Plug Formation

When vessel integrity is disrupted, reactants such as serotonin, histamine, prostaglandins (PGs), and other products that are vasoactive cause vasoconstriction of the microvascular bed in the area of the injury and the vessels contract. The immediate reflex vasoconstriction may alone be hemostatic in small vessels. Platelets are activated as well and adhere to the site of injury, forming a platelet plug that reduces or temporarily arrests blood loss.[8]

Endothelial injury activates endothelial cells to promote the recruitment of platelets, other cells, and procoagulant factors. This occurs in four steps (Figure 18-1).

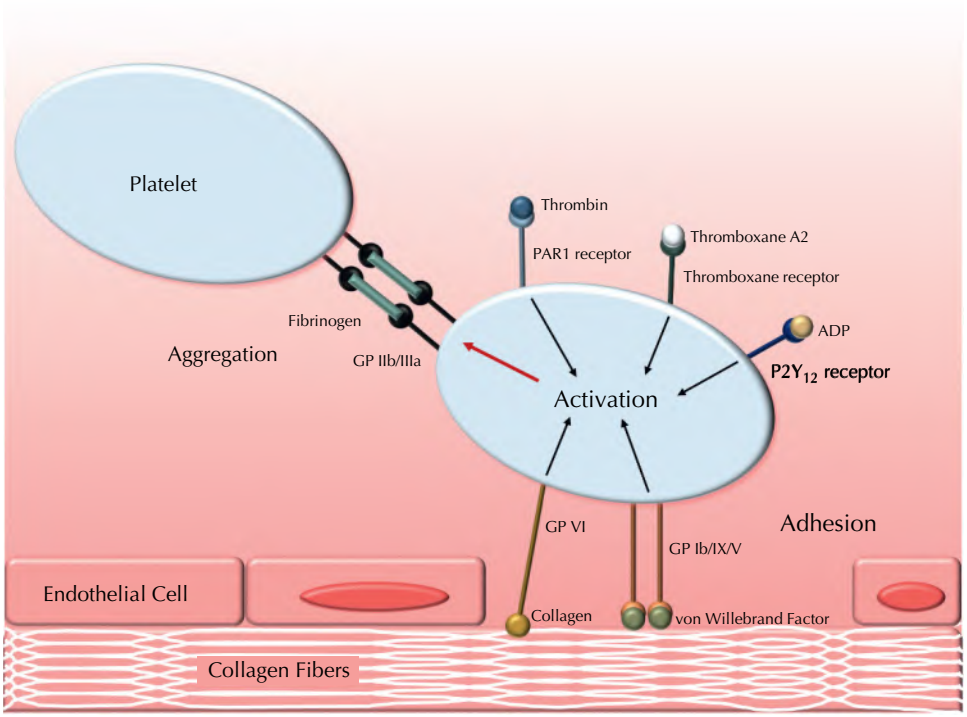

Figure 18-1 Platelet phase. Platelet adhesion occurs immediately (within 1–2 seconds) via the binding of platelet surface receptor glycoprotein (GP) Ib/IX/V complex to von Willebrand factor. Adenosine diphosphate (ADP) is a potent nucleotide that binds to receptors P2Y1 and P2Y12, activating and recruiting other platelets in the area and adding to the size of the plug. Once platelets are stimulated by thrombin, collagen, or ADP the integrin GPIIb/IIIa on platelet surfaces are activated and bind to fibrinogen, in which aggregation occurs (within 10–20 seconds). Platelets then secrete a number of other factors, including thromboxane A2, which promotes vasoconstriction and further platelet aggregation.

Step One: Adhesion

Once the endothelium is injured, subendothelial collagen, laminin, and microfibrils are exposed. Platelet stimuli include adenosine diphosphate (ADP), epinephrine, thrombin, and collagen. Platelet adhesion occurs via the binding of platelet surface receptor GPIb/IX/V complex to von Willebrand factor (VWF) in the subendothelial matrix.[9] GPIa/IIa and GPVI are important collagen receptors on the surface of platelets, involved in adhesion and activation, respectively.[10] ADP is a potent nucleotide that binds to receptors P2Y1 (which leads to calcium mobilization, platelet shape change, and aggregation) and P2Y12 (responsible for platelet secretion and stable aggregation), in effect activating and recruiting other platelets in the area and adding to the size of the plug. Platelets have two receptors for thrombin, protease-activated-receptors 1 and 4 (PAR-1 and PAR-4).[11] Platelet factor 3 is the intracellular phospholipid that activates F X and subsequently results in the conversion of prothrombin to thrombin.

Step Two: Aggregation

Once platelets are stimulated (e.g., by thrombin, collagen, or ADP), the integrin GPIIb/IIIa on platelet surfaces is activated and becomes a high-affinity fibrinogen receptor. The GPIIb/IIIa complex also binds to immobilized VWF, resulting in platelet spreading and clot retraction.

Step Three: Activation and Secretion

Platelets secrete a number of substances upon cell stimulation, including:

- ADP and serotonin—activates and recruits additional platelets.
- Fibronectin and thrombospondin—adhesive proteins that stabilize platelet aggregates.
- Fibrinogen.
- Thromboxane A2 (TXA A2)—promotes vasoconstriction and further platelet aggregation.
- Growth factors—mediate tissue repair at the site of vascular injury.

Step Four: Procoagulant Activity

This involves the exposure of procoagulant phospholipids (e.g., phosphatidylserine) and the assembly of the enzyme complexes in the coagulation cascade on the platelet surface.[12] This leads to fibrin formation and the generation of an insoluble fibrin clot that strengthens the platelet plug.[8]

The Coagulation Cascade and Propagation of Clotting

The generation of thrombin and fibrin is the end product of the coagulation phase. This process involves multiple proteins, many of which are synthesized by the liver (fibrinogen; prothrombin; F V, F VII, F IX, F X, F XI, F XII, and F XIII) and are vitamin K dependent (F II, F VII, F IX, and F X); see Table 18-1. Vitamin K is an essential cofactor for a carboxylase that catalyzes the carboxylation of glutamic acid residues on vitamin K–dependent proteins, thereby making them biologically active.

A sequence of interactions between the various clotting factors occurs following tissue injury. The scheme of reaction is a bioamplification, in which a precursor is altered to an active form, which, in turn, activates the next precursor in the sequence. The coagulation of blood requires the presence of both calcium ions and exposed phospholipid on platelet surfaces. Beginning with an undetectable biochemical reaction, the coagulation mechanism results in a final explosive change of a liquid to a gel.

Classical Coagulation Cascade Model

The traditional model of the cascade (Figure 18-2) is useful for interpreting in vitro tests of coagulation (e.g., prothrombin time [PT], international normalized ratio [INR]); however, it does not fully represent what occurs in vivo (i.e., in the body). It involves two separate pathways (intrinsic and extrinsic) that converge by activating a third (common) pathway:

- The intrinsic pathway is initiated by the exposure of blood to a negatively charged surface. F XII is activated by surface contact (e.g., with collagen or subendothelium), and it involves the interaction of F XII and F XI to an active form (F Xia). The next step, the activation of F IX to F IXa, requires a divalent cation such as calcium.[13] Once activated, F IXa forms a complex with F VIII, in a reaction that requires the presence of both calcium ions and phospholipid, which, in turn, converts F X to an activated form—F Xa.
- The extrinsic pathway is initiated by the release of tissue factor (TF), also called tissue thromboplastin, and does not require contact activation. TF binds to F VII in the presence of calcium, and this complex is capable of activating F IX and X, linking the intrinsic and extrinsic pathways.
- The common pathway begins through the activation of F X. Once activated, F Xa converts prothrombin to thrombin in a reaction similar to the activation of F X by F IXa. The activation of prothrombin by F Xa requires the presence of calcium ions and phospholipid as well as F V, a plasma protein cofactor.[14] Once formed, thrombin converts fibrinogen, a soluble plasma protein, to insoluble fibrin. Fibrin polymerizes to form a gel, stabilizing the platelet plug. Finally, F XIII, which has been converted to an activated form by thrombin,[15] produces covalent cross-links between the fibrin molecules that strengthen the clot and make it more resistant to lysis by plasmin.

In Vivo Coagulation Cascade

The current established in vivo physiologic model of clotting has three overlapping phases: initiation, amplification, and

Table 18-1 Coagulation factors.

	Coagulation Factor Affected		
Factor (Name)	**Intrinsic**	**Extrinsic**	***t*1/2 (h)**
XIII (fibrin-stabilizing factor)	*	*	336
XII (Hageman factor)	*		60

V (proaccelerin)	*	*	32
IV (calcium)	*	*	—
III (tissue thromboplastin)		*	—
II (prothrombin)	*	*	72
I (fibrinogen)	*	*	96

*t*1/2, half-life.

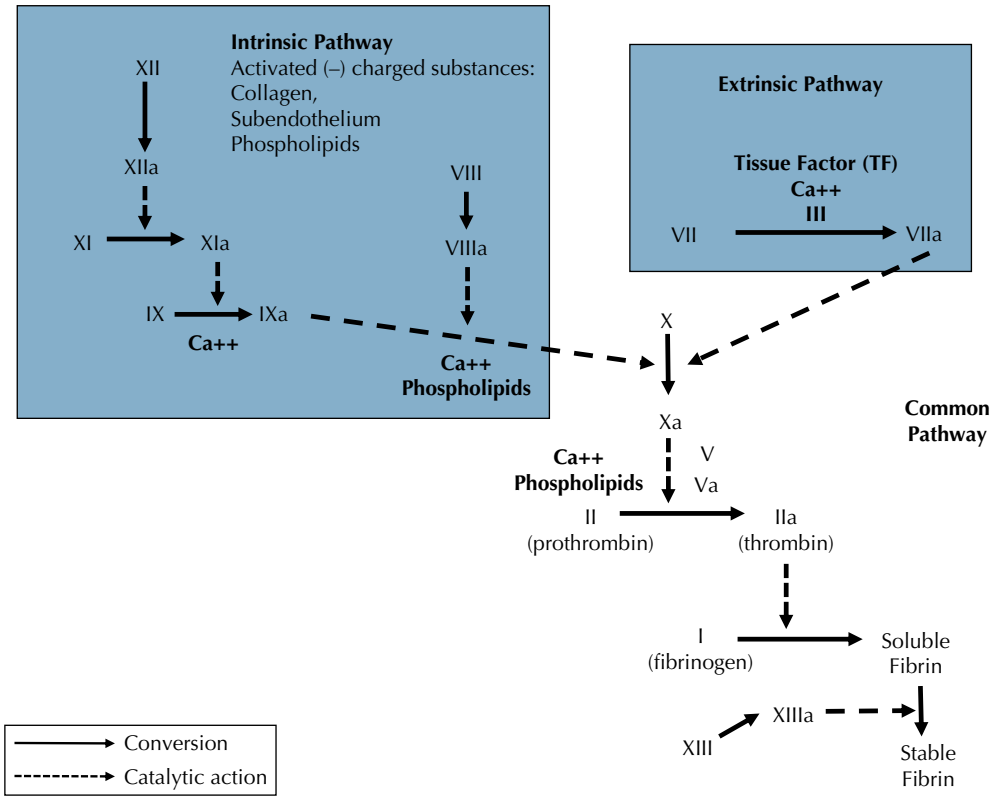

Figure 18-2 Classical in vitro coagulation cascade.

propagation (Figure 18-3). The activations and reactions of clotting factors occur on cell surfaces (e.g., activated platelets, endothelial cells) and a number of different cells (e.g., monocytes, fibroblasts). Standard laboratory clotting tests, which detect initial fibrin clot formation, primarily measure the initiation and not the propagation phase of clotting.

- The primary initiation event in clotting is the generation or exposure of TF at the wound site, on TF-bearing cells, and its interaction with and activation of F VII with the aid of F IXa.[16,17] This TF–F VIIa complex activates F X, which gives rise to a small amount of thrombin (minor).
- The amplification phase occurs on the surface of platelets. In addition to activating platelets, the small amount of thrombin also activates F V, F VIII, and F XI, which participate in generating large amounts of thrombin (major).[18]
- In the propagation phase, procoagulant complexes are assembled on platelet membrane surfaces in the presence of calcium. An extrinsic tenase (X-ase) complex consists of F Va and TF, and activates F X and F IX. An intrinsic X-ase complex consists of F IXa and F VIIIa, and activates F X. The F Xa generated from either X-ases binds with F Va to form the prothrombase on the surface of the platelet, which then generates a large amount of thrombin through the conversion from prothrombin (F II) to thrombin (F IIa). This ultimately leads to the conversion of fibrinogen to fibrin.[18] In addition, thrombin activates F XIII (fibrin-stabilizing factor), which cross-links the monomeric fibrin to stabilize the clot.

Termination

Coagulation is modulated by several mechanisms: dilution of procoagulants in flowing blood, removal of activated factors through the reticuloendothelial system by the liver, and control of the activated procoagulants and platelets by natural antithrombotic pathways, mostly on vascular endothelial cells.

The inhibitors of the coagulation pathways are:

- Tissue factor pathway—tissue factor pathway inhibitor (TFPI) inhibits factor X activation in two ways: by directly inhibiting F Xa and by inhibiting the extrinsic X-ase complex by complexing with factor Xa.
- Contact activation pathway—C1 esterase inhibitor (C1-inh).

The regulation of the terminating phase of coagulation involves:

- Antithrombin (AT)—a circulating plasma protease inhibitor, which neutralizes most of the enzymes (i.e., thrombin, F Xa, F IXa, F XIIa).
- Protein C pathway (Figure 18-4)—protein C is activated by thrombin after it binds to thrombomodulin during the

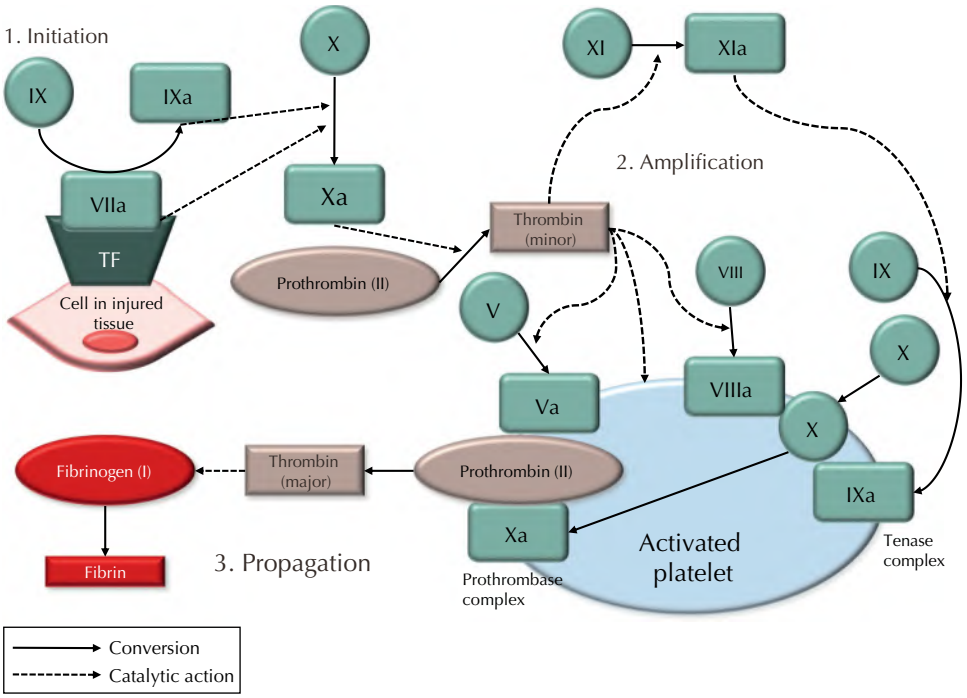

Figure 18-3 In vivo coagulation cascade. TF complexes with factor VIIa (F VIIa) at the site of tissue injury. Activation of F X produces small amounts of thrombin, which in turn activate platelets and F V and VII (F VIII), which assemble on the surface of platelets to form prothrombinase and tenase complexes, respectively. The tenase complex activates F X, which forms on the prothrombinase complex that converts prothrombin to thrombin, which then converts fibrinogen to fibrin for the stable clot.

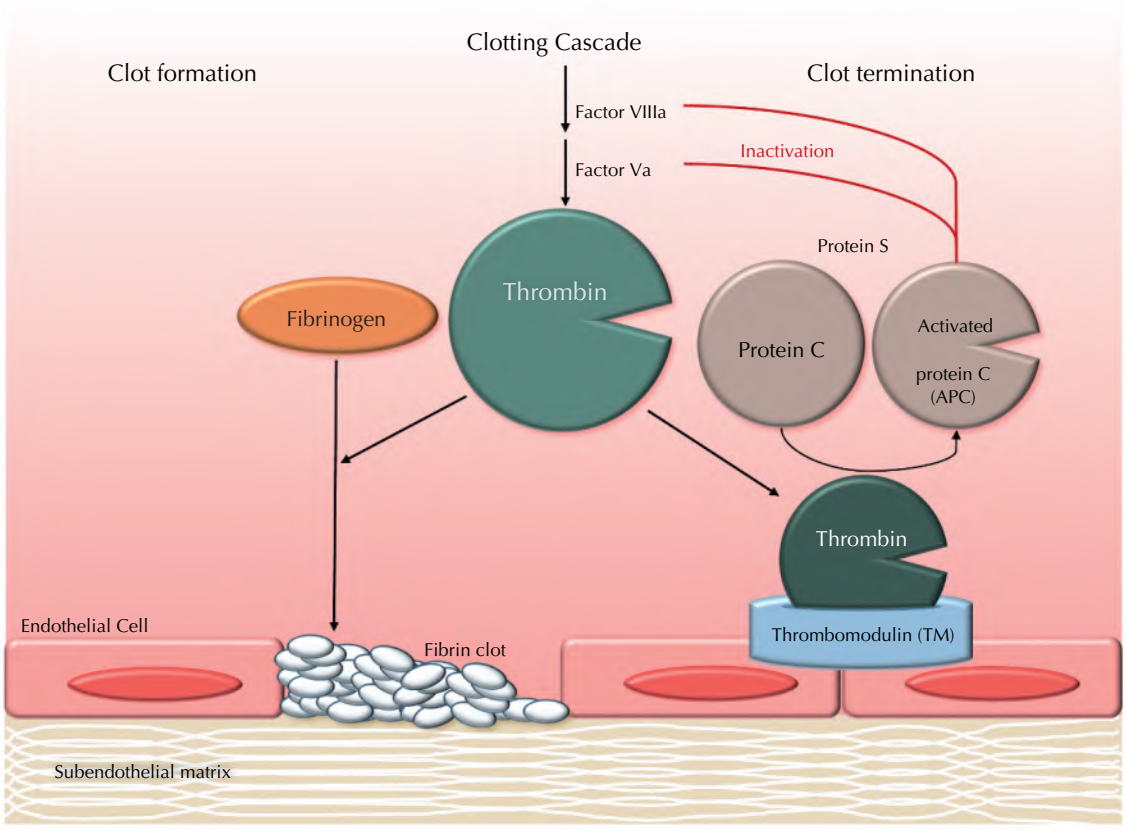

Figure 18-4 Termination of clotting.

process of clot formation, to form the protein C anticoagulant complex. Activated protein C, in association with protein S on phospholipid surfaces, inactivates F Va and F VIIIa, effectively inactivating the prothrombinase and intrinsic X-ase complex, respectively.[19]

Fibrinolysis

Fibrinolysis is considered the major means of disposing of fibrin after its hemostatic function has been fulfilled (Figure 18-5). This is critical to the process of wound healing, in order to restore vessel patency, and for tissue remodeling. Tissue plasminogen activator (tPA) is released from the endothelial cells and converts plasminogen to plasmin, which degrades fibrinogen and fibrin into fibrin degradation products (FDPs). tPA is a proteolytic enzyme that is nonspecific and also degrades F VIII and F V. Urokinase is also a plasminogen activator that is responsible for extravascular fibrinolysis. Kallikrein, which is an intrinsic activator of plasminogen, is generated when prekallikrein is bound to kininogen, thereby becoming a substrate for F XIIa. Activation of the fibrinolytic system can be turned off by inhibition of plasmin activity by α_2-antiplasmin, or inhibition of plasminogen activators by plasminogen activator inhibitors 1 and 2 (PAI-1 and PAI-2).[20,21]

GENERAL WORKUP OF PATIENTS WITH SUSPECTED BLEEDING OR CLOTTING DISORDER

Patient History and Clinical Features

Patient evaluation starts with a routine medical history, via a thorough questionnaire and interview. As part of the overall query, patients should be asked about any history of previous unusual bleeding episodes after surgery or injury, easy or frequent bruising, or spontaneous bleeding (Figure 18-6). Specifically, patients should be asked about prolonged bleeding after invasive dental procedures, spontaneous bleeding from the gingivae, and history of nasal bleeding. They should also be asked about a family history of bleeding disorders. For the purpose of history-taking, a clinically significant bleeding episode has been defined as follows:[22]

- Continues beyond 12 hours.
- Requires patient to call or return to treating dentist, or seek emergency care with a medical provider.
- Results in development of hematoma or ecchymosis in soft tissues.
- Requires blood product support.

A complete list of medications is essential, to include over-the-counter products, prescription drugs, and supplements, as they can have implications for hemostasis. A social history that determines alcohol consumption and illicit drug use is also essential.

A number of clinical features can be seen in patients with bleeding disorders:

- *Petechiae*. Petechiae are small, flat, red, discrete areas of skin bleeding that are typically <2 mm in diameter, nonblanching, and nonpalpable. Although typically occurring in lower extremities, sacral area, and areas of skin fragility, they can also occur in the oral cavity, especially with severe thrombocytopenia.
- *Bruise/ecchymosis*. A bruise (also called ecchymosis) is caused by subcutaneous/submucosal accumulation of

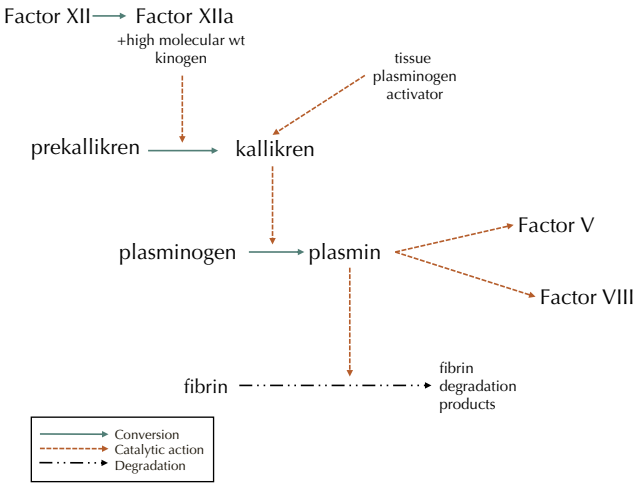

Figure 18-5 The fibrinolytic system.

Figure 18-6 Spontaneous gingival bleeding between the upper left lateral incisor and canine and labial petechiae in a 38-year-old white male with idiopathic thrombocytopenic purpura.

extravasated blood (Figure 18-7). The color can range from purplish blue to reddish brown to greenish yellow, indicative of breakdown of hemoglobin to biliverdin and bilirubin.

- *Hematoma*. A hematoma is a collection of blood in the extravascular space. A subcutaneous hematoma may raise the skin profile. Hematomas in deep tissues (e.g., muscle, retroperitoneal) may be suspected due to pain, a drop in hemoglobin level, or a fluid collection on imaging studies. Hematomas and hemarthroses are typical of coagulation factor deficiencies.

Features to look for in the general examination of a patient include multiple ecchymoses of the skin, bleeding wounds, hematomas, and swollen joints. Clinical manifestations of bleeding disorders can involve various systems, depending on the extent and type of disorder (Table 18-2). Individuals with mild disease may present with no clinical signs, whereas individuals with severe coagulopathies may have definite stigmata. When skin and mucosa are involved, individuals may present with petechiae, ecchymoses, spider angiomas, hematomas, or jaundice. Deep dissecting hematomas and hemarthroses of major joints may affect severe hemophiliacs and result in disability or death. Disorders of platelet quantity may result in hepatosplenomegaly, spontaneous gingival bleeding, and risk of hemorrhagic stroke. Specific clinical manifestations will be discussed in detail for the various conditions. Intraorally, petechiae, ecchymoses, hematomas, or excessive gingival bleeding should be of concern to the dentist.

Laboratory Studies

When a bleeding disorder is suspected, laboratory studies should be initiated prior to an invasive procedure. There are a variety of laboratory tests that help identify a deficiency of required elements or dysfunction of the phases of coagulation (Tables 18-3 and 18-4). To evaluate primary hemostasis involving platelets, there are platelet count and

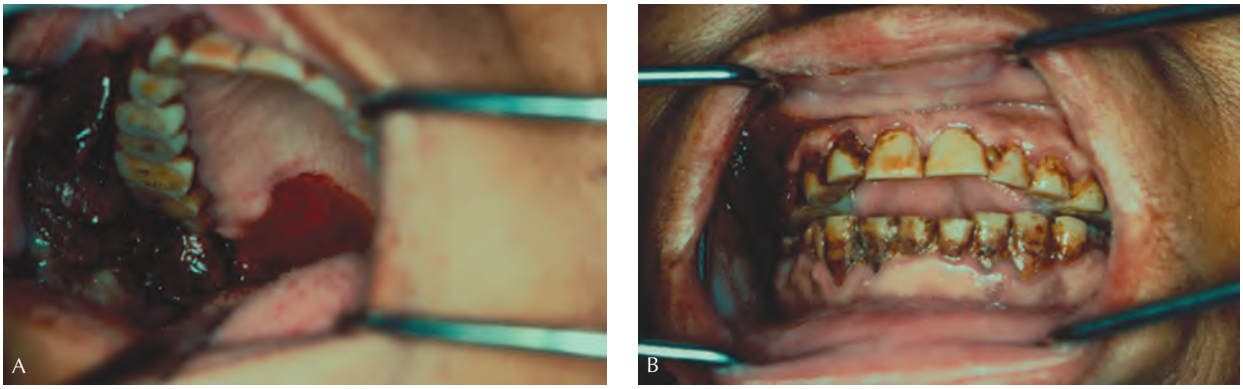

Figure 18-7 A 68-year-old woman with acute myelogenous leukemia and a platelet count of 9000/mm^3. Platelet transfusions and e-aminocaproic acid oral rinses were used to control bleeding. (A) Buccal mucosa and palatal ecchymoses. (B) Extrinsic stains on teeth from erythrocyte degradation following continual gingival bleeding.

Table 18-2 Clinical features of bleeding disorders.

Feature	Vascular or Platelet Disorders	Coagulation Disorders
Bleeding from superficial cuts and scratches	Persistent, often perfuse	Minimal
Delayed bleeding	Rare	Common
Spontaneous gingival bleeding	Characteristic	Rare
Petechiae	Characteristic	Rare
Ecchymoses	Characteristic, usually small and multiple	Characteristic, usually large and solitary
Epistaxis	Common	Common
Deep dissecting hematomas	Rare	Characteristic
Hematoma and hemarthrosis	Rare	Characteristic

Table 18-3 Laboratory tests for assessing hemostasis.

Test	Normal Range
Platelet count	150,000–450,000/mm^3
Bleeding time	<7 min (by simplate); 1–6 min (modified Ivy's test)
PFA-100 closure time	CT-EPI < 164 s; CT-ADP < 116 s
PT/INR	Control ± 1 s (e.g., PT: 11–13 s / INR 1.0)
Activated partial thromboplastin time (aPTT)	Comparable to control (e.g., 15–35 s)
Thrombin time (TT)	Control ± 3 s (e.g., 9–13 s)
Fibrin degradation products (FDPs)	<10 μg/dL
Fibrinogen assay	200–400 mg/dL
von Willebrand antigen	60–150% vWF activity
Coagulation factor assays (e.g., F VIII assay)	60–100% F VIII activity
Coagulation factor inhibitor assays (e.g., Bethesda inhibitor assay for F VIII)	0.0 Bethesda inhibitor units

CT-ADP, closure time with collagen and adenosine diphosphate membrane; CT-EPI, closure time with collagen and epinephrine membrane; F, factor; INR, international normalized ratio; PT, prothrombin time; vWF, von Willebrand factor

Table 18-4 Laboratory test results for select disorders.

	Screening Laboratory Tests			
Bleeding Disorder	Platelet Count	PT/INR	aPTT	BT
Thrombocytopenia Leukemia Liver disease	↓	N	N	↑
F VIII, IX, XI deficiency Heparin anticoagulation Thrombin inhibitor anticoagulation	N	N	↑	N
F II, V, X deficiency Vitamin K deficiency Intestinal malabsorption	N	↑	↑	N
F VII deficiency Coumarin anticoagulation F Xa inhibitor anticoagulation Liver disease	N	↑	N	N
von Willebrand disease	N, ↓	N	N, ↑	↑
DIC Severe liver disease	↓	↑	↑	↑
F XIII deficiency	N	N	N	N
Vascular wall defect	N	N	N	↑

aPTT, activated partial thromboplastin time; BT, bleeding time; DIC, disseminated intravascular coagulation; INR, international normalized ratio; N, normal; PT, prothrombin time; ↑ = increased; ↓ = decreased.

platelet function tests (e.g., bleeding time [BT]) and other assays (e.g., platelet function analyzer [PFA-100]). Tests to evaluate the status of coagulation function include PT/INR, activated partial thromboplastin time (aPTT), thrombin time (TT), FDPs, specific coagulation factor assays (e.g., F VII, F VIII, F IX, fibrinogen), and coagulation factor inhibitor screening tests (blocking antibodies).

Initial tests for patients with a suspected bleeding disorder include a complete blood count (CBC) with platelet count, PT/INR, and aPTT. Subsequent testing can be performed based on initial clinical and laboratory findings or the suspected underlying condition.

Platelet Count

Platelet counts are obtained as part of a standard CBC. Normal values are 150,000–450,000/mm^3. Spontaneous hemorrhage is usually not observed with platelet counts above 10,000–20,000/mm^3. Many hospitals have established a critical value of 10,000/mm^3 platelets, below which platelets are transfused to prevent serious bleeding sequelae, such as hemorrhagic stroke; however, such thresholds are dependent upon the anticipated risk of bleeding based on the procedure. Surgical or traumatic hemorrhage may be more likely with severely reduced platelet counts.

Tests of Platelet Function

The Platelet Function Analyzer (PFA-100) measures the time it takes for blood flow to stop under shear stress in a capillary tube that has a membrane lined with collagen and epinephrine, or collagen and ADP, and then exposed to shear stress, which is deemed the closure time (CT).[23] This test was found to be more sensitive to aspirin-induced platelet dysfunction and VWD, and was more rapid and less expensive than the BT.[24] However, because it is a global test system and also sensitive to low hematocrit, low platelet counts, and platelet dysfunction (both congenital and acquired), it is neither specific for, nor predictive of, any particular disorder (inclusive of VWD), therefore it is recommended that a CBC be performed along with this test.[25] It is also insensitive to other therapeutic antiplatelet agents such as clopidogrel, ticlopidine, and cyclooxygenase-2 (COX-2) inhibitors.[26,27] Though one clinical trial reported the use of the PFA-100 CT as a screening tool for oral surgery patients on antiplatelet therapy,[28] the role of the PFA-100 CT in routine therapeutic monitoring of platelet function for dental procedures remains to be established.

For assessing the response to clopidogrel, a US Food and Drug Administration (FDA)-approved test for assessing P2Y-12-mediated platelet function is called the "Plavix Response" or the "VerifyNow P2Y-12 assay." This uses anticoagulated whole blood for turbidometric detection of platelet aggregation in which activated platelets bind to nearby platelets via fibrinogen-coated beads in the assay.

Bleeding Time

The BT test was previously used as a screening test for platelet function. It is thought to identify qualitative or functional platelet defects. The modified Ivy test involves a standardized incision on a forearm distal to a blood pressure cuff inflated to 30 mm Hg. The wound is blotted with filter paper and monitored until absorption of blood on the paper ceases. Normal range is between 1 and 6 minutes and is considered significantly prolonged when greater than 15 minutes. However, because of the technique's sensitivity, it lacks specificity. The skin BT test has been shown to be a poor indicator of clinically significant bleeding at other sites, including oral postoperative bleeding after oral surgical procedures, and its use as a predictive screening test has been discouraged.[29,30]

Prothrombin Time and International Normalized Ratio

The PT and INR tests measure the time it takes for blood to clot by forming thrombin. They evaluate the extrinsic and common coagulation pathways, screening for the presence or absence of fibrinogen (F I), prothrombin (F II), and F V, F VII, and F X. The normal range of PT is approximately 11–13 seconds. Because of individual laboratory reagent variability and the desire to be able to reliably compare the PT from one laboratory with that from another, the PT test is commonly reported with the INR.[31,32] The INR, introduced by the World Health Organization in 1983, is the ratio of PT that adjusts for the sensitivity of the thromboplastin reagents, such that a normal coagulation profile is reported as an INR of 1.0, and higher values indicate abnormal coagulation.[33] Its most common use is to measure the effects of VKAs and reduction of the vitamin K–dependent F II, F VII, F IX, and F X. It is not effective for hemophilias A and B, since it does not measure F VIII or F IX. Although most patients on VKAs are monitored by monthly venous blood draws and laboratory analysis, the CoaguChek system allows Clinical Laboratory Improvements Amendments (CLIA)-waived point-of-care PT/INR testing of fingerstick blood in physicians' and dentists' offices.[34]

Activated Partial Thromboplastin Time

Also among the standard initial tests that measure clotting via thrombin formation, aPTT is used to evaluate the intrinsic coagulation pathway, and screen for deficiencies in F VIII, F IX, F XI, and F XII, in addition to prekallikrein and high molecular weight kiningen. It is performed by calcifying plasma in the presence of a thromboplastic material (i.e., phospholipid tablet) and a contact activator that is a negatively charged substance (e.g., kaolin) in the absence of TF. It is considered normal if the control aPTT and the test aPTT are within 10 seconds of each other. Control aPTT times are usually 15–35 seconds. Normal ranges depend on the manufacturer's limits, as each supplier varies slightly. As a screening test, the aPTT is prolonged only when the factor levels in the intrinsic and common pathways are less than approximately 30%. It is altered in hemophilias A and B and with the use of the anticoagulant heparin, which may result in clinical bleeding problems. However, elevated aPTT due to deficiencies in F X II, prekallikrein, and high molecular weight kiningen do not correlate with clinical bleeding.

Thrombin Time

TT measures the final step in the clotting cascade, the cleavage of fibrinogen to fibrin. It specifically tests the ability to form the initial fibrin clot from fibrinogen, by adding thrombin to plasma. Its normal range is 9–13 seconds, with values in excess of 16–18 seconds considered to be prolonged. It is used to measure the activity of thrombin inhibitor anticoagulants (e.g., heparin, dabigatran), FDPs, or other paraproteins that inhibit the conversion of fibrinogen to fibrin. Fibrinogen can also be specifically assayed and should be present at a level of 200–400 mg/dL.

Fibrin Degradation Products

Disorders of fibrinolysis (clot breakdown) often show delayed bleeding. FDPs are measured using a specific latex agglutination system to evaluate the presence of the D-dimer of fibrinogen and/or fibrin above normal levels. Such presence indicates that intravascular lysis has taken place or is occurring. This state can result from primary fibrinolytic disorders or disseminated intravascular coagulation (DIC).

Specific Clotting Factor Assays

Specific activity levels of factors are measured if one or more of the screening tests are abnormal, in order to further identify factor deficiencies and their level of severity. Normal factor activity is usually in the 60%–150% range. Coagulation factor inhibitor tests, often referred to as the Bethesda titer assay, measured in units, are essential when sufficient factor concentrate to correct the factor deficiency under normal conditions fails to control bleeding. To identify the specific type of VWD (types I–III and platelet type), additional studies, such as ristocetin cofactor, ristocetin-induced platelet aggregation studies, and monomer studies, are helpful. These are discussed in more detail later in this chapter.

Tests of Capillary Fragility

The tourniquet test for capillary fragility is useful for identifying platelet disorders and is the only test to demonstrate abnormal results in vessel wall disorders. A moderate degree of stasis is produced by a tourniquet or by inflating a blood pressure cuff around the arm in the usual manner to a pressure halfway between systolic and diastolic levels, and maintained for 5–10 minutes. At 2 minutes following tourniquet or cuff deflation and removal, a 2.5 cm diameter region (size of a quarter) of skin on the volar surface of the arm at 4 cm distal to the antecubital fossa is observed for petechial hemorrhages. This petechial display is called the Rumpel–Leede phenomenon; normally the petechiae count does not exceed 5 in men and 10 in women and children, and is considered abnormal at more than 10–20.

BLOOD VESSEL DISORDERS

Vessel wall disorders can be due to structural malformation of vessels and inherited or acquired disorders of connective tissue. They can result in hemorrhagic features, though bleeding is usually mild and confined to the skin, mucosa, and gingiva. Vascular purpura can result from damage to capillary endothelium, from abnormalities in the vascular subendothelial matrix or extravascular connective tissue bed, or from abnormal vessel formation.

Scurvy

Scurvy results from a dietary deficiency of water-soluble vitamin C, when dietary vitamin C falls below 10 mg/d. Vitamin C is necessary for the synthesis of hydroxyproline, an essential constituent of collagen. The US Recommended Daily Allowance of vitamin C is 90 mg daily for men and 75 mg daily for women. Scurvy is found primarily in regions of urban poverty, among either infants on nonsupplemented processed milk formulas, the elderly who cook for themselves, adults with alcohol or drug dependencies, children with special needs and underlying medical conditions such as sickle cell anemia or thalassemia with iron overload from multiple transfusions, neurologic conditions, and a history of chemotherapy or aversion to vitamin C–rich foods, or the intellectually disabled.[35,36,37,38] Many of the hemorrhagic features of scurvy result from defects in collagen synthesis. Among the first clinical signs are petechial hemorrhages, corkscrew hair at the hair follicles, and purpura on the back of the lower extremities that coalesce to form ecchymoses. Hemorrhage can occur in the muscles, joints, nail beds, and gingival tissues. Severe vitamin C deficiency is considered a systemic risk factor for periodontitis, as it compromises antioxidant micronutrient defenses to oxidative stress and adversely influences collagen synthesis, resulting in weakened capillary blood vessel walls and enhanced gingival bleeding.[39] Gingival involvement may include swelling, friability, bleeding, secondary infection, and loosening of teeth. Implementation of a diet rich in vitamin C and administration of 1 g/d of vitamin C supplements provides rapid resolution.

Cushing's Syndrome

Cushing's syndrome, resulting from excessive exogenous or endogenous corticosteroid intake or production, leads to general protein wasting and atrophy of supporting connective tissue around blood vessels. Patients may show skin bleeding or easy bruising. Aging causes similar perivascular connective tissue atrophy and lack of skin mobility. Tears in small blood vessels can result in irregularly shaped purpuric areas on arms and hands, called purpura senilis. Other metabolic or inflammatory disorders resulting in purpura include Schönlein–Henoch or anaphylactoid purpura, hyperglobulinemic purpura, Waldenström's macroglobulinemia, multiple myeloma, amyloidosis, and cryoglobulinemia.

Ehlers–Danlos Syndrome

Ehlers–Danlos syndrome (EDS) is an autosomal dominant or autosomal recessive inherited disorder of connective tissue matrix, generally resulting in fragile skin blood vessels and easy bruising. It is characterized by hyperelasticity of the skin and hypermobile joints. Thirteen types have been identified with unique biochemical defects and varying clinical features, and were sorted using a pathogenetic scheme into the 2017 International Classification:[40,41]

- Classic EDS (former type I) presents with soft, velvety, hyperextensible skin; easy bruising and scarring; hypermobile joints; varicose veins; and prematurity.[42]
- Periodontal EDS (former Type VIII), which was mapped to chromosome 12q13,[43] has skin findings similar to those in classic EDS, with easy bruising following minor trauma due mainly to the resulting fragility of the oral mucosa and blood vessels, and is characterized by early-onset periodontal disease with severe loss of alveolar bone and permanent dentition.[44]
- Children with arthrochalasia EDS (former type VII) may present with microdontia and collagen-related dentinal structural defects in primary teeth, in addition to bleeding after tooth brushing.[45]
- Patients with vascular EDS (former type IV) may have a characteristic facial appearance, gingival recession, and gingival fragility.
- Those with spondylodysplastic EDS (former progeroid type) may have characteristic facial features and tooth discoloration or dysplastic teeth.

Other oral findings include fragility of the oral mucosa, gingiva, and teeth, as well as hypermobility of the temporomandibular joint (TMJ) and stunted teeth and pulp stones on dental radiographs.[46] Oral health may be severely compromised as a result of specific alterations of collagen in orofacial structures. A number of tissue responses (mucosa, periodontium, pulp) and precautions (e.g., prevention of TMJ dislocation) should be considered when planning dental treatment.[47]

Hereditary Hemorrhagic Telangiectasia

Hereditary hemorrhagic telangiectasia (HHT), also called Rendu–Osler–Weber syndrome, is a group of autosomal dominant disorders with abnormal telangiectatic capillaries, frequent episodes of nasal and gastrointestinal (GI) bleeding, and associated brain and pulmonary lesions.[48,49,50] The Scientific Advisory Board of the HHT Foundation International's consensus clinical diagnostic criteria, known as the Curaçao criteria, requires the presence of at least three of the four following criteria:[51]

- Spontaneous and recurrent epistaxis.
- Multiple telangiectasia at characteristic sites (lips, oral cavity, nose, fingers).
- Visceral arteriovenous malformations.
- First-degree relative with HHT history.

Perioral and intraoral angiomatous nodules or telangiectases are common with progressive disease, involving areas of the lips, tongue, and palate that may bleed upon manipulation during dental procedures.[52] Small nonpulsating visceral arteriovenous malformations may blanch in response to applied pressure, unlike petechiae or ecchymoses. Mucocutaneous lesions may bleed profusely with minor trauma, or on occasion spontaneously.[53] Persistently bleeding oral lesions may be treated with cryotherapy, laser ablation, electrocoagulation, or antifibrinolytics.[54] Submucosal and intravenous (IV) bevacizumab, a humanized recombinant monoclonal antibody to the angiogenic vascular endothelial growth factor that is elevated in HHT, has recently shown promise in treatment of epistaxis in HHT.[55] It has also been suggested that antibiotic prophylaxis should be considered before dental care to reduce the occurrence of cerebral abscesses for patients with HHT and concomitant pulmonary arteriovenous malformation.[56]

PLATELET DISORDERS

Congenital Platelet Disorders

Congenital abnormalities of platelet function or production are rare and the causes are quite diverse. Causes range from defects in receptors critical to platelet adhesion and aggregation, to defects in signaling molecules, or in transcription factors important for the production of functional platelets. Conditions may present with large, small, or normal-sized platelets and be associated with other diseases or clinical features (Table 18-5).[57]

Bernard–Soulier Syndrome

Bernard–Soulier syndrome, a hemorrhagioparous thrombocytic dystrophy, is a rare autosomal recessive disorder that results from an identified absence of the platelet membrane GPIb-IX-V complex from the platelet membranes, rendering the platelets unable to interact with VWF.[58,59] Features include epistaxis as the most common clinical sign, giant platelets, decreased platelet count, and increased bleeding time. The main treatment modality for Bernard–Soulier syndrome is supportive measures combined with specific treatment of bleeding episodes, typically with human leukocyte antigen (HLA)-matched platelet transfusions.[58]

Glanzmann's Thrombasthenia

Glanzmann's thrombasthenia is a qualitative disorder characterized by mucocutaneous bleeding due to mutations in the *ITGA2B* and *ITGB3* genes encoding the integrin αIIbβ3.[60] As a result, platelet membrane GPIIb/IIIa cannot bind to fibrinogen and cannot aggregate with other platelets, although platelet count is not altered. Clinical signs include bruising, epistaxis, gingival hemorrhage, and menorrhagia. Rarely, Glanzmann's thrombasthenia may be acquired in association with pregnancy, autoimmune conditions (e.g., systemic lupus erythematosus [SLE], immune thrombocytopenia), and therapeutic GPIIb/III antagonists (e.g., abciximab, eptifibatide). Treatment of oral surgical bleeding involves platelet transfusion, antifibrinolytics, recombinant factor (rF) VIIa, and local hemostatic agents, alone or in combination.[61] Treatment of bleeding episodes in the patient with Glanzmann's thrombasthenia is usually not warranted unless hemorrhage is life-threatening.

Wiskott–Aldrich Syndrome

Wiskott–Aldrich syndrome is a rare X-linked recessive disease, with ill-defined pathophysiology, characterized by mild to severe presentation of cutaneous eczema (usually beginning on the face), bleeding from thrombocytopenic purpura, and propensity to infection due to an immunologic defect.[62] It is a quantitative and qualitative platelet disorder. Oral manifestations include gingival bleeding and palatal petechiae. Thrombocytopenia of Wiskott–Aldrich syndrome may be managed with platelet transfusions, antifibrinolytic drugs, splenectomy (with risk of increased infections), or allogeneic hematopoietic stem cell transplantation, with hope of gene therapeutic approaches available in the future.[62]

Table 18-5 Classification of platelet disorders. *Source:* Based on Sharma R, Perez Botero J, Jobe SM. Congenital disorders of platelet function and number. *Pediatr Clin North Am*. 2018;65(3):561–578.

May–Hegglin Anomaly

May–Hegglin anomaly, one of the now four autosomal dominant MYH9-related inherited thombocytopenias (along with Sebastian, Fechtner, and Epstein syndromes), is a rare hereditary condition characterized by the triad of thrombocytopenia, giant platelets, and inclusion bodies in leukocytes.[63] Clinical symptoms include mild bleeding, and possible kidney dysfunction, deafness, and cataracts later in life.

Acquired Platelet Disorders—Systemic

An outline of acquired platelet disorders is found in Table 18-5.

Primary Immune Thrombocytopenia

Primary immune thrombocytopenia (also known as idiopathic thrombocytopenic purpura [ITP] or immune

thrombocytopenic purpura) is caused by autoantibodies against platelet antigens.

In reviews from the United States, prevalence was approximately 9.5 per 100,000 persons, with 8 per 100,000 in children, 12 per 100,000 in adults, and an overall female to male ratio of 1.9:1.[64,65]

ITP is assumed to be caused by accelerated antibody-mediated platelet consumption. While genetic factors are considered for the onset of ITP, some cases have inciting events, either infections and/or systemic conditions that disrupt immune function.

Viral infections are the most common infectious cause. Human immunodeficiency virus (HIV), hepatitis C virus (HCV), cytomegalovirus (CMV), and varicella zoster virus have been implicated. It has been proposed that antibodies against viral antigens may cross-react with normal platelet antigens.[66,67,68] Bacterial infection is a less common trigger, with proposed mechanisms including lipopolysaccharide attachment to platelet surfaces and increased platelet phagocytosis, molecular mimicry via antibodies, immune alterations, and activities of bacterial products.[69,70] Immune-mediated thrombocytopenia may occur in conjunction with HIV disease in approximately 15% of adults, being more common with advanced clinical disease and immune suppression, although less than 0.5% of patients have severe thrombocytopenia with platelet counts below 50,000/mm^3.[71]

In autoimmune disorders, the development of autoantibodies occurs, as seen in antiphospholipid syndrome (APS), SLE, Evans syndrome, hematopoietic cell transplantation, chronic lymphocytic leukemia (CLL), and other low-grade lymphoproliferative disorders.[72,73] Antibody production in ITP is driven by CD4-positive helper T cells reacting to platelet surface glycoproteins, with splenic macrophages being the major antigen-presenting cells.[74,75] Autoimmune thrombocytopenia is found in patients with SLE, with mild thrombocytopenia (platelet counts between 100,000 and 150,000/mm^3) noted in 25%–50% of patients and severe thrombocytopenia (platelet counts <50,000/mm^3) in 10% of patients.[76] Severe bleeding from ITP due to SLE is only experienced by a minority of patients; however, when it occurs it requires aggressive treatment.[77]

Many patients with ITP are asymptomatic and overall risk of bleeding is low. Symptomatic patients can have fatigue and reduced quality of life. Bleeding may occur in up to two-thirds of patients. Clinical symptoms include petechiae and purpura over the chest, neck, and limbs, usually more severe on the lower extremities. Mucosal bleeding may occur in the oral cavity and GI and genitourinary tracts. In severe cases of ITP, oral hematomas and hemorrhagic bullae may be the presenting clinical sign (Figure 18-6).[78]

There is a lack of sensitive or specific diagnostic tests for ITP and other causes of thrombocytopenia, therefore posing a challenge, relying on a diagnosis of exclusion. Primary diagnostic investigations in patients with suspected ITP should include CBC with differential, peripheral blood smear, and HIV and HCV testing. Secondary tests may include PT, aPTT, *Helicobacter pylori* testing, antinuclear antibody, and vitamin B_{12} and folate levels. By consensus, the criteria for ITP is a platelet count of <100,000/mm^3, with greatest concern for bleeding with platelet counts <20,000/ mm^3.[79] Large platelets are often noted on the peripheral blood smear; however, their absence does not exclude the diagnosis. ITP is not accompanied by abnormal numbers or morphology of red and white blood cells, or abnormal coagulation parameters. If any of these are seen, then other conditions should be considered (e.g., infection, leukemia, thrombotic thrombocytopenic purpura [TTP], and DIC).

The goal of ITP therapy is to reduce the risk of clinically significant bleeding. Active interventions are guided by clinical symptoms and the platelet count. The objectives during treatment are to provide a safe, rather than normalized, platelet count.[80]

For ITP patients with severe bleeding, treatment is immediate platelet transfusion along with IV immunoglobulin (IVIg) and high-dose corticosteroids. For a new diagnosis of ITP and a platelet count <20,000/mm^3, IVIg and corticosteroids are also indicated to prevent thrombocytopenia from persisting and worsening. Target platelet counts are between 20,000 and 30,000/mm^3, except in the case of those with a history of bleeding at higher counts, other hemostatic defects, those requiring surgery, or at increased risk of bleeding in general (e.g., peptic ulcer, high activity, high risk of falls).

Splenectomy may be necessary in chronic ITP to prevent antiplatelet antibody production and sequestration and removal of antibody-labeled platelets.[81]

ITP may be acute and self-limiting (2–6 weeks) in children. In adults, ITP is typically more indolent in its onset, and the course is persistent, often lasting many years, and may be characterized by recurrent exacerbations of disease. The natural history and long-term prognosis of adults with chronic ITP remain incompletely defined.[82]

Platelet count thresholds for surgery are higher than those to prevent spontaneous bleeding. While there are no published guidelines for oral and maxillofacial surgery, 50,000/mm^3 has been the recommended threshold for most major surgery, and as high as 100,000/mm^3 for neurosurgery or ocular surgery[83] with lower values (i.e., 20,000/mm^3) acceptable for less invasive procedures such as central line placement. A recent systematic review failed to find evidence to support this 50,000/mm^3 threshold for the safety of invasive dental procedures in thrombocytopenic patients.[84]

Thrombotic Thrombocytopenic Purpura

TTP is a rare acute disease that, until recently, was uniformly fatal. It can be hereditary or acquired due to an autoantibody inhibitor. Incidence of acquired TTP is 3 cases per million adults per year, and 1 per 10 million per year in children.[85] It is a thrombotic microangiopathy caused by severely reduced activity of the VWF-cleaving protease ADAMTS13. Small-vessel platelet-rich thrombi form that cause thrombocytopenia, microangiopathic hemolytic anemia, and sometimes organ damage. Causes include metastatic malignancy, pregnancy, mitomycin C, and high-dose chemotherapy. If untreated, it carries a high mortality rate.

Initial presentation may include fatigue, dyspnea, petechiae, or other bleeding. In addition to thrombocytopenia, clinical presentation of TTP includes GI symptoms, weakness, and neurologic findings ranging from coma, stroke, and seizure to headache and confusion. Microangiopathic hemolytic anemia, fluctuating neurologic abnormalities, renal dysfunction, and occasional fever also can occur. Microvascular infarcts due to the thrombi occur in gingival and other mucosal tissues and are present in about 60% of cases. Serial studies of plasma samples from patients during episodes of TTP have often shown VWF multimer abnormalities.[86]

Although there are numerous therapeutic options, there is no consensus among experts or clear algorithms to treat TTP. Plasma exchange therapy combined with acetylsalicyclic acid (ASA)/dipyridamole or corticosteroids have recently lowered the mortality rate for patients with TTP over that previously obtained by treatment with fresh frozen plasma (FFP) infusions.[87,88] In addition, there is a role for newer therapies with diverse mechanisms of action, such as rituximab, anti-D, and thrombopoietin-like agents.[89]

Liver Disease

Patients with liver disease may have a wide spectrum of hemostatic defects, depending upon the extent of liver damage, which affect both the platelet and coagulation phases of hemostasis.[90] These changes increase the risks of both bleeding and thrombosis.

Liver disease, both chronic and acute, results in both quantitative and qualitative platelet defects. Chronic liver disease with cirrhosis leads to thrombocytopenia due to portal hypertension, and sequestration and breakdown of platelets by the spleen, in addition to decreased thrombopoietin production. Thrombocytopenia in acute hepatitis is hypothesized to be linked to systemic inflammatory response syndrome and resultant multiorgan system failure.[91] Liver failure may also be considered as a potential cause of unexplained thrombocytopenia.[92] For more on clinical manifestations, diagnosis, and management of patients with liver disease, see the section on liver disease–associated coagulation disorders.

Chronic Kidney Disease

The failure of the kidney to properly eliminate the breakdown products of proteins results in increased levels of urea and creatinine in the blood, creating a uremic bleeding risk, which, although multifactorial in pathogenesis, is largely related to platelets. Proposed mechanisms for platelet disorders in chronic kidney disease (CKD) include platelet metabolic defects, deficiencies in platelet-endothelial interactions, and the effect of anemia on normal platelet function.[93] With anemia, it is proposed that the decreased number of red blood cells allows platelets to be more dispersed within the lumen of blood vessels, making them less likely to adhere to the endothelium and form a platelet plug in the event of injury. In addition, anemia may also affect ADP and TXA release, circulating nitric oxide (an inhibitor of platelet aggregation), and cyclic guanosine monophosphate concentrations.[94] In addition to platelet disorders, bleeding tendencies in CKD patients are also increased due to coexisting coagulopathies and the heparin use during hemodialysis. Ecchymoses, epistaxis, and GI and genitourinary bleeding are commonly seen in renal failure patients. Spontaneous intraoral mucocutaneous bleeding can also occur.

The routine use of dialysis has decreased the incidence of spontaneous bleeding episodes.[95] While the severity of CKD does not directly correlate with abnormal platelet aggregation, the degree of anemia secondary to decreased renal erythropoietin production due to CKD does. Therefore, correction of anemia with blood transfusions, erythropoietin, or erythropoiesis-stimulating agents reduces the bleeding time in many patients; however, it does not decrease the incidence or risk of bleeding.[96] Desmopressin (DDAVP) is an analog of antidiuretic hormone with vasopressor activity. It appears to work by increasing the release of F VIII/VWF multimers from endothelial cells and increase platelet membrane glycoprotein expression.[97] DDAVP is administered at a dose of 0.3 μg/kg IV (in 50 mL of saline over 15–30 minutes), or 3 μg/kg intranasally, as in Stimate nasal spray (one spray per nostril, 150 μg each spray) 1–2 hours before procedure. Improvement in BT is seen in approximately 1 hour, and lasts 4–8 hours.[98] Conjugated estrogens, 0.6 mg/kg IV daily for 5 days, or 2.5–25 mg orally per day, or 50–100 μg of transdermal estradiol twice weekly, are most commonly indicated in patients on dialysis who have chronic GI tract bleeding when other treatment is contraindicated.[99] Cryoprecipitate is thought to enhance platelet aggregation by increasing F VIII/VWF multimers and fibrinogen. When administered IV (10 units every 12–24 hours), BT improves in uremic patients, beginning in 1 hour and lasting for 4–24 hours.[100]

Cardiopulmonary Bypass

Cardiopulmonary bypass (CPB), also known as a heart–lung machine or extracorporeal membrane oxygenation (ECMO),

causes significant platelet dysfunction due to platelet interaction with nonphysiologic surfaces of the bypass machine, complement activation, release of cytokines, thrombin generation, and hypothermia during bypass. Collectively, these lead to premature platelet activation, secretion of contents, and alteration in surface glycoprotein expression (decreased GPIb and IIb/IIIa), leading to compromised adhesion, activation, and aggregation. Due to the dysregulated activation and secretion of contents, platelet–neutrophil and platelet–monocyte conjugates are formed, thought to be central in a post-CPB inflammatory syndrome. Thrombocytopenia also occurs in CPB due to hemodilution, and adherence of platelets to nonphysiologic surfaces in the machine. Bleeding occurs in 30%–50% of patients on CPB and this can be life-threatening.[101]

Dysproteinemia

Patients with multiple myeloma or Waldenström macroglobulinemia may have platelet dysfunction due to the presence of abnormal paraproteins in these conditions, which can affect platelet adherence, activation, aggregation, and procoagulant activity. A paraprotein for platelet surface membrane glycoprotein GPIIIa has been described in a patient with multiple myeloma. In Waldenström macroglobulinemia, chronic epistaxis and gingival bleeding are common, along with perioperative and postoperative GI bleeding during surgery.[102] Laboratory studies include prolongation of the BT, impaired clot retraction, defective in vivo; platelet aggregation, and decreased in vitro; platelet adhesion. In the absence of clinical bleeding, or planned surgical procedures, routine studies to test bleeding and clotting function are not necessary. In such patients, evaluation for clotting should include PT, PTT, TT, and F X activity.

Myeloproliferative Disorders

Thrombocytopenia may also be a component of other hematologic diseases, such as myelodysplastic disorders,[103] aplastic anemia,[104] and leukemia.[105] Symptoms include gingival hemorrhage, epistaxis, GI bleeding, and bruising.[106]

Diabetes

Patients with diabetes mellitus (DM) are prone to increased platelet reactivity due to increased receptor expression and increased downstream signaling, with intensified adhesion, activation, and aggregation, and a higher percentage of circulating immature platelets.[107,108] These may account for a higher risk of acute coronary syndrome in DM patients, and a lesser response to antiplatelet agents in DM patients when compared to non-DM patients. As a result, it is suggested that patients with DM may require increased dosages of therapeutic antiplatelet agents (e.g., aspirin, clopidogrel) than normal to have an optimal therapeutic effect, or may require a more potent platelet inhibitor (e.g., prasugrel, ticagrelor).[109]

Acquired Platelet Disorders—Drug-Induced/Therapeutic

Medications can also reduce absolute numbers of platelets or interfere with their function, resulting in postsurgical hemorrhage.[110,111] Bone marrow suppression from cytotoxic cancer chemotherapy can result in severe thrombocytopenia, requiring platelet transfusions for prevention of spontaneous hemorrhage.

Antiplatelet agents are routinely used therapeutically for thromboembolic protection in patients with ischemic heart disease, prosthetic heart valves, coronary artery stents, and those at risk of ischemic cerebrovascular accidents. Antiplatelet therapy reduces the risk of death from cardiovascular causes by about one-sixth, and the risk of nonfatal myocardial infarction and stroke by about one-third for patients with unstable angina or a history of myocardial infarction, transient ischemia, or stroke.[112] A science advisory panel consisting of the American Heart Association and American Dental Association recommends that 12 months of dual antiplatelet therapy is required after the placement of drug-eluting coronary artery stents.[113]

Acetylsalicyclic Acid

ASA, also known as aspirin, is an inexpensive and effective drug that is widely used. ASA induces a functional defect in platelets detectable as altered PFA-100 CTs and prolongation of BT. It inactivates an enzyme called prostaglandin synthetase, resulting in inactivation of cyclooxygenase (COX) catalytic activity and decreasing biosynthesis of prostaglandin and thromboxanes (such as thromboxane A2), which are needed to regulate interactions between platelets and the endothelium.[112] A single 100 mg dose of ASA provides rapid complete and irreversible inhibition of platelet COX activity and thromboxane production. This type of drug-related platelet disorder is compensated for within 7–10 days. In addition, there is no increase in this antiplatelet effect at levels beyond the low daily dosages, therefore lower-dose formulations (e.g., 81 mg) are standard for this therapeutic indication.

Other COX Inhibitors

Most nonsteroidal anti-inflammatory drugs (NSAIDs) have a similar but less significant antiplatelet effect, thereby are of mild concern to patients who have other disorders of hemostasis. The COX-2 inhibitors, such as celecoxib (Celebrex), generally do not inhibit platelet aggregation at indicated doses.

Antiplatelet Medications

Other therapeutic antiplatelet medications work by different mechanisms affecting platelet adhesion, activation, and aggregation, which include the inhibition of ADP receptor (e.g., clopidogrel and ticolopidine); adenosine reuptake

(dipyridamole); phosphodiesterase (e.g., cilostazol); and GPIIb/IIIa (e.g., abciximab, eptifibatide, tirofiban). Clopidogrel bisulfate (Plavix) alone carries less risk of prolonged bleeding than ASA; however, it is commonly used in dual antiplatelet therapy.[114]

Medical Management of Platelet Disorders

The decision to actively manage is based on a patient history of clinically significant bleeding suggestive of platelet dysfunction, in combination with appropriate laboratory tests, keeping in mind that these do not necessarily predict whether there will be clinically significant bleeding or its extent. In the case of treatment, there are limited treatment options for the correction of platelet disorders, with little strong evidence from randomized trials to form the basis for recommendations.[115]

Platelet Transfusion

Platelet transfusions are indicated for an actively bleeding patient due to platelet disorder, preparation for an invasive procedure, and prevention of spontaneous bleeding. The thrombocytopenias are primarily managed acutely, with transfusions of platelets to maintain the minimum level of 10,000–20,000/mm^3 necessary to prevent spontaneous hemorrhage (Table 18-7). This has also been indicated for thrombocytopenias secondary to liver disease and for Glanzmann's thrombasthenia, and is the main therapy for Bernard–Soulier disease.[116] However, repeated platelet transfusions may carry the risk of development of antiplatelet isoantibodies, thereby losing its effectiveness. As a consequence, transfusions are usually reserved for cases in which there is concern over excessive surgical or traumatic bleeding, or in active cases of severe, uncontrolled bleeding, in which prior treatments (discussed below) are unsuccessful.

The standard dose of platelets for prevention in adults is approximately 4–6 units of pooled platelets, or 1 apheresis unit (or 1 random donor unit per 10 kg of body weight), which translates to approximately 3 or 4 x 10^{11} platelets, transfused for approximately 20–30 minutes.[117] A standard pediatric dose is 5–10 mL/kg. In general, this platelet dosing is expected to raise the platelet count by approximately 30,000/mm^3 within 10 minutes of the infusion, with peak being 10–60 minutes, and a gradual decline over 72 hours. For prevention of bleeding, transfusion platelet transfusions once a day should suffice. For those who are being transfused therapeutically, either for active bleeding or for preparation for an invasive procedure, higher dosages or more frequent platelet transfusions may be indicated.

There are several risks from platelet transfusion. Infection by bacteria is a serious complication that can be fatal, occurring in approximately 1 in 2000 platelet transfusions,[118] which is more than 10-fold the rate of those receiving red blood cells. Volume overload is of concern for certain patients (e.g., those with congestive heart failure, renal failure, respiratory failure), as platelet transfusion introduces approximately 200 mL of volume per transfusion. Incidence of transfusion-associated circulatory overload is 1–3 per 100,000 platelet transfusions.[119] As mentioned earlier, the risk of production of autoantibodies to class I HLA antigens expressed on platelets increases with repeated transfusions and can decrease the response. Allergic reactions to platelet transfusion occur due to IgE directed against proteins in the donor plasma, with common occurrences being urticaria and pruritis in mild cases, and wheezing, shortness of breath, and hypotension in more severe cases. Anaphylactic reactions due to platelet transfusion are very rare. Transfusion-associated graft-versus-host disease occurs with any transfusion that contains lymphocytes. Another complication is acute lung injury following transfusion, which can cause respiratory distress.

Patients with confirmed antibody development due to anti-HLA antibodies should receive HLA-matched platelets, platelets negative for the corresponding antigen(s), or cross-matched compatible platelets, to reduce the number of platelet transfusions needed for hemostasis. Apheresis involves running blood through a process of separating and removing constituents, to include plasma (plasmapheresis), platelets (plateletpheresis), and leukocytes (leukapheresis). Apheresis platelets remove circulating isoantibodies and limit the recipient's exposure to a single blood donor, which potentially reduces the possibility of infection and antibody development, as some centers use apheresis platelets exclusively. Use of apheresis platelets also permits transfusion of platelets from specific donors selected based on HLA matching or platelet cross-matching, cytomegalovirus (CMV) status, and ABO group. For patients without antibody development, either pooled and apheresis platelets can be used.[120]

In the absence of satisfactorily compatible platelets, blood volume and constituents can be maintained with low-antigenicity blood products. Leukoreduction passes platelets through a filter that blocks the passage of most white blood cells (WBCs). Irradiation prevents graft-versus-host disease, in which contaminating WBCs attack host tissues, by damaging the nuclei of WBCs.

Desmopressin

DDAVP is used in the management of VWD, in which it works by releasing endogenous VWF from the endothelium. In case reports and cohort studies, it has been shown to be effective in preventing postoperative bleeding in patients with milder platelet disorders after dental procedures and minor surgery.[121,122] In patients with acquired platelet dysfunction, DDAVP has been demonstrated to decrease bleeding time; however, it did not correlate with changes in

actual VWF levels, in vitro; platelet aggregation, or decreased bleeding risk.[123,124,125]

Estrogens

Conjugated estrogens have been used most commonly for patients with mild to moderate type 1 VWD, or for uremic bleeding. The effective dose is IV estrogen 0.6 mg/kg daily for 5 days, 2.5–25 mg orally per day, or 50–100 μg of transdermal bestradiol twice weekly.

Recombinant Factor VIIa

rFVIIa has been used successfully in patients with congenital platelet disorders[126] and is also useful for patients who cannot receive platelet transfusions due to autoantibody formation, and for Glanzmann thrombasthenia and Bernard–Soulier syndrome. Proposed mechanisms include a tissue factor–independent thrombin generation induced by binding of rFVIIa to the surface of activated platelets, and a local procoagulant effect at sites of vascular damage.[127]

COAGULATION DISORDERS

Congenital Coagulation Disorders

Inherited disorders of coagulation can result from deficiency of a number of factors (Table 18-1) that are essential in the coagulation cascade, or a deficiency of VWF. Clinical bleeding can vary from mild to severe, depending on the specific clotting factor affected and the level of factor deficiency.

Von Willebrand Disease

VWD is the most common inherited bleeding disorder, affecting between 0.1% and 1% of the population.[128,129] However, only a fraction of patients are symptomatic and seek medical attention due to bleeding symptoms. Described originally by Erik von Willebrand in 1926,[130] it can be due to quantitative or qualitative defects in VWF, a multimeric high molecular weight glycoprotein.[131] VWF has two functions that qualify it as both a platelet disorder and a disorder affecting coagulation: (1) it mediates the initial platelet adhesion to the injured blood vessel wall; and (2) binds and stabilizes F VIII in plasma.[132] The normal plasma VWF level is 10 mg/L, with a half-life of 6–15 hours.

There are three major types of inherited VWD based on clinical, laboratory, and genetic information, and each has distinct therapeutic requirements.[129]

Type 1

Type 1 VWD, an autosomal dominant disease, is the most common, accounting for approximately 75% of patients. It represents a partial quantitative deficiency of VWF. Laboratory findings include decreased VWF activity and antigen.

Type 2

Type 2 VWD, which is usually an autosomal dominant disease, is characterized by several qualitative abnormalities of VWF. Four subtypes have been identified: 2A, 2B, 2M, and 2N:

- Type 2A, which accounts for 10%–20% of individuals with VWD, includes variants with decreased platelet adhesion caused by selective deficiency of high molecular weight VWF multimers and reduced binding to platelet GPIb.
- Type 2B accounts for 5% of cases of VWD. The defect is an increase in the binding of VWF to platelet GPIb, which results in sequestration or loss of the bound platelets and VWF from the circulation due to the clearance of the platelet aggregates that are formed, which can cause thrombocytopenia.[133]
- Type 2M includes variants with markedly defective platelet adhesion, despite a relatively normal size distribution of VWF multimers, due to reduced binding of VWF to platelet GPIb.
- Type 2N includes variants with markedly decreased binding affinity of VWF to F VIII.

Type 3

Type 3, a total deficiency of VWF, is a rare autosomal recessive disorder that leads to severe disease with undetectable levels of VWF. Levels of F VIII may be reduced in types I and 2, while types 2N and 3 have a dramatic decrease in F VIII.[134]

A rare autosomal dominant fourth type is called pseudo- or platelet-type VWD with hyperresponsive platelets, and it is a primary platelet disorder that mimics VWD.[134] The increased platelet affinity for large multimers of VWF, with subsequent removal of VWF and platelets from circulation, results primarily in mild to moderate mucocutaneous bleeding, which increases during pregnancy or following use of antiplatelet medications such as ASA, making diagnosis difficult.[135] Unlike the other types of VWD, the platelet type is rare and presents with less severe clinical bleeding, and requires platelet transfusion for correction.

The clinical features of VWD are usually mild and include mucosal bleeding, soft tissue hemorrhage, and menorrhagia in women; however, there can be instances of moderate to severe bleeding, with type 1 having the lowest bleeding risk and type 3 having the highest bleeding risk.[129] VWD types 2N and 3 would have symptoms similar to hemophilia A, with hemarthrosis and soft tissue and urinary bleeding (Figure 18-8).

Patients are assessed for history of prior bleeding symptoms, such as bruising and/or bleeding with procedures (e.g., needles) and minor trauma, spontaneous bleeding episodes, or hemostatic challenges such as during menstrual cycles, trauma, dental extractions, or other surgical interventions. A physical examination notes any areas of ecchymoses

Figure 18-8 A 27-year-old man with Type 3 von Willebrand disease and a 2-week duration of bleeding from the tongue that reduced his hematocrit to 16%. Hemorrhage control was obtained with cryoprecipitate.

and hematomas, and evidence of mucosal bleeding. A family history is important and is also helpful in deciding between different inherited bleeding disorders. In terms of laboratory studies, individuals with VWD will have a normal CBC and platelet count (with the exception of mild thrombocytopenia in type 2B VWD), a normal or prolonged aPTT, and a normal PT. Tests that assess the quantity and function of VWF include VWF antigen (VWF:Ag), a quantitative measure of total VWF protein level and VWF activity via ristocetin cofactor (VWF:RCo), or the newer VWF:GPIbM assay.[129] Functional assays of VWF binding to platelets or collagen and F VIII activity are also assessed in some cases.

DDAVP in intranasal, IV, or subcutaneous injections may be used for bleeding episodes in VWD patients, with the exception of type 3 for which it is not effective. As DDAVP releases stored endothelial cell VWF, it should be tested initially in a trial dosing and with laboratory testing of response in order to assure effectiveness (defined as a threefold increase and assured hemostasis).[129] Stimate nasal spray is most commonly used, at 1 spray for patients under 50 kg weight and 2 sprays for those over 50 kg weight, due to convenience and effectiveness in 80% of type I VWD patients.[129] Plasma-derived intermediate and high-purity concentrates containing both VWF and F VIII, or recombinant VWF concentrates, are administered IV in moderate to severe patients in types 1, 2A, 2B, and 2M VWD. F VIII replacement is used in VWD types 2N and 3. Antifibrinolytics also have a hemostasis-supportive role in VWD, as does hormone therapy in women with heavy menstrual bleeding.[129]

Hemophilia

Hemophilia A

Hemophilia A is inherited as an X-linked recessive disorder that affects males (hemizygous), and the trait is carried in the female (heterozygous) without clinical evidence of the disease, although a few affected females do manifest mild bleeding symptoms. Males with hemophilia transmit the affected gene to all their female offspring, yet their sons are normal, and the effects skip a generation unless the mother was a carrier and their daughters received the maternal affected X chromosome as well. Only 60%–70% of families with newly diagnosed hemophiliacs report a family history of the disease, suggesting a high mutation rate. There is no racial predilection. Hemophilia A involves a deficiency of F VIII, the antihemophilic factor, and accounts for 79% of all hemophiliacs. There is a severe factor deficiency (<1% F VIII) in 43% of hemophiliacs, 26% have a moderate deficiency (1%–5% F VIII), and 31% present with a mild deficiency (6%–30% F VIII).[133]

Clinical symptoms and F VIII levels vary from pedigree to pedigree. Those with severe factor deficiency are more likely to have severe and spontaneous bleeding, and onset of bleeding episodes at an earlier age.[136] In contrast to the more superficial signs of bleeding observed in individuals with platelet-associated disorders, individuals with hemophilia exhibit bleeding into more deep-seated spaces, although bleeding from small cuts is uncommon. Immediate and delayed bleeding after trauma is common, ranging from very significant bleeds to continuous oozing for days or weeks. The more common signs include hematomas, hemarthroses, hematuria, GI bleeding, and bleeding from lacerations, or head trauma, or spontaneous intracranial bleeding that requires factor replacement therapy.[135] Retroperitoneal and central nervous system bleeds, occurring spontaneously or induced by minor trauma, can be life-threatening. Severe hemorrhage leads to joint synovitis and hemophilic arthropathies, intramuscular bleeds, and pseudo-tumors (encapsulated hemorrhagic cysts).

People with moderate deficiency often bleed in response to minor injury and invasive procedures, although with less frequent bleeding, typically 4–6 times yearly. Those with mild hemophilia only have bleeding in response to injury or trauma, such as prolonged bleeding following tooth extraction, other surgical procedures, or severe trauma.

Hemophilia B

Hemophilia B (Christmas factor; F IX) occurs in approximately 1 in 15,000–30,000 live male births. The genetic background, factor levels, and clinical symptoms are similar to those in hemophilia A. The distinction was made only in the late 1940s between these two X-linked diseases. Concentrates used to treat F VIII and F IX deficiencies are specific for each state; therefore, a correct diagnosis must be made to ensure effective replacement therapy.

Circulating blocking antibodies or inhibitors to F VIII and F IX may be seen in patients with these disorders. These inhibitors are specific for F VIII or F IX, more often develop in patients with severe hemophilia, and render the patient

refractory to the normal mode of treatment with concentrates. Significant morbidity in hemophiliacs with inhibitors relates to bleeding risk, allergic/anaphylactic reactions, and nephrotic syndrome.[137]

Diagnosis

Patients are assessed for prior bleeding history. A thorough family history is obtained. Genetic testing is also often performed to identify the presence of a specific gene mutation.

Hemophilia is characterized by a prolonged aPTT, with a normal platelet count and PT. However, aPTT may be normal in those with milder factor deficiencies. Diagnosis is made based on the measurement of factor activity levels when compared to normal controls (F VII in hemophilia A; F IX in hemophilia B). In patients with F VIII deficiency, it is important to rule out VWD. The diagnostic criteria are as follows:

- *Hemophilia A*. Confirmation of an F VIII activity level below 40% of normal (below 0.40 international units [IU]/mL) or, in some circumstances where the F VIII activity level is ≥40%, a pathogenic F VIII gene mutation. A normal VWF:Ag should also be documented to eliminate the possibility of some forms of VWD.
- *Hemophilia B*. Confirmation of an F IX activity level below 40% of normal or, in some circumstances where the F IX activity level is ≥40%, a pathogenic F IX gene mutation. Newborns have a lower normal range of F IX activity; the normal newborn range should be used as a reference when evaluating factor levels in newborns.
- *Hemophilia carrier*. Requires identification of a hemophilia gene mutation. Factor levels are important for managing carriers, but are not optimal for determining or eliminating the diagnosis of a hemophilia carrier.

Rare Coagulation Factor Deficiencies

Rare coagulation deficiency disorders include inherited qualitative or quantitative deficiencies of coagulation factors including F I (fibrinogen), F II (prothrombin), F V, F VII, F X, F XI, and F XIII, together accounting for 3%–5% of all congenital bleeding disorders.[138]

F II Deficiency

Prothrombin (F II) deficiency is the most rare congenital bleeding disorder. It is found to disproportionately affect Latinos in North America. Inheritance is autosomal recessive and both PT and aPTT are elevated.[137] Management is with prothrombin complex concentrates (PCCs).

F V Deficiency

Proaccelerin (F V) deficiency, like F XI and F X deficiencies, is a rare autosomal recessive trait that presents with moderate to severe clinical symptoms. When compared with hemophilia A and B, this hemorrhagic diathesis is moderate, only occasionally resulting in soft tissue hemorrhage and only rarely presenting with hemarthrosis. It does not involve the devastating degenerative joint disease seen in severe hemophilia A and B. FFP is the mainstay of treatment.

F VII Deficiency

Proconvertin (F VII) deficiency, with a prevalence of 1 in 500,000 population, makes it the most common of the rare coagulation factor deficiencies. Clinical bleeding is not as well correlated to level of deficiency as in hemophilia A or B, although PT is often prolonged with no effect on aPTT, and development of alloantibodies or inhibitors has been reported.[137] Treatment is with rFVIIa.

F X Deficiency

Stuart factor (F X) deficiency, also a rare bleeding diathesis, is inherited as an autosomal recessive trait. Clinical bleeding symptoms in the patient with levels less than 1% are similar to those seen in hemophilia A and B.

F XI Deficiency

Plasma thromboplastin antecedent (F XI) deficiency is clinically a mild disorder seen in pedigrees of Jewish descent; it is transmitted as an autosomal dominant trait. Bleeding symptoms do occur, but are usually mild. In the event of major surgery or trauma, hemorrhage can be controlled with infusions of FFP.

F XII Deficiency

Hageman factor (F XII) deficiency is another rare disease that presents in the laboratory with prolonged PT and aPTT. Clinical symptoms are nonexistent, therefore treatment is contraindicated.

F XIII and F I Deficiencies

Fibrin-stabilizing (F XIII) deficiency and fibrinogen (F I) deficiency are very rare, and these diagnoses can be made only with extensive laboratory tests, usually available only in tertiary-care medical centers. Both are autosomal recessive traits. Most dysfibrinogenemias result in no symptoms, others lead to moderate bleeding, and a few induce a hypercoagulable state. F XIII deficiency appears to have different forms of penetrance and in some families appears only in males. Treatment has historically been with cryoprecipitate; however, purified plasma-derived and recombinant products have been recently developed.[137]

Acquired Coagulation Disorders—Systemic

Vitamin K Deficiency

Vitamin K is a fat-soluble vitamin that is absorbed in the small intestine and stored in the liver. It plays an important role in hemostasis by activating various coagulation factors. Vitamin K deficiency is associated with having poorly

functioning vitamin K–dependent F II, F VII, F IX, and F X.[139] Deficiency is rare, but can result from inadequate dietary intake, intestinal malabsorption, or loss of storage sites due to hepatocellular disease. Biliary tract obstruction and long-term use of broad-spectrum antibiotics, particularly the cephalosporins, can also cause vitamin K deficiency.

Although there is a theoretic 30-day store of vitamin K in the liver, severe hemorrhage can result in acutely ill patients in 7–10 days. A rapid fall in F VII levels leads to an initial elevation in INR and subsequent prolongation of aPTT. When vitamin K deficiency results in coagulopathy, supplemental vitamin K by injection restores the integrity of the clotting mechanism within 12–24 hours.

Liver Disease

In addition to platelet defects, liver disease affects the coagulation cascade, and formation and removal of clots. Owing to impaired protein synthesis, important factors and inhibitors of the clotting and fibrinolytic systems are markedly reduced. Acute or chronic hepatocellular disease may display decreased vitamin K–dependent factor levels, with other factors still being normal. This is due to decreased bile salt synthesis, which leads to impaired vitamin K absorption and, as noted previously, decreased storage sites. Additionally, abnormal vitamin K–dependent factor and fibrinogen molecules have been encountered. In a cirrhotic patient, oral manifestations may include petechiae, hemorrhage, and gingival bleeding (Figure 18-9).

Liver disease that results in bleeding from deficient vitamin K–dependent clotting factors (F II, F VII, F IX, and F X) may be reversed with 3 days of vitamin K injections, either IV or subcutaneous. Infusion of FFP may be necessary when more immediate hemorrhage control is necessary, such as prior to dental extractions or other surgical procedures.[140] Cirrhotic patients with moderate thrombocytopenia and functional platelet defects may benefit from DDAVP therapy.[141] Antifibrinolytic drugs, if used cautiously, have markedly reduced bleeding and thus lowered the need for blood and blood product substitution.[90] Platelet transfusions may be required for liver disease patients who are thrombocytopenic.

Figure 18-9 A 46-year-old man with severe liver cirrhosis due to hepatitis C infection. Shown is purpura of facial skin 1 week after full-mouth extractions.

Acquired von Willebrand Syndrome

Acquired von Willebrand Syndrome (aVWS) occurs as a result of an underlying cause, as opposed to the genetic disorder. Of all cases of VWD, only 1.2% were aVWS.[142] However, it is reported to be prevalent in significant numbers in certain conditions, such as myeloproliferative neoplasms (10%–20%), autoimmune disorders, congenital cardiac abnormalities or aortic stenosis (10%–70%), and left ventricular assist device (LVAD) or extracorporeal membrane oxygenation (ECMO; up to 100%).

Reduced VWF activity in aVWS can occur via immune and nonimmune mechanisms. For immune mechanisms, autoantibodies to the VWF protein may occur from lymphoproliferative neoplasms and autoimmune disease, in which they interfere with VWF function and lead to bleeding.[143] In terms of nonimmune mechanisms, VWF protein is damaged or cleaved secondary to changes in fluid flow and shear stress, which can occur whenever there is vessel stenosis, as is the case in ventricular septal defect, aortic stenosis, post mitral valve replacement, LVAD, and ECMO. In addition, VWF can be removed from circulation due to adsorption into cells, which may occur in multiple myeloma, Waldenström macroglobulinemia, and non-Hodgkin lymphoma.[144]

Lymphoproliferative disorders associated with aVWS include monoclonal gammopathy, multiple myeloma, Waldenström macroglobinemia, CLL, and non-Hodgkin lymphoma.[145,146] There have been case reports of aVWS occurring in SLE, though prevalence in SLE and other autoimmune disorders has not been established.[147]

Hypothyroidism can cause aVWS, though the prevalence is unknown and thought to be rare, with synthesis reduced in the setting of low thyroid hormone levels. In autoimmune thyroiditis, autoantibodies against VWF have been reported.[148] aVWS is also caused by medications, including valproic acid, ciprofloxacin, and griseofulvin. New-onset unexplained bleeding, usually involving mucosal surfaces, is found in patients with an underlying condition known to predispose them to having reduced VWF levels.

Initial tests include a CBC with platelet count, and coagulation testing to include PT, aPTT, and INR. Specific tests for VWF include VWF:Ag, VWF:RCo, and F VIII:C. Further tests include VWF collagen binding, VWF multimers, and VWF propeptide. aVWS may exhibit decreased collagen binding, decreased VWF multimers, and/or a high ratio of VWF propeptide to VWF:Ag.

Distinguishing aVWS from inherited VWD can be determined by onset of bleeding later in life, with a history of uneventful surgical procedures, negative family history of VWD, and remission of bleeding after treatment of underlying aVWS-associated disorder.

Treatment of the underlying aVWS-associated disorder will usually correct aVWS; however, treatment may take days to weeks to become effective. For immune-mediated causes of aVWS (e.g., SLE, CLL), immunosuppressive therapy (e.g., corticosteroids, cyclophosphamide, rituximab), or IVIg is appropriate. Plasmapheresis can be used to rapidly reduce VWF antibody levels, in cases of serious bleeding.[149]

For acute bleeding episodes, a number of interventions are available. VWF concentrate is administered IV. A dose of VWF concentrate of 40–60 IU per kg of body weight is initially given to reach a plasma level of VWF:RCo of 50–100 IU/dL, and subsequent doses of 20–40 IU per kg of body weight are given every 12 hours. DDAVP can be administered every 12–24 hours, either intranasally, subcutaneously, or IV. Topical antifibrinolytic agents are useful for bleeding from mucosal sites, including the mouth. Examples include tranexamic acid and aminocaproic acid, in addition to Gelfoam or Surgicel soaked in topical thrombin.

For patients requiring an invasive procedure, there are several specific prophylactic strategies. DDAVP is administered for minor procedures, with the first perioperative dose given 1 hour before the procedure, and subsequent dosages every 6–12 hours after surgery. VWF concentrates are used for major and high-bleeding-risk procedures. For dental procedures, topical antifibrinolytic agents are also used.

Disseminated Intravascular Coagulation

DIC is a process that causes both thrombosis and hemorrhage, occurring in approximately 1% of hospital admissions.[150] It is triggered by potent stimuli that activate both F XII and TF to initially form microthrombi and emboli throughout the microvasculature.[151] Thrombosis results in rapid consumption of both coagulation factors and platelets, while also creating FDPs that have antihemostatic effects. The most frequent triggers for DIC are obstetric complications, metastatic cancer, massive trauma, and infection with sepsis. Clinical symptoms vary with disease stage and severity. Most patients have bleeding at skin and mucosal sites. Although it can be chronic and mild, acute DIC can produce massive hemorrhage and be life-threatening.

In acute DIC, it is important to expeditiously identify the underlying triggering disease or condition and deliver specific and vigorous treatment of the underlying disorder to promote long-term survival. Diagnosis is made by laboratory studies that confirm increased thrombin generation (e.g., decreased fibrinogen, prolonged PT and aPTT) and increased fibrinolysis (e.g., increased FDPs and D-dimer). For chronic DIC, diagnosis is based on the evidence of microangiopathies on the peripheral blood smear, and increased FDPs such as D-dimer. The dentist may be called upon to provide a gingival or oral mucosal biopsy specimen for histopathologic examination to confirm the diagnosis of DIC by the presence of microthrombi in the vascular bed.

Although somewhat controversial, active DIC is usually treated initially with IV unfractionated heparin or subcutaneous low molecular weight heparin (LMWH), to prevent thrombin from acting on fibrinogen, thereby preventing further clot formation.[152] Infusion of activated protein C, ATIII, and agents directed against TF activity are being investigated as new therapeutic approaches.[153] Replacement of deficient coagulation factors with FFP and correction of the platelet deficiency with platelet transfusions may be necessary for improvement or prophylaxis of the hemorrhagic tendency of DIC prior to emergency surgical procedures. Elective surgery is deferred due to the volatility of the coagulation mechanism in these patients.

Fibrinolytic Disorders

Disorders of the fibrinolytic system can lead to either hemorrhage or excessive clotting and thrombosis, when clot breakdown is enhanced or when clot breakdown mechanisms are retarded, respectively.

Primary fibrinolysis typically results in bleeding and may be caused by a deficiency in α_2-antiplasmin or plasminogen activator inhibitors, natural proteins that turn off activation of the fibrinolytic system. Laboratory coagulation tests are normal, with the exception of decreased fibrinogen and increased FDP levels. In liver disease, impaired clearance of tPA may contribute to prolonged bleeding. As discussed above, deficiency of F XIII, a transglutaminase that stabilizes fibrin clots, is a rare inherited disorder that leads to hemorrhage. Patients with primary fibrinolysis are treated with FFP therapy and antifibrinolytics.

Differentiation must be made from the secondary fibrinolysis that accompanies DIC, a hypercoagulable state that predisposes individuals to thromboembolism. Dialysis patients with CKD show a fibrinolysis defect at the level of plasminogen activation.[154]

Reduced fibrinolysis may be responsible, along with other factors, for the development of thrombosis, atherosclerosis, and their thrombotic complications. Activators of the fibrinolytic system (tPA, streptokinase, and urokinase) are frequently used to accelerate clot lysis in patients with acute thromboembolism, for example to prevent continued tissue damage in myocardial infarction or treat thrombotic stroke.

Acquired Coagulation Disorders—Drug-Induced/Therapeutic

There are a variety of traditional and newer pharmaceutical agents that alter hemostasis (Table 18-6).

Heparin

Heparin is a potent anticoagulant that binds with AT to significantly inhibit activation of clotting enzymes, thereby reducing thrombin generation and fibrin formation. Indications for

Table 18-6 Drugs that therapeutically alter hemostasis.

Drug	Mechanism	Laboratory tests
Antiplatelet medications		
ASA	COX inhibition	BT, PFA-100
Clopidogrel	ADP receptor antagonist	BT, Platelet Function P2Y12
Ticlopidine		
Dipyridamole	ADP reuptake inhibitor	BT
Anticoagulant medications		
Heparin Low molecular weight heparins (enoxaparin, tinzaparin, dalteparin)	Binds to antithrombin, reducing thrombin generation	aPTT
Vitamin K antagonists Warfarin Dicumarol	Vitamin K antagonist	PT/INR
Direct oral anticoagulants Thrombin inhibitors (dabigatran)	Inhibition of thrombin (Factor IIa)	aPTT, TT
Factor Xa inhibitors (rivaroxaban, apixaban)	Inhibition of Factor Xa	Chromogenic anti-Xa assays

ADP, adenosine diphosphate; aPTT, activated partial thromboplastin time; ASA, acetylsalicylic acid; BT, bleeding time; INR, international normalized ratio; P2Y12, platelet receptor; PFA-100, platelet function analyzer 100; PT, prothrombin time

heparin therapy include prophylaxis or treatment for venous thromboembolism, including prophylaxis in medical and surgical patients.[155] Heparin has a relatively short duration of action of 3–4 hours and so is typically used for acute anticoagulation, whereas chronic therapy is initiated with VKA drugs. For acute anticoagulation, IV infusion of 1000 units of unfractionated heparin per hour, sometimes following a 5000-unit bolus, is given to raise the aPTT to 1.5–2 times the preheparin aPTT. Alternatively, subcutaneous injections of 5000–10,000 units of heparin are given every 12 hours. The most common outpatient use of subcutaneous heparin is for the treatment of deep venous thrombophlebitis during pregnancy,[156] with the goal being regulation of the aPTT between 1.25 and 1.5 times control. Protamine sulfate can rapidly reverse the anticoagulant effects of heparin.

The major bleeding complications from heparin therapy are bleeding at surgical sites and bleeding into the retroperitoneum. Newer biologically active LMWHs (e.g., enoxaprin [Lovenox], tinzaparin [Innohep], dalteparin) are administered subcutaneously once or twice daily and are less likely to result in thrombocytopenia and bleeding complications.

Vitamin K Antagonists

VKAs such as the coumarin anticoagulants (which include warfarin and dicumarol [Coumadin]) slow thrombin production and clot formation by blocking the action of vitamin K, leading to decreased levels of vitamin K–dependent factors (F II, F VI, F IX, and F X). They are routinely used for anticoagulation to prevent recurrent thromboembolic events, such as pulmonary embolism, venous thrombosis, stroke, and myocardial infarction. They are also used commonly in patients with atrial fibrillation, and in patients with prosthetic heart valves.[157]

Daily doses of 2.5–7.5 mg warfarin are typically required to maintain adequate anticoagulation. PT/INR is used to monitor anticoagulation levels, with target therapeutic ranges varying based on medical indication, with PT of 18–30 seconds or INR of 1.5–4.0, but seldom above 3.5. Patients with paroxysmal atrial fibrillation and porcine heart valves require minimal anticoagulation (INR target 1.5–2.0), venous thrombosis is managed with intermediate-range coagulation (INR 2.0–3.0), whereas mechanical prosthetic heart valves and hypercoagulable states require more intense anticoagulation (INR target 3.0–4.0).[156]

VKA therapy requires continual laboratory monitoring, (i.e., typically every 12 weeks), as fluctuations can occur. It has a longer duration of action, with coagulant activity in blood decreased by 50% in 12 hours and 20% within 24 hours of therapy initiation. Coagulation returns to normal levels in approximately 2–4 days following discontinuation of coumarin drugs.

Coumarin drugs are particularly susceptible to drug interactions. Drugs that potentially increase warfarin potency (i.e., elevate the INR) do so by either inhibiting the cytochrome P450 enzymes in the liver that break down the drug, or by altering gut bacterial flora that affect GI absorption of the drug. Drugs that increase potency include metronidazole, penicillin, erythromycin, cephalosporins, tetracycline, fluconazole, ketoconazole, chloral hydrate, and propoxyphene. Those that reduce its potency (i.e., decrease the INR) include barbiturates, ascorbic acid, dicloxacillin, and nafcillin.[158] In addition, a synergistic antihemostatic

effect is seen when VKAs are used in combination with ASA or NSAIDs.

Warfarin is among the top 10 drugs with the largest number of serious complications, including death, as reported to the US FDA, with intracranial hemorrhage being the most feared complication due to its morbidity and mortality.[159] An observational study of over 100,000 outpatient adults on warfarin therapy showed an overall rate of 3.8% of bleeding episodes that required a hospital visit.[160] The anticoagulant effect of VKAs may be reversed immediately by infusion of FFP or PCC, or over a longer period of time by administration of vitamin K.

Direct Oral Anticoagulants

DOACs, also referred to as NOACs (e.g., dabigatran, apixaban, rivaroxaban, edoxaban, and betrixaban), have been recommended for prevention of pulmonary embolism and deep vein thromboses, or for reducing the risk of stroke and systemic embolism in patients with nonvalvular atrial fibrillation. They are favored over warfarin mainly due to equivalent efficacy, more targeted action, predictable and stable anticoagulant effect at regular fixed dosages (thereby eliminating the need for regular monitoring), shorter half-lives, fewer drug and food interactions, and the significantly decreased incidence of intracranial hemorrhage.[161] There are two main types of DOACs based on their mechanisms: direct thrombin (or F IIa) inhibitors, and F Xa inhibitors.

Dabigatran (Pradaxa) is a competitive and reversible F IIa inhibitor, with an incidence of major bleeding episodes that is decreased or similar to that of warfarin.[162,163] While not routinely monitored, elevated thrombin time, accompanied by an elevated aPTT, is consistent with therapeutic levels of the drug. Idarucizumab (Praxbind) is an antidote to dabigatran, the only one available for the DOACs.

The direct F Xa inhibitors include rivaroxaban, apixaban, edoxaban, and betrixaban, and are desirable due to their rapid onset of action. While PT may be prolonged in patients treated on rivaroxaban, it is not useful for monitoring the effects of apixaban. Moreover, aPTT is not useful in detecting the therapeutic level of these drugs. The main drawback to these medications is the lack of specific antidotes, which are currently in the development stages.

PCC has been shown to reverse the prolongation of PT in those treated with rivaroxaban, but not dabigatran,[164] and there are some data supporting the use of rFVIIa to reverse the effects of both of these drugs.[165] Current recommended algorithms for management of severe bleeding episodes due to these new oral anticoagulants include cessation of the drugs, local hemostatic measures at the source of bleeding, volume replacement, and transfusion of blood products if needed.[166]

Medical Management of Coagulation Disorders

Medical intervention for individuals with inherited coagulation disorders is for active bleeding due to an injury, preparation for an invasive procedure, or for prophylaxis for spontaneous bleeding (Table 18-7). For hemophilia, prophylactic factor replacement therapy has been shown to be effective for reducing bleeding, specifically intracerebral hemorrhage, and long-term complications such as chronic arthropathy, hospitalizations, and absenteeism from school and work.[167] However, there are risks, including high costs, burdens of IV infusions, risk of thrombosis and inhibitor development, and interference with daily life. All of the available products are effective, with the choice based on safety (specifically from viral infections such as HIV, hepatitis B and C virus), purity, risk of inhibitor development, product half-life, and cost. In addition to factor concentrates, a new class of non-blood-product prophylactic emicizumab (Hemlibra) administered subcutaneously up to every 4 weeks, has shown promise for preventing joint bleeding and deterioration of joint status.[168]

Fresh Frozen Plasma

FFP is prepared from whole blood or apheresis and frozen within 8 hours of collection. It is frozen at -18 to -30 °C, and is usable for 1 year from the date of collection. Standard FFP units from a single unit of whole blood have a volume of approximately 200–250 mL. It is indicated for coagulation factor replacement during management of major bleeding due to warfarin, vitamin K deficiency, liver disease, DIC, and rare inherited coagulation disorders (e.g., deficiencies of F XIII, F X, F VII, F V, F II). It is not used to correct excessive anticoagulation due to medications or other causes of prolonged INR in the absence of bleeding. However, for cases in which the INR is elevated, and an invasive procedure is required in the near future, transfusion of FFP is a consideration.

FFP should not be used as primary therapy to replace specific coagulation factors (e.g., in the case of hemophilia) because of their disadvantages of potential viral transmission and the large fluid volumes needed to raise factor levels adequately for hemostasis. FFP contains all coagulation factors in nearly normal concentrations and may aid hemorrhage control in a patient with mild hemophilia B. In the average-size patient, 1 unit of FFP raises F IX levels by 3%. Postoperative bleeding in mild to moderate F X deficiency can be managed with FFP, and PCCs may be held in reserve for severely deficient patients.[169] The typical dose of FFP is approximately 10–15 mL/kg (i.e., approximately 3–5 units) in most adults; however, this represents a significant volume challenge of 750–1250 mL of plasma, which can precipitate pulmonary edema.

Table 18-7 Principal products for systemic management of patients with bleeding disorders.

Product	Description	Source	Common Indications
Platelets	"One pack" = 50 mL; raises count by 6000	Blood bank	<10,000 in nonbleeding individuals; <50,000 presurgical;<50,000 in actively bleeding individuals; nondestructive thrombocytopenia
Fresh frozen plasma	Unit = 150–250 mL 1 h to thaw Contains F II, F VII, F IX, F X, F XI, F XII, F XIII and heat-labile F V and F VII	Blood bank	Undiagnosed bleeding disorder with active bleeding; severe liver disease; when transfusing >10 units blood Immune globulin deficiency
Cryoprecipitate	Unit = 10–15 mL Contains F VIII and F XIII, vWF, and fibrinogen	Blood bank	Hemophilia A, von Willebrand disease, when factor concentrates/DDAVP are unavailable Fibrinogen deficiency
F VIII concentrate (purified antihemophilic factor)*	Unit raises F VIII level by 2% Heat treated contains vWF Recombinant and monoclonal technologies are pure F VIII	Pharmacy	Hemophilia A, with active bleeding or presurgical; some cases of von Willebrand disease
F IX concentrate (PCC)*	Unit raises F IX level by 1–1.5% Contains F II, F VII, F IX, and F X Monoclonal F IX is only F IX	Pharmacy	Hemophilia B, with active bleeding or presurgical PCC used for hemophilia A with inhibitor
DDAVP	Synthetic analogue of antidiuretic hormone 0.3 µg/kg IV or SQ Intranasal application	Pharmacy	Active bleeding or presurgical for some patients with von Willebrand disease, uremic bleeding, or liver disease
ε-Aminocaproic acid	Antifibrinolytic 25% oral solution (250 mg/mL) Systemic: 75 mg/kg every 6h	Pharmacy	Adjunct to support clot formation for any bleeding disorder
Tranexamic acid	Antifibrinolytic 4.8% mouth rinse—not available in US Systemic: 25 mg/kg q8h	Pharmacy	Adjunct to support clot formation for any bleeding disorder

DDAVP, desmopressin acetate; F, factor; IV, intravenously; PCC, prothrombin complex concentrate; SQ, subcutaneously; vWF, von Willebrand factor.

Additional risks of plasma exposure include infection and allergic reactions. Infection risks for FFP are the same as that for most whole blood products, which include (with estimated incidences in the United States): hepatitis B virus (1:1 million), HCV (1:1.2 million), human T-lymphotropic virus (1:2.7 million), and HIV (1:1.5 million), with other considerations including syphilis, West Nile virus, Zika virus, CMV, and *Trypanosoma cruzi*.

Cryoprecipitate

Cryoprecipitate is the cold insoluble precipitate remaining after FFP is thawed at 4 °C. A typical bag (1 unit in a 10–15 mL volume) of cryoprecipitate contains approximately 80–150 units of F VIII, 50–75 units of F XIII, 100–150 units of VWF, and 150–250 mg of fibrinogen. Cryoprecipitate is widely used for surgical bleeding and trauma when the fibrinogen level is low (e.g., DIC, liver disease, fibrinogen disorders) and for uremic bleeding. Other uses of cryoprecipitate include management of postpartum hemorrhage, and as a part of massive transfusion protocols. Clinical use of cryoprecipitate has declined or become obsolete in some places due to the availability of specific coagulation factor concentrates, fibrinogen concentrates, and/or recombinant factor products that have a lower risk of complications. It is no longer routinely used to treat hemophilia A, VWD, and F XIII deficiency, except in unusual circumstances.

Desmopressin acetate

DDAVP (1-deamino-8-D-arginine vasopressin) is thought to stimulate endogenous release of F VIII and VWF from blood vessel endothelial cell storage sites. This synthetic vasopressin analog is now considered the treatment of choice for bleeding events in patients with these bleeding diatheses, owing to its absence of viral risk and lower cost. It provides adequate transient increases in coagulation factors in some

patients with mild to moderate hemophilia A and type I VWD, avoiding the need for plasma concentrates.[129] However, DDAVP is ineffective for individuals with severe hemophilia A.

DDAVP can be given at a dose of 0.3 μg/kg body weight by IV or subcutaneous route or as intranasal spray application of DDAVP (Stimate), with 2 sprays for adults weighing over 50 kg and 1 spray (150 μg) for children and adults under 50 kg. It should be given within 1 hour prior to dental extractions or surgery or to treat spontaneous or traumatic bleeding episodes, resulting in approximately a threefold increase in VWF and F VIII.[131] A DDAVP trial or test dose response may be indicated prior to extensive surgery to evaluate the level of drug effect on assayed F VIII activity in the individual patient. Prolonged use of DDAVP (such as for 3 or more days) results in exhaustion of F VIII storage sites and diminished hemostatic effect, therefore antifibrinolytic agents are useful adjuncts to DDAVP therapy.

Factor Replacement Therapy

Since partially purified F VIII and F IX complex concentrates prepared from pooled plasma were first used in the late 1960s and 1970s, multiple methods of manufacturing products with increased purity and reduced risk of viral transmission have been developed, including intermediate-purity products prepared by heat or solvent/detergent treatment. Included in this group are high-purity F VIII products manufactured using recombinant or monoclonal antibody purification techniques, and the newer extended half-life F VIII and F IX products made with crystallizable fragment fusion technology or PEGylation.[170] All available factor replacement products are administered IV, with the majority requiring reconstitution of powder with sterile water.

F VIII concentrates are dosed by units, with 1 unit of F VIII being equal to the amount present in 1 mL of pooled fresh normal plasma. The plasma level of F VIII is expressed as a percentage of normal. Since 1 unit of F VIII concentrate per kg of body weight raises the F VIII level by 2%, a 70 kg patient would require infusion of 3500 units to raise his factor level from <1 to 100%. A dose of 40 U/kg F VIII concentrate typically is used to raise the F VIII level to 80%–100% for management of significant surgical or traumatic bleeding in a patient with severe hemophilia. Additional outpatient doses may be needed at 12-hour intervals, or continuous inpatient infusion may be established.

Highly purified recombinant and monoclonal F IX concentrates are the treatment of choice for hemophilia B patients undergoing surgery. F IX complex concentrates or PCCs, which contain F II, F VII, F IX, and F X, are also widely used for patients with hemophilia B. One unit of PCC or higher-purity F IX concentrates given by bolus per kg body weight raises the F IX level by 1%–1.5%. Thus, a dose of 60 U/kg of F IX concentrate typically is needed to raise the F IX level to 80%–100% for management of severe bleeding episodes in a patient with a severe F IX deficiency. Repeat outpatient doses may be needed at 24-hour intervals.

Properly supervised home therapy, for which patients self-treat with factor concentrates at the earliest evidence of bleeding, is a cost-effective method offered to educable and motivated patients by some medical centers. Complications of factor replacement therapy include allergic reactions, viral disease transmission (hepatitis B and C, CMV, and HIV), thromboembolic disease, DIC, and development of antibodies to factor concentrates. Since 1987, with viral screening of donated plasma, there have been no transfusion-related HIV seroconversions in the United States.

Development of F VIII or F IX inhibitors is a significant complication. These pathologic circulating antibodies of the IgG class, which specifically neutralize F VIII or F IX procoagulant activity, arise as alloantibodies in some patients with hemophilia. Inhibitors are more common for F VIII deficiency, where it is estimated that 20%–30% with severe and 5%–10% with mild to moderate disease have inhibitors compared to less than 5% of those with severe hemophilia B.[171] Inhibitor level is quantified by the Bethesda inhibitor assay and is reported as Bethesda units (BU).

The inhibitor titer and responsiveness to further factor infusion (responder type) dictate which factor replacement therapy should be used. Patients with inhibitors are classified according to titer level—low (<5 BU/mL) or high (>5 BU/mL)—and also by responder type. Low responders typically maintain low titers with repeated factor concentrate exposure, whereas high responders show a brisk elevation in titer due to the amnestic response and are the most challenging to manage. Patients with low inhibitor titers are usually low responders and those with high titers are often high responders.

For hemorrhage with hemophilia A patients, activated PCC (e.g., FEIBA [factor eight inhibitor bypassing activity; anti-inhibitor coagulant complex]) or rFVIIa (NovoSeven), are the therapies of choice. The standard dose of rFVIIa is 90 μg/kg to achieve plasma FV II activity levels of 17–24 IU/mL with a 2.5-hour half-life, creating a 2–3-hour treatment dosing interval, in bleeding patients.[172] A new antibody, emicizumab (Hemlibra), binds fragments of F X/XA and F IX/IXa and has been approved for routine prophylaxis in patients with F VIII inhibitors.[171] Immune tolerance protocols may be used in some inhibitor patients in an attempt to eradicate inhibitors.[173]

Dental Management of Coagulation Disorders

Determination of factor replacement requirements should be accomplished in consultation with the patient's

hematologist, and is dependent on the invasiveness of the procedure. Only an estimated 2% of hemophilic patients experience one or more delayed bleeding episodes after dental treatment when managed in a hemophilia treatment center.[174] Appropriate precautionary measures now allow surgery to be performed safely, with no significantly greater risk of bleeding than in patients without hemophilia.[175]

For surgical hemostasis, clinical practice guidelines recommend target replacement factor activity levels of 40%–50% of F VIII (dose 20–25 U/kg) and F IX (dose 40–50 U/kg) for 1–2 days, in conjunction with antifibrinolytics.[176,177] Recommended minimum factor level during the healing phase is 20%. Higher hemostatic factor levels are needed for larger wounds from extraction of multiple or multirooted teeth, or when gingival inflammation, bleeding, tooth mobility, or apical lesions are present. Special consideration is made for the more significant risks associated with extraction of impacted mandibular third molars due to the potential for retropharyngeal bleeding and airway compromise. Factor activity levels required for postextraction hemostasis have been reported to vary from 3.5% to 25% for deciduous teeth and 5.5% to 20% for permanent teeth. Gingival bleeding unresponsive to antifibrinolytics requires 20%–30% clotting F VIII or F IX.

Three methods of replacement therapy have been employed to maintain circulating factor levels during surgical and healing phases. These include intermittent replacement therapy, continuous IV factor infusion therapy, and a single preoperative factor concentrate infusion combined with an antifibrinolytic mouthwash.[178] When single-bolus infusion is used for outpatient procedures, transfusion recommendations generally aim for replacement of missing coagulation factors to levels of 50%–100%. This accounts for the possible failure of factor activity to rise to target levels, and variable plasma half-lives (8–12 hours for F VIII, and 18–24 hours for F IX). F VIII levels may be sufficiently raised by DDAVP in some patients with mild to moderate hemophilia A and VWD to allow dental extractions without transfusion. For extensive surgery, additional postoperative factor maintenance may be indicated, accomplished by infusion of factor concentrates, DDAVP, cryoprecipitate, or FFP.

Postsurgical bleeding due to fibrinolysis commonly starts 3–5 days after surgery and can usually be controlled by local measures and use of antifibrinolytics. Continual oozing from unstable fibrinous clots (i.e., "liver clots") may require their removal and the repacking of the extraction socket with local hemostatic agents. The use of fibrin sealants has allowed reduction in factor concentrate replacement levels in hemophiliacs undergoing dental surgeries when used in combination with antifibrinolytics.[179,180,181] However, the use of fibrin glue does not obviate the need for factor concentration replacement in severe hemophiliacs.[182]

Periodontal surgical procedures warrant elevating circulating factor levels to 50% and use of post-treatment antifibrinolytics. Periodontal packing material aids in hemostasis and protects the surgical site; however, it may be dislodged by severe hemorrhage or subperiosteal hematoma formation.

Dental Management of Patients on Anticoagulant Therapy

Management of the dental patient on anticoagulant therapy involves consideration of the degree of anticoagulation achieved as gauged by the laboratory values, the dental procedure planned, and the level of thromboembolic risk for the patient.[183] In general, higher INRs result in higher bleeding risk from surgical procedures.[184]

Vitamin K Antagonists

It is generally held that nonsurgical dental treatment can be accomplished without alteration of the anticoagulant regimen, provided that the PT/INR is not well above the therapeutic range and trauma is minimized.[185,186,187] Some controversy exists over the management of anticoagulated patients for oral surgical procedures.[188,189,190] Patients who discontinue warfarin preoperatively are exposed to 3–4 days at subtherapeutic anticoagulation levels postoperatively after immediate resumption of therapy. Risks of a life-threatening thromboembolic event are 3–5-fold greater than that of significant uncontrollable postoperative bleeding.[191] The American Heart Association and American College of Cardiology scientific statement recommends that for patients undergoing dental procedures, tranexamic acid or EACA (Amicar) mouthwash can be applied without interrupting anticoagulant therapy.[192] The 2012 American College of Chest Physicians Evidence-Based Clinical Practice Guidelines recommend continuing VKAs with coadministration of oral prohemostatic agent or stopping VKAs 2–3 days before minor dental procedures.[193] Systematic reviews and meta-analyses of randomized controlled trials examined the bleeding potential in dental practice of patients on warfarin therapy.[194,195] Among all patients, there were no major bleeding episodes, and there were no differences in the incidence of clinically significant minor bleeding episodes between those who continued their regular dose of warfarin and those who discontinued or altered their dose of warfarin, with local and oral hemostatic agents showing hemostatic benefit.

Preparation of the anticoagulated patient for surgical procedures depends on the extent of bleeding expected and the thromboembolic risk. For surgical procedures, physician consultation is advised in order to determine the patient's most recent PT/INR level and the best treatment approach

based on the patient's relative thromboembolic and hemorrhagic risks. When the likelihood of thrombotic and embolic complications is small and hemorrhagic risk is high, warfarin therapy can be discontinued briefly by the physician at the time of surgery, with reinstitution within a day postoperatively.[181,196,197] Warfarin's long half-life of 42 hours necessitates dose reduction or withdrawal 2 days prior to surgery in order to return the patient's PT/ INR to an acceptable level for surgery.[181,198] For patients with moderate thromboembolic and hemorrhagic risks, warfarin therapy can be maintained in the therapeutic range with the use of local measures to control postsurgical oozing.[199,200]

For surgical treatment for those with a supratherapeutic INR of >3.5–4.0, either deferral, dose modification, or proceeding with precautions (e.g., in a hospital setting with physician support) is considered. With an INR <3.5–4.0, minor surgical procedures with minimal anticipated bleeding may require local measures, but no dose modification. When moderate to significant bleeding is expected (multiple extractions or removal of third molar teeth), local measures should be used and INR reduction may be considered in consultation with the patient's physician. High-risk cardiac patients undergoing high-bleeding-risk surgical procedures may be managed with LMWH bridging. LMWH is a less costly alternative to IV heparin substitution therapy, rarely used today, that does not require hospital admission (e.g., enoxaparin). Using this management technique, a LMWH is substituted for warfarin a few days before surgery, and it is withheld from the patient for only a few hours on the day of the surgery.[201]

Use of additional local hemostatic agents such as microfibrillar collagen, oxidized cellulose, or topical thrombin is recommended for anticoagulated patients. Fibrin sealant has been used successfully as an adjunct to control bleeding from oral surgical procedures in therapeutically anticoagulated patients with INRs from 1.0 to 5.0, with minimal bleeding complications.[202] Use of antifibrinolytics may have value in control of oral wound bleeding, thereby alleviating the need to reduce the oral anticoagulant dose.[203] Tranexamic acid solution used as an mouthwash has proven effective in control of oral surgical bleeding in patients with INRs between 2.1 and 4.8, and is slightly superior when compared to an autologous fibrin glue preparation.[201,204,205] As previously discussed, the use of medications that interact with and alter warfarin's anticoagulant effectiveness is to be avoided.

Heparin

Continuous IV unfractionated heparin, which has the greatest hemorrhagic potential among the heparin techniques, is discontinued 6–8 hours prior to surgery to allow adequate surgical hemostasis. In general, oral surgical procedures can be carried out without great risk of hemorrhage when local hemostatics are used in a patient receiving LMWH subcutaneously; however, on consultation, the patient's physician may recommend withholding the scheduled injection only a few hours prior to the operation. One small retrospective study found no postoperative bleeding events after invasive dental procedures for patients on LMWH alone, with several instances in patients who were concurrently on LMWH and warfarin.[206] If a bleeding emergency arises, the action of heparin can be reversed by protamine sulfate. Dosage for unfractionated heparin reversal is 1 mg protamine sulfate IV for every 100 units of active heparin. If given within 8 hours of the LMWH injection, then the maximum neutralizing dose of 1 mg protamine/100 units of LMWH given in the last dose is used.

Direct Oral Anticoagulants

The Scottish 2015 guideline recommends that the provider have a discussion with the patient about possible benefits and harms for continuing or interrupting medications and consider short-term interruption of DOACs only for high-risk invasive dental procedures (e.g., >3 extractions, flap surgery, periodontal surgery, crown lengthening, biopsies).[207] Because of the short half-lives of these agents, the recommendations entail morning procedure appointments, in which the morning dose or daily dose is skipped, and then the evening or next-day dose is resumed, in the case of twice-a-day medications (e.g., apixaban or dabigatran) and once-a-day medications (e.g., rivaroxaban), respectively. Additional advice includes treatment early in the day and beginning with a limited treatment area (i.e., 1–2 teeth) to allow hemostasis monitoring and reassessment, and use of local hemostatic measures.[207] A 2019 systematic review evaluated the literature concerning the dental management of patients on DOACs, assessing for the incidence of postoperative bleeding complications.[208] They found that there were no differences in the incidence and severity of postoperative bleeding complications in patients who continued DOACs versus those that discontinued DOACs prior to dental procedures, including extractions, in addition to the absence of any thromboembolic events recorded.

GENERAL DENTAL MANAGEMENT CONSIDERATIONS

Dental modifications for patients with bleeding disorders depend on both the type and invasiveness of the dental procedure and the type and severity of the bleeding disorder. Thus, little or no modification is needed for patients with mild coagulopathies prior to dental procedures with limited consequences from bleeding. More modification is needed for those with severe coagulopathies or prior to

dental procedures anticipated to have great risks of bleeding. When there is greater concern for significant bleeding, the goal of management is to restore the hemostatic system preoperatively to an acceptable range while utilizing adjunctive and/or local measures. For reversible or acute hemostatic disorders, it may be best to treat the primary illness or defect in order to allow the patient to return to a manageable bleeding risk for the dental treatment period. With respect to therapeutic alterations in hemostasis due to medications (e.g., clopidogrel, warfarin, dabigatran), local hemostatic measures usually suffice; however, there are limited instances in which drug discontinuation or dose alteration may be recommended and accomplished by the patient's physician. For irreversible inherited coagulopathies, the missing or defective element may need to be replaced from an exogenous source. Assessment of the coagulopathy and delivery of appropriate therapy prior to dental procedures are best accomplished in consultation with a hematologist and may dictate treatment in specialized hospital facilities.[209]

Local Hemostatic Measures

Local hemostatic agents and techniques include pressure, surgical packs, vasoconstrictors, sutures, surgical stents, topical thrombin, and use of absorbable hemostatic materials (Table 18-8). Although having no direct effect on hemostasis, primary wound closure aids patient comfort, decreases blood clot size, and protects clots from masticatory trauma and subsequent bleeding.[210] Sutures can also be used to stabilize and protect packing, with resorbable and nonresorbable suture materials shown to be equally effective. Microfibrillar collagen fleeces (e.g., Avitene, Helitene) aid in hemostasis when placed against the bleeding bony surface of a well-cleansed extraction socket. This acts to attract platelets, triggering aggregation of platelets into thrombi in the interstices of the fibrous mass of the clot.[211] Surgifoam and Gelfoam are absorbable gelatin compressed sponges with intrinsic hemostatic properties. A collagen absorbable hemostat manufactured as a 3 in. × 4 in. sponge (INSTAT) or fabricated as a nonwoven pad or sponge (Helistat, Gelfoam, Ultrafoam) is also a useful adjunct.

Topical thrombin (Thrombogen) directly converts fibrinogen in blood to fibrin, and is an effective adjunct when applied directly to the wound or carried to the extraction site in a nonacidic medium on oxidized cellulose. Surgical acrylic stents may be useful if carefully fabricated to avoid traumatic irritation to the surgical site.

Fibrin sealants or fibrin glue is a biologic tissue adhesive that simulates the final stages of coagulation and has been used effectively as an adjunct with adhesive and hemostatic effects to control bleeding at wound or surgical sites.[212] Commercially available as Tisseel, it has been useful in periodontal surgery, or even as an alternative to sutures.[213]

Diet restriction to full liquids for the initial 24–48 hours, followed by intake of soft foods for 1–2 weeks, will further protect the clot by reducing the mechanical trauma from chewing.

Table 18-8 Local hemostatic agents.

Brand Name	Generic Name or Description
Gelfoam (Pfizer, New York, USA) Surgifoam (Ethicon, Somerville, NJ, USA)	Absorbent gelatin sponge material
INSTAT (Ethicon)	Collagen absorbable sponge
Surgicel (Ethicon)	Oxidized cellulose
Thrombogen (Ethicon)	
Avitene (Davol, Cranston, RI, USA) Helitene (Integra Life Sciences, Plainsboro, NJ, USA)	Microfibrillar collagen fleeces
Bleed-X (QAS, Orlando, FL, USA)	Microporous polysaccharide hemispheres
Tisseel VH (Baxter, Deerfield, IL, USA) Tissucol (Termo trattato, Wien, Austria)	Fibrin sealant
Cyklokapron (Pfizer)	Tranexamic acid
Amicar (Wyeth-Ayerst, Wayne, PA, USA)	Episilon-aminocaproic acid

Antifibrinolytics

Antifibrinolytic drugs such as ε-aminocaproic acid (EACA; Amicar 25% syrup) and tranexamic acid (AMCA; Lysteda, Cyklokapron) inhibit fibrinolysis by blocking the conversion of plasminogen to plasmin, resulting in clot stabilization. They are very useful for oral procedures because fibrinolysis is highly active on mucosal surfaces. Products are available for use systemically (oral or IV) and/or topically, as a mouthwash. Postsurgical use of EACA has been shown to significantly reduce the quantity of factor required to control bleeding when used in conjunction with presurgical concentrate infusion sufficient to raise plasma F VIII and F IX levels to 50%.[178,214,215] A regimen of 50 mg/kg of body weight EACA given topically and systemically as a 25% (250 mg/mL) oral rinse every 6 hours for 7–10 days appears adequate as an adjunct. Tranexamic acid (4.8%) oral rinse, not commercially available in the United States, was found to be 10 times more potent than EACA in preventing postextraction bleeding in hemophiliacs, with fewer side effects.[216,217] Systemic antifibrinolytic therapy can be given orally or IV as EACA 75 mg/kg

(up to 4 g) every 6 hours or AMCA 25 mg/kg every 8 hours until bleeding stops.[176] For the treatment of acute bleeding syndromes due to elevated fibrinolytic activity, it is suggested that 10 tablets (5 g) or 4 teaspoons of 25% syrup (5 g) of Amicar be administered during the first hour of treatment, followed by a continuing rate of 2 tablets (1 g) or 1 teaspoon of syrup (1.25 g) per hour. This method of treatment would ordinarily be continued for about 8 hours or until the bleeding has been controlled. Amicar syrup–soaked gauze packs, used for application of pressure to wound sites, are also often successful at assisting hemostasis.

Susceptibility to Infection

Susceptibility to infection among patients with congenital bleeding disorders is not a significant concern. However, hemophiliacs may have had a total joint replacement due to bleeding into weight-bearing joints, for which some authorities would recommend antibiotic prophylaxis prior to invasive dental procedures;[218] however, hemophilic arthropathy as cause of orthopedic implants does not meet current guidelines for elevated risk.[216] Should a hematoma form as a result of an anesthetic injection, other dental or intubation trauma, or spontaneously, it should be observed for clinical signs of infection, and if these develop use of a broad-spectrum antibiotic may be indicated during resolution.[219] If bleeding results from bone marrow–suppressive systemic disease or chemotherapeutic drug use, antibiotics may be used to prevent infection from bacteremia-inducing dental procedures when production of mature functional neutrophils is substantially diminished.

Pain Control and Local Anesthesia

The use of ASA and other NSAIDs for pain management is generally avoided in patients with bleeding disorders, due to inhibition of platelet function and potentiation of bleeding episodes.

Caution must be exercised when administering local anesthetic via nerve-block injections in hemophiliacs, as there is a risk of hematoma formation when anesthesia is administered in a highly vascularized area. Nerve blocks might be avoided by use of nitrous oxide–oxygen analgesia for some restorative procedures. Local anesthetic procedures in hemophiliacs that do not require preoperative factor infusion include buccal infiltration, interpapillary injection, endodontic (root canal) treatment, and intraligamentary injections.[220] Patients on anticoagulants and with platelet disorders generally are not at increased risk from block anesthesia.

Block injections place anesthetic solutions in highly vascularized, loose connective tissue with no distinct boundaries, where formation of a dissecting hematoma is possible, occurring in 8% of hemophilic patients not treated with prophylactic factor replacement prior to mandibular block injection (Figure 18-10).[221] Extravasation of blood into the soft tissues of the oropharyngeal area in hemophiliacs can produce gross swelling, pain, dysphagia, respiratory obstruction, and risk of death from asphyxia. For routine anesthetic blocks, minimum clotting factor levels of 20%–30% are required.[222] In addition, an anesthetic with vasoconstrictor should be used. Intramuscular injections should also be avoided due to the risk of hematoma formation.

Ability to Withstand Care

Patients with bleeding disorders, appropriately prepared preoperatively, are generally able to tolerate invasive dental procedures, although consultation with the patient's physician is recommended for guidance on medical management for higher-risk surgical procedures.

Figure 18-10 A 24-year-old man with severe hemophilia A and low-titer inhibitor, 3 days after inferior alveolar nerve block–induced parapharyngeal hemorrhage. The patient presented with difficulty swallowing and pending airway compromise 8 hours after nerve block. Subsequent treatment with PCCs over 3 days controlled the bleeding and began the resolution of facial swelling.

Extended dental treatment sessions or dental treatment in the operating room under general anesthesia may help to maximize treatment accomplishments at one visit and thereby minimize the risk and cost from some medical management protocols for severe bleeding disorders (e.g., coagulation factor replacement for severe hemophiliacs, warfarin withdrawal–heparinization approach for patients at high risk of thrombosis). The general anesthesia approach may also be useful when patient cooperation or anxiety prohibits outpatient clinic or office treatment, or the patient has extensive treatment needs. Although oral endotracheal intubation creates an access challenge for the dentist, it is preferred over nasal endotracheal intubation with its risk of inducing a nasal bleed.

Preventive and Periodontal Therapies

Periodontal health is of critical importance for the patient with a coagulopathy, because hyperemic gingiva contributes to spontaneous and induced gingival bleeding. Periodontitis is a leading cause of tooth morbidity and often necessitates extraction(s). Individuals with bleeding diatheses are unusually prone to oral hygiene neglect due to fear of toothbrush-induced bleeding; however, regular oral hygiene can be accomplished without risk of significant bleeding. Periodontal probing and supragingival scaling and polishing can generally be done routinely without modification. Careful subgingival scaling with fine scalers rarely warrants replacement therapy. Inflamed and swollen tissues are best treated initially with chlorhexidine oral rinses, or by superficial gross debridement with ultrasonic or hand instruments to allow gingival shrinkage prior to deep scaling. Deep subgingival scaling and root planing should be performed by quadrant to reduce the gingival area exposed to potential bleeding. Locally applied pressure and post-treatment antifibrinolytic oral rinses are usually successful in controlling any protracted bleeding.[223,224] Surgical periodontal therapy is considered to have a high risk of bleeding, if it involves raising a flap.[225] However, expert opinion recommends that treatment may continue for those on anticoagulant therapy, if INR is within the therapeutic range in the case of VKAs.

Restorative, Endodontic, and Prosthodontic Therapy

General restorative, endodontic, and prosthodontic procedures do not result in significant bleeding beyond the ability to control with local measures. Rubber dam isolation is advised to minimize the risk of lacerating soft tissue in the operative field and to avoid creating ecchymoses and hematomas with high-speed evacuators or saliva ejectors. It is important to select a rubber dam clamp that does not traumatize the gingiva. Matrices, wedges, and a hemostatic gingival retraction cord may be used with caution to protect soft tissues and improve visualization when subgingival extension of cavity or crown preparation is necessary. Cold water or antifibrinolytic-impregnated gauze pressure may aid in hemostasis.

Endodontic therapy is often the treatment of choice over tooth extraction for patients with severe bleeding disorders, due to the higher risk of hemorrhage from the latter. As always, instrumentation and filling beyond the apical seal should be avoided. Application of epinephrine intrapulpally to the apical area is usually successful in providing intrapulpal hemostasis. Endodontic surgical procedures require the same factor replacement therapy as do oral surgical procedures.

Removable prosthetic appliances can be fabricated without complications, but the postdelivery appointments are important to prevent against mucosal trauma. Denture trauma should be minimized by prompt and careful postinsertion adjustment.

Pediatric Dental Therapy

The pediatric dental patient occasionally presents with prolonged oozing from exfoliating primary teeth. In a child with factor deficiencies, administration of factor concentrates and extraction of the deciduous tooth with curettage may be necessary for patient comfort and hemorrhage control. One suggestion is the extraction of mobile primary teeth using periodontal ligament anesthesia without factor replacement after 2 days of vigorous oral hygiene to reduce local inflammation.[226] Hemorrhage control is obtained with gauze pressure, and hemostasis is achieved in 12 hours. Pulpotomies can be performed without excessive pulpal bleeding. Stainless-steel crowns should be prepared to allow minimal removal of enamel at gingival areas.[227]

Orthodontic Therapy

Orthodontic treatment can be provided with little modification. Care must be observed to avoid mucosal laceration by orthodontic bands, brackets, and wires. Bleeding from minor cuts usually responds to local pressure. Properly managed fixed orthodontic appliances are preferred over removable functional appliances for the patient with a high likelihood of bleeding from chronic tissue irritation. The use of extraoral force and shorter treatment duration further decrease the potential for bleeding complications.[228]

Dental Implants

Surgery for dental implant placement is approached with preparation in a similar manner as dental extractions, including

augmentation of hemostasis before surgery and postoperative use of antifibrinolytic and other topical approaches.[229]

Dental Surgery (Extractions)

Dental surgical management draws on disease-specific approaches to management of the underlying bleeding diathesis, some of which were discussed in the medical management section. All patients with bleeding disorders should be specifically educated about possible prolonged intraoral bleeding and intraoral and extraoral ecchymosis as part of informed consent. Risks and benefits of preoperative and postoperative management strategies should be discussed among physician, dentist, and patient to allow shared decision-making.

THE IMMUNE SYSTEM: PROTECTION FROM PATHOGEN CHALLENGE

A significant number of oral diseases result from defects or deficits in the immune system. The immune system is extremely complex, but is composed of both the innate and adaptive immune systems, served by diverse cell types that have the primary function of defending the body against infection. To achieve this, the immune system has to distinguish between self and non-self and identify foreign invaders as distinct from self.[1] In this way, the immune system can recognize and clear invading pathogens such as viruses, bacteria, or parasites, but tolerate antigens derived from innocuous proteins, and self-antigens as well as commensal microbiota. When responding to an invading pathogen, the immune system is responsible for coordinating an effective immune response, which will not only neutralize the invading pathogen, but remove dead or damaged cells and turn itself off once the pathogen has been removed. Furthermore, the immune system is tasked with mediating responses to injury, cell death, and tumor surveillance. An appropriately functioning immune system is vital for life and its importance is highlighted by the fact that its dysfunction underpins a plethora of diseases, ranging from infection to cancer and autoimmunity; within the oral cavity, immune system dysfunction contributes to the pathology of gingivitis, periodontitis, oral infections, and autoimmune manifestations of systemic or local disease.

Immune responses in humans, and indeed all vertebrates, are mediated by two distinct yet connected systems: the *innate* and the *adaptive* immune systems.[2] The innate immune system is immediately activated upon injury or pathogen encounter. This activation occurs in a nonspecific manner, but is often capable of independently eliminating the invading insult. However, when the innate immune response is unable to control the insult, it will recruit and activate an adaptive immune response. The adaptive immune system is highly targeted, not only ensuring that the right type of immune response is activated for the type of infection, for example viral verses parasitic, but also becoming targeted to the specific invader. Moreover, it will later provide memory for the specific pathogen, allowing a faster, more effective immune response to be mounted upon any subsequent encounter with the same pathogen. The two systems are heavily connected. However, the innate immune system is absolutely vital for effective protection against injury and infection, particularly at mucosal sites.

THE IMMUNE SYSTEM OF THE MOUTH

Successful defense of oral mucosal barriers requires secretion of saliva, an effective epithelial barrier, and activation of innate and adaptive immune cells. Indeed, we consider saliva, a mucosal barrier, and the immune cell network to be the pillars of the oral immune system (Figure 19-1).

Saliva

Saliva, the extracellular fluid secreted by salivary glands in the mouth, plays a critical role in immune protection at the oral mucosal barrier. Saliva contains 99% water, but also electrolytes, enzymes for digestion (amylase, lipase), mucus, and antimicrobial components. Key antimicrobial components in saliva are secretory immunoglobulin (Ig) A, microbiocidal enzymes such as lysozyme, lactoperoxidase, lactoferrin, proline-rich proteins, and antimicrobial peptides (histatins, defensins, secretory leukocyte protease inhibitor [SLPI]). Saliva provides constant lubrication and ensures the health and integrity of the mucosal barrier. Indeed, patients with reduced or absent saliva (dry mouth to hyposalivation) suffer from mucosal inflammation and ulcerations, which lead to pain and difficulty eating. Saliva also clearly provides effective antimicrobial defense, particularly toward specific microbial pathogens. In fact, patients with xerostomia present predominantly with oral candidiasis (a mucosal infection with *Candida albicans*) as well as severe to rampant dental infections with "cariogenic" (dental caries–causing) bacteria, such as *Streptococcus mutans*.

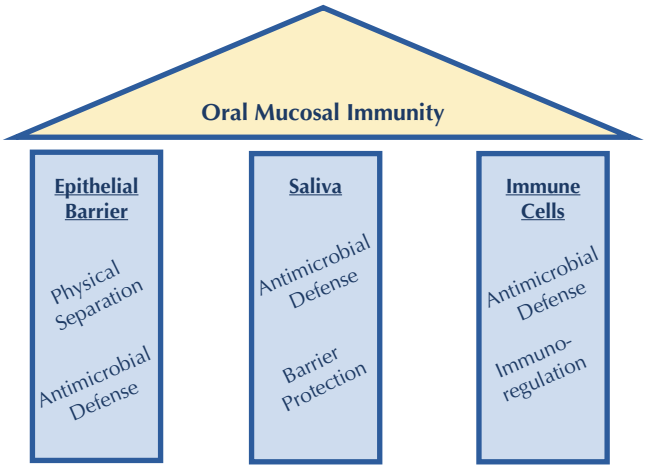

Figure 19-1 Epithelial barrier, saliva, and immune cell network are the three pillars of oral mucosal immunity, providing physical separation, antimicrobial defense, and immuno-regulation to achieve a balance between host and environment.

Oral Epithelium

The oral epithelial barrier is a key interface of the human body with the external environment, providing physical, structural, and immunologic protection to infectious challenge. The oral mucosa is lined with a multilayer squamous cell epithelium. This epithelium is fortified to a different extent depending on the area of the oral cavity and its functional needs. In the hard palate, dorsum of tongue, and gingiva, the epithelium is fully keratinized to withstand the constant mechanical damage induced during mastication. However, the majority of the oral epithelial barrier is composed of lining epithelium, a multilayered squamous cell epithelium with minimal keratinization. Such epithelium lines the buccal mucosa, the labial mucosa, the gingival crevice, and the floor of the mouth. These areas are more exposed to the outside environment, not only because of minimal keratinization, but because some of them have thinner epithelium and increased vascularity (such as the floor of the mouth).

However, possibly the most exposed and vulnerable site of the oral mucosal barrier is the junctional epithelium (the connection between teeth and mucosa). The junctional epithelium, which directly attaches to the surface of the tooth, is only three to four cells thick at its narrowest points near the teeth and is nonkeratinized. This means that the junctional epithelium is a weak point in the oral mucosal barrier. However, by being nonkeratinized, it is permeable, and therefore serves as the primary pathway for the transmigration of immune cells, particularly neutrophils, and fluid into the oral space. This fluid, termed gingival crevicular fluid, contains host-defensive proteins that are then at a high concentration on the external side of the junctional epithelium. Thus, the oral epithelium is locally specialized, providing a physical barrier protecting underlying tissues. Alongside this, oral epithelial cells are key sources of pro-inflammatory cytokines and chemokines and directly respond to pathogens; as such, disruption of the epithelium constitutes a risk factor for infection and aberrant inflammation.

Immune Cells

The oral cavity is constantly exposed to environmental stimuli, including a resident commensal bacterial community, continuous damage from mastication, and pathogen challenge. The ceaseless nature of these local triggers requires active immune surveillance within the mouth. This means that in addition to saliva and specialized epithelium, immune cells are resident even within healthy oral mucosa to ensure effective barrier defense, regulation, and healing. Here we will introduce the main mediators of the immune system, first those of the innate and then the adaptive immune system, outlining how these systems play key roles in safeguarding health and driving pathology.

Innate Immunity

The major innate immune cells present within the oral mucosa are *neutrophils*. These are short-lived (24–48 hours) cells that make up about 70% of peripheral blood white blood cells. Neutrophils are activated by bacterial products, exhibiting profound antimicrobicidal activity, through ingestion of bacteria (phagocytosis) and release of soluble and nonsoluble components that can trap and kill extracellular pathogens.[3] These cells are rapidly mobilized to sites of pathogen invasion, being the first innate immune cells to extravasate from blood vessels, via a well-defined series of events, and migrate toward the infection. Here, neutrophils release reactive oxygen species (ROS), granules containing cytotoxic compounds and antimicrobial peptides, and neutrophil extracellular traps (NETs), which combined create an environment proficient at pathogen killing, degradation, and removal.

Even in health, neutrophils constitute the majority of immune cells present in the gingival oral barrier. Neutrophils constantly traffic from the circulation, through gingival tissue and junctional epithelium, into the gingival crevice. It has been demonstrated that about 30,000 neutrophils undertake this journey every minute in humans, and as such neutrophils can be found within the oral cavity.[4] The functional contributions of neutrophils outside the tissue, within the oral cavity, remain to be defined, but it is clear that effective neutrophil surveillance of the gingival barrier is vital for oral health, as oral inflammation routinely occurs when neutrophil functions and numbers are dysregulated.

Other innate immune cells resident within the oral mucosa include mononuclear phagocytes, phagocytic cells including *monocytes*, *macrophages*, and *dendritic cells* (DCs).[5] The main function of monocytes, and their macrophage progeny, is to internalize pathogens and dead/dying cells and degrade them in an organelle that has a low pH and is filled with hydrolytic enzymes: the phagosome. In this way, monocytes and macrophages are considered functionally plastic, as they mediate key roles in both pathogen protection, but also tissue repair and healing. At other mucosal sites, macrophages are crucial for the maintenance of barrier homeostasis, adopting barrier-specific functions that support health. For example, in the gastrointestinal tract, macrophages constitutively produce the anti-inflammatory cytokine interleukin (IL)-10. However, the functional characteristics and importance of macrophages within the oral barrier remain to be determined.

The main function of DCs is to internalize and process foreign particles to generate small peptide antigens that can be presented on their cell surface to T cells. Therefore, DCs are considered "professional" *antigen-presenting cells* (APCs) and are key initiators of the adaptive immune response. Upon activation, barrier-resident DCs become more effective at processing and presenting antigens and drain to local lymph nodes, where they interact with, and activate, T cells. *Langerhans cells* are perhaps the best studied of the oral DCs, residing in the oral epithelium, but multiple populations of DCs have been described, each of which exhibits enhanced capabilities at initiating specific types of T-cell response. Although the DC populations at certain oral barriers have been well characterized, we are only just beginning to understand how distinct subsets contribute to the mounting of effective T-cell responses within the oral cavity.

The *complement system* is a major arm of innate immunity that enhances pathogen clearance by promoting pathogen phagocytosis, antigen presentation, and immune cell activation, and can also attack the cell surface of any invader. The complement system consists of multiple plasma proteins (C1-9), pattern-recognition molecules, and proteases that operate in a cascade to opsonize pathogens and induce proinflammatory responses. As such, complement plays a vital role in promoting effective immune responses upon pathogen challenge. However, complement can also become dysregulated and has been shown to contribute to pathology in diseases such as cancer and autoinflammatory diseases; in particular, excessive complement activation is seen in patients with periodontitis.

Alongside these key innate immune mediators are populations of cells that exhibit characteristics of both the innate and adaptive immune systems. These include *innate lymphoid* cells (ILCs), *natural killer* (NK) cells, and *γδ-T* cells. Although lymphocytes, these cells are not activated by peptide antigens and instead rapidly respond to signals of tissue and cellular perturbation, either producing an array of immunomodulatory cytokines or inducing cell death of infected cells. In mediating such functions, ILCs, NK, and γδ-T cells are all at low frequencies in peripheral blood but are enriched at mucosal barrier sites. Within the oral cavity all these immune cells have been identified,[6] with specialized populations of ILCs and NK cells present in salivary glands and oral barrier-resident γδ-T cells being shown to safeguard gingival immune homeostasis and limit periodontitis development.

Adaptive Immunity

Activation of innate immunity culminates in the development of highly specific immune responses, which are antigen specific and coordinated by cells of the adaptive immune system, specifically *lymphocytes*. There are two types of lymphocytes, *B cells* and *T cells*, which express genetically rearranged and extremely diverse antigen receptors. These receptors allow the B or T cell to be activated in an antigen-specific manner, thus imparting the specificity exhibited by these cells.

The B-cell receptor is a surface-bound immunoglobulin molecule, which recognizes both linear and conformation antigens. Recognition of antigen via this immunoglobulin receptor, alongside some additional activation signals, allows B cells to start producing soluble immunoglobulins, also known as *antibodies*. Antibodies can neutralize pathogens, for instance bind to viruses and prevent cell entry, activate immune cells, and activate the complement cascade. Initially B cells will produce IgM; however, as the immune response develops, B cells undergo class switching, a genetic rearrangement that allows B cells to produce other antibody isotypes: IgG, IgA, IgD, or IgE. The different isotypes have distinct constant regions that do not participate in antigen binding, but instead are important for the effector function of the antibody. For example, IgE will preferentially bind to antibody receptors expressed on mast cells, triggering the release of histamine during parasitic worm infection and allergy. IgG is the dominant antibody found in plasma and can be transported across the placenta to impart a degree of fetal protection.

The mouth is part of the mucosal immune system, embracing all mucosal epithelium including that of the gut, lungs, respiratory and genital tracts, breast, and eyes and with a total surface area of 400 m^2. The surfaces are protected by mucins but adaptively by secretory IgA, which can be induced by immunization in the gut or nose and independently from serum IgA. Thus, antibodies found in secretions, such as saliva or bronchial secretions, are usually IgA (or sometimes IgM) produced by plasma cells within mucosal tissues. The IgA secreted by plasma cells in the lamina propria links to the secretory component, which facilitates antibody transport through the secretory epithelium. Mucosal IgA is mainly dimeric, in contrast to serum IgA. It protects by virus or enzyme neutralization, by aggregation of bacteria, and by preventing adherence of pathogens to the host.

Oral commensal bacteria-specific antibodies, predominantly IgA, can be detected in the oral fluids of even healthy individuals and certain oral commensals have been shown to be coated in IgA. In addition, autoantibodies in various autoimmune diseases can be detected in saliva, which can be used as a diagnostic fluid. Serum antibodies against oral commensal bacteria have also been detected, and there are some indications that they may help regulate the bacterial communities on the surfaces of the teeth and more generally within the oral cavity, acting via crevicular fluid.

For T cells to become activated, antigen must be processed and bound to a class I or class II major histocompatibility complex (MHC) molecule on the surface of an APC. Antigens recognized by the T-cell receptor are short linear peptide sequences, which are recognized in the context of the MHC in which they are presented. In terms of T-cell activation, encounter of cognate antigen bound to MHC is considered "signal 1," but an additional signal is required for full T-cell activation. "Signal 2" is co-stimulation, whereby ligand-receptor pairs on the surface of the T cell and APC interact to further promote T-cell activation; in this way T-cell activation is strictly controlled.

There are two types of T cells: $CD4^+$ and $CD8^+$ T cells. *$CD8^+$ T cells* are activated by peptide antigens of intracellular origin (therefore most likely viral antigens), which are presented by MHC class I molecules. Activated $CD8^+$ T cells proliferate and differentiate to become *cytotoxic lymphocytes* (CTLs), which are highly effective killing machines capable of inducing the cell death of multiple target cells presenting their specific antigen. *$CD4^+$ T cells* are activated by peptides bound to MHC class II molecules, whereupon they differentiate into different subsets of T-helper (Th) cells.[7] $CD4^+$ T cells can be considered to require a "signal 3," which drives the activated $CD4^+$ T cell to differentiate into either a Th1, Th2, Th17, or regulatory T cell (Treg). Th1 and Th2 cells were the first $CD4^+$ T cell subsets identified in the 1980s. *Th1 cells* help promote the clearance of bacteria and viruses, whereas *Th2 cells* are generated in response to parasitic worm infections and help fight off these large extracellular pathogens. Th1 cells predominantly produce the cytokine IFNγ, which activates macrophages, making them more effective at phagocytosing and killing pathogens and supports $CD8^+$ T cell differentiation into CTLs. Th2 cells predominantly produce the cytokines IL-4 and IL-13. These cytokines subsequently promote a coordinated immune response that clears worm infection by promoting eosinophil recruitment and epithelial shedding.

More recently, *Th17 cells* have been identified, which are distinguished by their production of the cytokines IL-17A and IL-17F.[8] This subset is vital for defending against fungal infection, and individuals with defects in the generation or function of this subset frequently present with persistent candidiasis. Th17 cells promote neutrophil recruitment to the site of infection and also enhance the production of antimicrobial peptides by epithelial cells. The final classical subset of $CD4^+$ T cells is *Tregs*; unlike the other subsets, Tregs do not promote effective immunity, but instead play key roles in the suppression of immune responses. Tregs are defined by the expression of the transcription factor Foxp3 (or scurfin) and have been shown to be vital mediators of peripheral tolerance. Their importance to health is highlighted by the severe autoinflammatory disease that results in their absence; individuals with mutations in the *Foxp3* gene develop IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked), a lymphoproliferative disease in which self-reactive T cells target multiple bodily organs and inappropriate T-cell responses are mounted to harmless antigens. Indeed, defects in Treg numbers and function have been identified in patients with a plethora of different inflammatory diseases. Of note from a therapeutic standpoint is that in experimental systems, increases in Tregs have been shown to limit the pathology of autoinflammatory diseases, including periodontitis.

Following the clearance of any invading organism, most activated, differentiated T-cell populations undergo apoptosis as pathogen-derived antigens are removed. However, a subset of antigen-specific T cells survives and persists long-term after pathogen clearance. These are known as *memory T cells* and remain within the body to rapidly respond should reinfection with the same pathogen occur. Different types of memory T cells exist. Some continuously circulate through the body similar to naïve T cells, awaiting reactivation. Others become resident in the tissues in which the pathogen challenge occurred. In this way, mucosal barriers show increased proportions of resident memory T cells, which promote rapid effector responses and site-specific protection against pathogens.

Within oral barriers, most resident T cells exhibit a memory phenotype, and most are $CD4^+$ T cells. In health, resident effector $CD4^+$ T cells predominantly produce the cytokine IFNγ, as outlined earlier, the canonical Th1 cytokine. Alongside these effector cells, resident within the oral mucosa are Tregs, presumably to help regulate local inflammatory reactions. At other barrier sites, most notably the gastrointestinal tract and skin, Th17 cells are resident during health, help the host establish an appropriate dialogue with the commensal bacterial community, and also promote epithelial barrier function. This is not the case in the oral cavity, where Th17 numbers are low in healthy tissues but are dramatically expanded during periodontitis.[8] Indeed, emerging studies indicate that Th17 cells are key mediators of pathology in periodontitis, and that targeting these cells could provide a novel opportunity in the treatment of this disease.

Maintenance of Immune Homeostasis in the Oral Cavity

Maintenance of immunologic health within the oral cavity is an active process, with local immune mediators of both the innate and adaptive arms of the immune system acting in coordination to reinforce barrier integrity and prevent pathogen invasion.[9] This local immune activity will also shape and constrain the local commensal bacterial community.

Ongoing studies have begun to delineate the immune populations present at distinct oral sites and what is becoming clear is that a unique immune network polices oral mucosal barriers compared to other mucosal barrier sites. The unique aspects of immune functioning at oral barriers likely reflect the need for specific immune activities that are required to maintain homeostasis at these sites. For example, given that oral mucosal sites constantly experience mechanical damage as a result of mastication, there is a requirement for rapid and continuous healing; immune mediators within the oral cavity would promote this. The unique nature of the oral immune network can most readily be seen in the high numbers of neutrophils present at this site, as well as the continuous recruitment and extravasation of neutrophils through the oral epithelium that occur during health. Indeed, the continuous extravasation of neutrophils through the oral epithelium does not happen across any other healthy mucosal barrier. Ultimately, the combined activities of both innate and adaptive immune cells are required for effective defense of oral barriers. The complex nature of this defensive network is readily highlighted by the plethora of oral pathologies that result when any aspect of it malfunctions.

PRIMARY IMMUNODEFICIENCIES

Primary immunodeficiencies (PIDs, also known as inborn errors of immunity) include a group of more than 300 genetic disorders, which are typically caused by single-gene mutations and impair specific mechanisms of immune function. Although PIDs were previously thought to be very rare conditions, they are now known to affect 1 of every 1200–2000 individuals, with growing prevalence due to increased testing and recognition. The clinical presentation of PIDs is variable and often includes severe or unusual infections with a single type of infectious agent. Importantly, autoimmunity, autoinflammation, and malignancy are increasingly recognized as signs of PID disease. In 2015 the expert committee of the International Union of Immunological Societies (IUIS) developed an updated classification scheme[10] to categorize PID diseases into nine categories based upon the segment of the immune system affected, and it provides a clinically oriented strategy for disease categorization that can facilitate diagnosis and management.[11]

Multiple PIDs present with significant oral manifestations, ranging from oral infections to severe periodontal disease, craniofacial anomalies, and malignancy. Recognition of such disease is key in oral medicine, as such patients often present with significant and challenging clinical needs and therefore diagnosis and disease understanding are necessary to provide specialized care in coordination with a multidisciplinary team of experts. From a scientific standpoint, understanding and characterization of relevant diseases provide insights into the role of specific arms of the immune system in oral health and disease.

This chapter will introduce the basic current classification scheme for PIDs, and present the main features of each major category as well as examples of genes implicated in these diseases (Table 19-1). PIDs with significant oral manifestations will be given increased attention and summarized in the text and in table format (Table 19-2).

Table 19-1 Major categories of primary immunodeficiencies.

Immune FunctionAffected	Genes Affected (Examples)	Clinical Phenotype
1) **Immunodeficiencies affecting cellular and humoral immunity**		
TB^+ SCID	*IL2RG, JAK3, IL7R, CD3D CD3E*	Broad range of life-threatening infections
TB- SCID	*RAG1, RAG2*	As above
CID	*CD40, CD40L, TAP1, TAP2 DOCK8*	Broad range of infections, Milder than SCID
2) **Combined immunodeficiencies with associated syndromic features**		
CID congenital thrombocytopenia	*LOF WAS*	CID with low platelets
CID due to DNA repair defects (e.g., ataxia telangiectasia)	*ATM*	CID with intrauterine growth restriction, facial dysmorphisms
CID due to thymic defects with additional congenital anomalies (e.g. Di George syndrome)	*22q11.2* deletion	CID with structural heart defects, hypoparathyroidism, facial dysmorphisms
CID with immuneosseous dysplasia		CID with skeletal anomalies
Hyper-IgE syndromes (HIES)	*LOF STAT3*	CID with hyper-IgE, AD-HIES, or Job's syndrome (oral features)

Table 19-1 (Continued)

Immune FunctionAffected	Genes Affected (Examples)	Clinical Phenotype
Dyskeratosis congenita (DKC), myelodysplasia, defective telomere	Multiple gene targets	CID with syndromic features DKC is associated with risk for oral cancer
3) **Predominantly antibody deficiencies**		
All serum Ig isotypes affected	*BTK, CD79A, CD79B*	Severe bacterial infections
At least two serum Ig isotypes affected	*CD19, CD20, BAFF-R*	Recurrent infections
Severe reduction in IgG/IgA	*UNG*	Recurrent infections
Specific isotype or functional		May be asymptomatic
4) **Diseases of immune dysregulation**		
Regulatory T-cell defects	*FOXP3, IL2RA, CTLA4*	Multiorgan inflammation and autoimmunity
Autoimmune lymphoproliferative syndrome (ALPS)	*FASLG, FADD, TNFRSF6*	Spenomegaly, adenopathies, autoimmune cytopenias
Immune dysregulation with colitis	*IL10, IL10RA, IL10RB*	Colitis
Familial hemophagocytic lymphohistiocytosis syndromes (e.g. Chédiak–Higashi syndrome)		Fever and cytopenias
Autoimmunity with/without lymphoproliferation (e.g., APECED)	*AIRE, ITCH*	Autoimmunity
5) **Congenital defects of phagocyte number or function**		
Congenital neutropenias	*HAX1, ELANE/ELA2*	Infections, periodontitis
Defects in neutrophil motility	*ITGB2, CTSC, FPR1, RAC2*	Infections, periodontitis
Defects in myeloid respiratory burst	*CYBB, CYBA, NCF1, NCF2*	Infections, hyperinflammatory phenotype
Nonlymphoid defects	*GATA2*	Mycobacterial susceptibility
6) **Defects in intrinsic and innate immunity**		
Mendelian susceptibility to mycobacterial disease (MSMD)	*IL12RB1, IL12B, INFGR1/2, TYK2*	Mycobacterial infections and *Salmonella*
Epidermodysplasia verruciformis (e.g. WHIM)	*TMC6, TMC8, CORO1A, CXCR4*	HPV infections
Predisposition to severe viral infection (NK/T-cell defects)	*STAT1/2, IFNAR2*	HSV, EBV, HHV, VZV
Herpes simplex encephalitis		Encephalitis
TLR signaling pathway deficiency	*IRAK1/4, MYD88*	Pyogenic bacterial infections
Predisposition to invasive fungi	*CARD9*	Invasive candidiasis
Predisposition to mucocutaneous fungal disease	*RORC, IL-17RA, IL17F* *IL17RC, TRAF3IP2*	Mucocutaneous candidiasis
7) **Autoinflammatory disorders**		
Type I interferonopathies	*PSMB8*[a]	Fever, contractures, panniculitis
Defects affecting the inflammasome	*MEFV, NLRP3, NLRP12, NLRP1*	Fevers, inflammatory tissue lesions (IBD or arthritis), rashes
Non-inflammasome-related conditions	*PSTPIPI, IL1RN*	Inflammatory tissue lesions
8) **Complement deficiencies**		
Affecting early complement components	*C1-C4* *C1R-C1S*	SLE Periodontitis
Terminal classic components	*C5-C9*	Neisserial infections
9) **Phenocopy of PID**		
Autoimmune lympho-leuko proliferation	*TNFRSF6, KRAS, NRAS*	Splenomegaly, lymphadenopathy, cytopenia
Autoantibody diseases	*AIRE*	Infections due to antibodies to cytokines

AD-HIES, autosomal dominant hyper-immunoglobulin E syndrome; APECED, autoimmune polyendocrinopathy candidiasis ectodermal dystrophy; CID, combined immunodeficiencies; EBV, Epstein–Barr virus; HHV, human herpesvirus; HPV, human papillomavirus; HSV, herpes simplex virus; IBD, inflammatory bowel disease; Ig, immunoglobulin; NK, natural killer; PID, primary immunodeficiency; SCID, severe combined immunodeficiency; SLE, systemic lupus erythematosus; TLR, toll-like receptor; VZV, varicella-zoster virus; WHIM, warts, hypogammaglobulinemia, recurrent infections, and myelokathexis.

Table 19-2 Common oral manifestations in primary immunodeficiency.

Oral Manifestations	Immune Mechanism Involved	Specific Mutations/Syndromes
Recurrent herpetic infections Human papilloma viruses	T-cell/NK T-cell function	Tapasin genes/MHCI deficiency MHCII deficiency Deletion chromosome 22q11.2/ DiGeorge *DOCK8* *WAS*/Wiskott–Aldrich syndrome SCID
Odontogenic infections	B cells	*BTK*/BTK deficiency Select IgG deficiencies

AD-HIES, autosomal dominant hyper-immunoglobulin E syndrome; APECED, autoimmune polyendocrinopathy candidiasis ectodermal dystrophy; CGD, chronic granulomatous disease; CID, combined immunodeficiencies; HPV, human papillomavirus; HSV, herpes simplex virus; Ig, immunoglobulin; LAD, leukocyte adhesion deficiency; LJP, localized juvenile periodontitis; NK, natural killer; PFAPA, periodic fever, aphthous stomatitis, pharyngitis, and adenitis; PID, primary immunodeficiency; SCID, severe combined immunodeficiency.

Immunodeficiencies Affecting Cellular and Humoral Immunity (T Cells/B Cells)

This group of diseases significantly affects adaptive immune responses by impairing the development and function of T cells and B cells. They are also called combined immunodeficiencies (CIDs), as they tend to affect the development and function of multiple cellular subtypes.[11,12] The most severe example of CID is severe combined immunodeficiency (SCID). Patients with this condition are born with almost no T cells. Although many patients with SCID may have B cells, antibody production is absent because there is no T-cell help. Patients present within the first few months of life with life-threatening infections. Without curative therapy (hematopoietic stem-cell transplantation or gene therapy), patients typically die from overwhelming infection before 1 year of age. Other CIDs are somewhat arbitrarily distinguished from SCID in that they typically do not lead to death in the first year of life and typically have higher T-cell

numbers and T-cell function compared with SCID. Patients with CID defects can present with a broad range of infections, including viral, fungal, and/or bacterial infections. Such patients are also susceptible to opportunistic infections (e.g., *Pneumocystis jirovecii* pneumonia) and infections from live vaccinations (e.g., measles, mumps, and rubella [MMR] and varicella).

This category includes SCID, both with absence of T cells and NK cells but presence of B cells (T^-B^+) as well as without T or B cells (T^-B^-); and milder forms of CID. Mutations associated with T^-B^+ typically affect the maturation and survival of T cells and NK T cells by affecting either cell development or signaling through the T-cell receptor (*CD3D*, *CD3E*), and T/NK cell survival and activation (*IL2RG, IL7R*, *JAK3*).[13] Mutations leading to T^-B^- SCID include those affecting the rearrangement of the T-cell receptor and of immunoglobulins (*RAG1/ RAG2*). Milder forms of non-SCID CID are caused by MHCI/II deficiencies (*TAP1*, *TAP2*), *CD40* deficiency, or *Dock8* deficiency.[13]

DOCK8

DOCK8 deficiency has been reported to present with significant oral manifestations. It is caused by loss-of-function (LOF) mutations in the *DOCK8* gene, which encodes a guanine nucleotide exchange factor that regulates the actin cytoskeleton and is highly expressed in lymphocytes. Patients have impaired B-, T-, and NK T-cell survival and long-lived memory responses.[14] Clinically such patients present with eczema, recurrent respiratory as well as persistent mucocutaneous viral infections: varicella-zoster virus (VZV), molluscum contagiosum, herpes simplex virus (HSV), and human papillomavirus (HPV). Persistent infection, particularly with HPV, leads to increased risk of cancer (typically viral-driven, squamous cell carcinomas), which affects up to 17% of patients. In the oral cavity, severe HPV and HSV infections have been reported in DOCK8 patients as well as susceptibility to HPV-associated squamous cell carcinoma (Figure 19-2).

Combined Immunodeficiency with Syndromic Features

This category includes diseases in which patients are affected by combined immunodeficiency in conjunction with other clinical features outside the immune system, such as congenital anomalies and manifestations in the skeletal system. It includes the following subcategories:

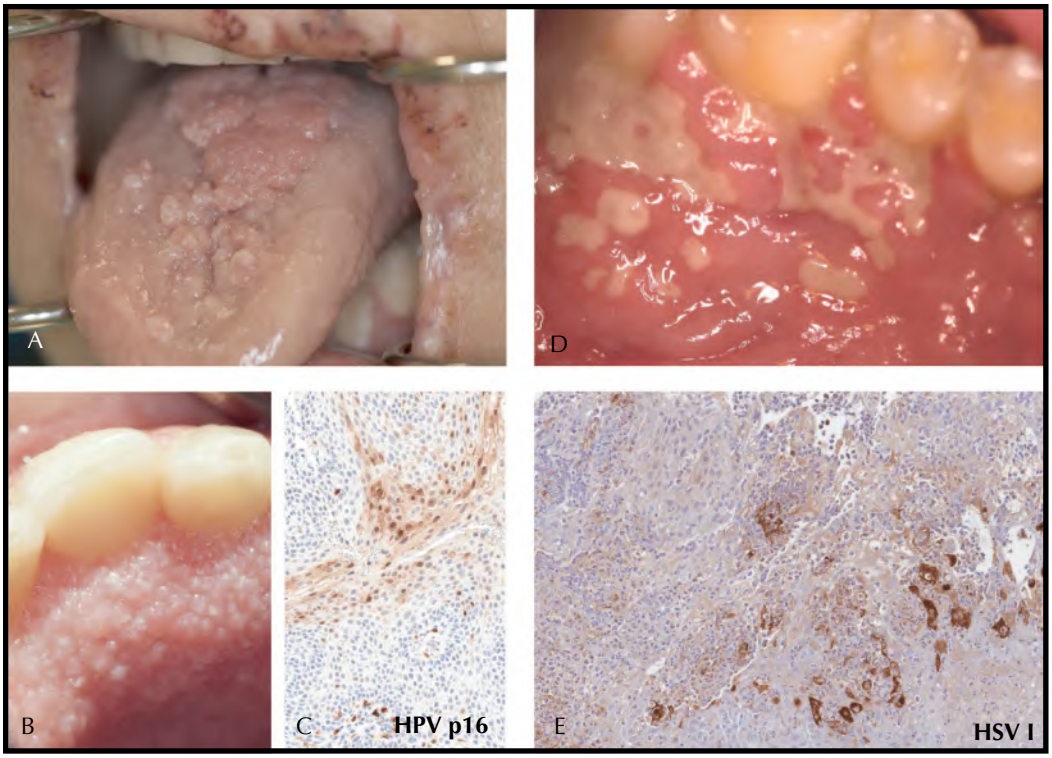

Figure 19-2 Oral mucosal viral infections in patients with DOCK8 deficiency. Patient 1 (A–C) suffers from severe oral human papillomavirus (HPV) infections despite antiviral treatment. Widespread condylomas are apparent throughout the tongue dorsum (A) and on the palate (B). Histopathologic evaluation of palatal lesions reveals p16 positivity indicative of HPV infection (C, brown staining). Patient 2 (D–E) suffers from oral herpes simplex virus 1 (HSV-1) infection. A nonhealing palatal ulcer is shown (D), which upon biopsy and immunohistochemical staining revealed HSV-1 positivity (E).

- *CID with congenital thrombocytopenia*. Disorders in this subcategory are characterized by CID with low platelets as a key clinical feature. A classic example is Wiskott–Aldrich syndrome (WAS, LOF mutation), characterized by thrombocytopenia with small platelets, bloody diarrhea, and eczema.[15]
- *CID due to DNA repair defects*. DNA repair defects can result in both T- and B-cell abnormalities because it is essential for V(D)J recombination to generate T-cell/B-cell diversity and for effective class-switch recombination. In addition to a CID phenotype, many of these conditions such as ataxia telangiectasia (caused by *ATM* mutations) are characterized by other clinical features including intrauterine growth restriction (IUGR), facial dysmorphisms, and increased radiosensitivity.
- *CID due to thymic defects with additional congenital anomalies*. Genetic disorders in this category result in impaired development of the thymus, which ultimately affects T-cell development and can result in CID. One of the most common (1:3000 live births) and well-characterized syndromes with underlying immunodeficiency is DiGeorge (*22q11.2* deletion) syndrome. This syndrome is characterized by structural heart defects, hypoparathyroidism (resulting in hypocalcemia), characteristic facial features, and T-cell immunodeficiency.
- *CID with immuneosseous dysplasia*. These disorders are characterized by CID features with skeletal abnormalities.
- *Hyper-IgE syndromes (HIES)*. These disorders are all characterized by CID and elevated IgE. One well-characterized such PID with documented oral/craniofacial features is autosomal dominant hyper-IgE syndrome (AD-HIES/Job's syndrome). AD-HIES is caused by LOF mutations in the signal transducer and activator of transcription (STAT) 3 gene. Clinical manifestations occurring in >75% of patients are recurrent staphylococcal abscesses, recurrent airway infections, and increased concentration of IgE in serum.[16] Patients also present with atopy and skeletal manifestations. In the craniofacial/oral region, manifestations include characteristic facial features, retention of primary teeth, and recurrent oral candidiasis (Figure 19-3).
- *Dyskeratosis congenita (DKC), myelodysplasia, defective telomere maintenance*. Telomeres are structures that prevent the loss of genetic material that normally occurs with every cell division. Without proper telomere maintenance, cell senescence and apoptosis can occur, especially in highly proliferative cell types such as lymphocytes. As such, in the presence of defects in telomere maintenance, patients can present with CID combined with syndromic features affecting the skin, nails, and hair and leading to lung fibrosis and enteropathy.[17] Such patients also have an increased risk for malignancy, including *increased risk for oral cancer*, and therefore oral cancer screening becomes particularly significant for this patient population.

Predominantly Antibody Deficiencies

B cells differentiate into plasma cells that produce antibodies or immunoglobulins. Human antibodies are classified into five isotypes (IgM, IgD, IgG, IgA, and IgE) according to their H chains, which provide each isotype with distinct characteristics and roles. IgG is the most abundant antibody isotype in the blood (plasma), accounting for 70–75% of human immunoglobulins. Antibody deficiencies are categorized into the following:

- Severe reduction in all serum Ig isotypes with absent B cells (e.g., *BTK* deficiency Bruton's agammaglobulinemia, Igα and Igβ deficiency due to *CD79A/B* mutations).
- Severe reduction in at least two serum Ig isotypes with normal or low numbers of B cells (e.g., B-cell deficiencies including mutations in *CD19*, *CD20*, and *BAFF-R*).
- Severe reduction in serum IgG and IgA with increased IgM and normal numbers of B cells (*UNG* deficiency).
- Isotype or light-chain deficiencies with normal numbers of B cells (such as Ig heavy-chain mutations, K chain deficiency, and isolated IgG subclass deficiencies).

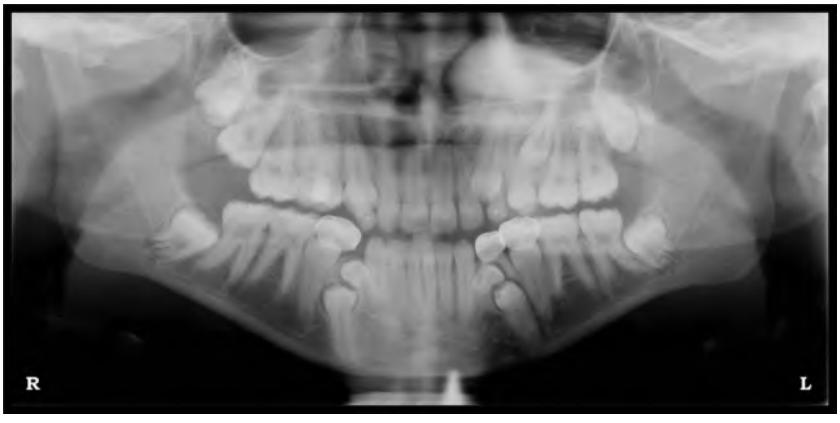

Figure 19-3 Retention of primary dentition is a hallmark oral sign for autosomal dominant hyper-immunoglobulin E syndrome (AD-HIES or Job's syndrome). Panoramic radiograph of a 25-year-old patient with AD-HIES (*GOF STAT3*). Multiple primary teeth are still present. Permanent mandibular premolars have failed to erupt despite normal tooth development. In such patients, timely removal of primary teeth allows for eruption of the permanent dentition.

Patients with antibody deficiency commonly present with recurrent bacterial infections of the upper and lower respiratory tracts (ear infections, sinus infections, and pneumonia, including odontogenic infections) from encapsulated bacteria, such as *Streptococcus pneumoniae*. However, more invasive bacterial infections such as sepsis, meningitis, and osteomyelitis can occur. These patients have also been reported to be susceptible to severe odontogenic infections.

Diseases of Immune Dysregulation

It is increasingly recognized that numerous PIDs present with features of dysregulated inflammatory responses that often lead to autoimmune phenomena, including cytopenias and solid organ autoimmunity, in addition to lymphoproliferation and malignancy. The treatment of immune disorders with coexisting immune deficiency and immune dysregulation is challenging, as it requires careful balancing of immunosuppression and control of infection. Subcategories of PID with immune dysregulation include the following:

- *Regulatory T-cell defects.* Tregs play a critical role in peripheral tolerance by suppressing autoreactive and activated T cells. Reduced or impaired function of Tregs results in systemic autoimmunity. Examples in this category include IPEX (due to *FOXP3* mutations), CD25 deficiency (*IL2RA*), and cytotoxic T-lymphocyte-associated antigen 4 (*CTLA4*) deficiency.
- *Autoimmune lymphoproliferative syndrome* (ALPS). ALPS results from defects in the
  Fas/Fas ligand (FasL) pathway. This pathway normally eliminates autoreactive lymphocytes. Relevant mutations include *FASLG*, *FADD*, and *TNFRSF6*.[18]
- *Immune dysregulation with colitis*, classically associated with *IL10* and *IL10RA/RB* mutations.
- *Familial hemophagocytic lymphohistiocytosis syndromes* are linked to decreased NK and CTL cells with increased activation of T cells. One disease in this category, Chédiak–Higashi Syndrome, is linked to severe periodontitis; it is caused by mutations in the lysosomal trafficking regulator gene (*CHS1*/*LYST*).[19] Beyond aberrant inflammatory responses, these patients present with significant neutrophil defects, including destruction of neutrophils early in myelopoiesis, decreased chemotactic responses, and impaired diapedesis. Neutrophil defects in these patients have been linked to susceptibility to periodontal disease.
- *Autoimmunity with/without lymphoproliferation*, as seen in autoimmune polyendocrinopathy candidiasis ectodermal dystrophy (APECED; mutations in *AIRE*) and ITCH syndrome (*ITCH* mutations). APECED is of increased interest to the oral medicine provider as these patients present with dental enamel defects, susceptibility to oral candidiasis, and have been reported to have an increased risk for oral squamous cell carcinoma.

Congenital Defects of Phagocyte Number and/or Function

Phagocytes such as neutrophils and macrophages act as a first line of defense to protect the body from harmful bacteria and fungi by phagocytosis and destruction of these pathogens and through initiation and engagement of adaptive immune responses. Through phagocytosis and release of immune mediators, these cells also play crucial roles in wound healing as well as in the resolution of inflammation.

Main subcategories in this section include the following:

- Congenital neutropenia (due to defective neutrophil development).
- Defects in neutrophil motility.
- Defects in myeloid respiratory burst.
- Nonlymphoid defects (which include defects in the development of monocyte/macrophages due to *GATA2* mutations). Congenital neutrophil defects as well as defects in neutrophil motility and function have been linked to severe aggressive periodontitis at a young age as well as recurrent oral ulcerations, and thus specific examples of these diseases are discussed here.

Congenital Neutropenia

Congenital neutropenia is caused by mutations in genes affecting granulopoiesis (development of neutrophils in the bone marrow), such as mutations in *HAX1* (Kostman syndrome), in the elastase *ELA2/ELANE* gene, or in the (HCLS) 1-associated gene X1. Patients with such mutations have peripheral neutrophil counts below 0.5×10^9/L (1.5– 1.8×10^9/L in health) and frequent bacterial/fungal infections, as well as severe periodontitis that begins in childhood. Granulocyte colony-stimulating factor (G-CSF) treatment leads to improvement of infection susceptibility with varying results in the resolution of periodontitis. Hematopoietic stem-cell transplant has been shown to reverse the phenotype of periodontitis in these patients.

Leukocyte Adhesion Deficiency I

Leukocyte adhesion deficiency 1 (LAD-1) is a rare disorder of leukocyte adhesion and transmigration, which results from mutations in the *ITGB2* gene encoding for the β2 integrin component, CD18. Deficiency in CD18 prevents neutrophil adhesion to endothelial surfaces and extravasation into tissues. This results in severe tissue neutropenia. Patients with LAD-1 suffer from recurrent infections, defective wound healing, and in the oral cavity present with severe to aggressive periodontitis and recurrent oral ulcers.[20] Periodontitis in these patients has been shown to be recalcitrant to standard-of-care treatment with loss of dentition in the teenage years (Figure 19-4).

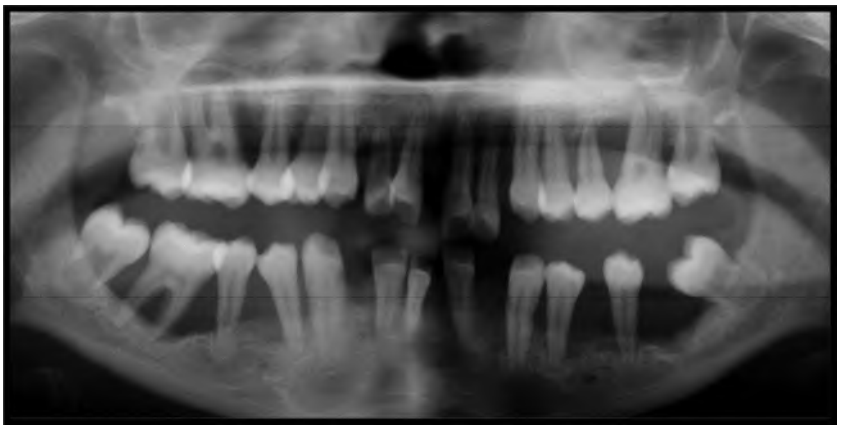

Figure 19-4 Severe periodontitis in leukocyte adhesion deficiency-1. Panoramic radiograph of a 13-year-old male with leukocyte adhesion deficiency-1. Severe (almost complete) bone loss is evident through the entire dentition.

Papillon–Lefèvre

Papillon–Lefèvre syndrome is a rare autosomal recessive genetic disorder, caused by mutations in the gene encoding lysosomal cysteine protease cathepsin C (*CTSC*). CTSC is necessary for post-translational modification and activation of serine proteases stored primarily in azurophilic granules, such as neutrophil elastase, cathepsin G (CTSG), proteinase 3 (PR3), and neutrophil serine protease 4 (NSP4). It is thought that patients have defective antimicrobial responses at mucosal surfaces due to this defect. These patients also present with severe periodontitis at an early age, but have limited infection susceptibility.

Localized Juvenile Periodontitis

Localized juvenile periodontitis (LJP) is a genetic defect impairing formylpeptide-induced chemotaxis of neutrophils (*FPR1*), which presents with specific predisposition to a severe but localized form of periodontitis in the teenage years.

Defects of Intrinsic and Innate Immunity

The innate immune system typically provides initial nonspecific immunity to pathogens, including initial recognition and responses, and is mediated primarily through phagocytes, APCs, and innate lymphocytes. *Mendelian susceptibility to mycobacterial disease* (MSMD) is related to defects in IL-12 and INFγ signaling, which is important for clearance of intracellular pathogens. Examples of genes involved are *IL12RB1*, *IL12B*, *INFGR1/2*, and *TYK2*. Susceptibly to viral infection is most often related to defects in NK cells and innate lymphocytes that protect the body from HSV, VZV, Epstein–Barr virus (EBV), and cytomegalovirus (CMV) infections and also play a role in tumor surveillance. Three subcategories in this section are related to viral susceptibility: epidermodysplasia verruciformis (HPV susceptibility), predisposition to severe viral infection (NK/T cell deficiencies, *STAT1/2*, *IFNAR2*), and herpes simplex encephalitis due to defects in signaling in resident central nervous system (CNS) innate cells.

Predisposition to fungal disease is associated with defective recognition of fungi (*CARD9* deficiency, leading to invasive fungal disease) or defective IL-17 responses (leading to mucocutaneous candidiasis).[21] Defects in microbial recognition through toll-like receptors (TLRs) and related signaling (IRAK1/4, MYD88) and TLR signaling pathway deficiencies predispose to bacterial infections.

In this category, diseases with prominent oral manifestations are as follows:

- *WHIM*, which stands for warts, hypogammaglobulinemia, recurrent infections, and myelokathexis (impaired egress of mature neutrophils from bone marrow), is caused by gain-of-function mutations in the chemokine receptor *CXCR4*. Constituent expression of CXCR4 impairs immune cell egress from the bone marrow and these patients present with pan-leukocytopenia. The signature pathogen in this disease is HPV. The dominant oral manifestation is severe periodontitis at an early age (teenage years), which is attributed to the neutropenia observed in these patients. Due to HPV susceptibility, these patients also are at increased risk for HPV-associated mucosal squamous cell carcinomas.
- *Mucocutaneus (oral) candidiasis*. Defective responses to the IL-17 cytokine have unequivocally been linked to oral fungal susceptibility.[21] Patients with mutations in the IL-17 receptor (*IL17RA, IL17RC*), the IL17 cytokine F (*IL17F*), IL-17 signaling (*TRAF3IP2*), as well as defects in the development of IL-17-secreting cells (*RORC*, *STAT3*) all present with severe, recurrent oral candidiasis. IL-17 responses have been shown to be critical for the induction of epithelial-mucosal antifungal immunity (Table 19-2, Figure 19-5).

Figure 19-5 Severe oral candidiasis in a patient with IL-17 deficiency. A 23-year-old male patient with severe oral candidiasis despite antifungal treatment. A dense white coating is present on the tongue dorsum, which can be removed with a gauze upon examination.

Autoinflammatory Disorders

In the autoinflammatory disorders, overactivation of innate inflammatory pathways occurs in a nonspecific, antigen-independent manner and most commonly will cause recurrent fevers, skin rashes, and tissue damage. In this category of disorders, recurrent inflammation occurs without evidence of other disorders (e.g., cyclic neutropenia) or infections. Genetic testing is necessary to confirm the diagnosis. Subcategories in this group include the following:

- *Type I interferonopathies*. Defective regulation of type I interferon response is associated with severe inflammatory phenotypes and autoimmunity, presenting as atypical, severe, early-onset rheumatic diseases (e.g., CANDLE syndrome, *PSMB8*[a] mutation).[22]
- *Defects affecting the inflammasome*. The inflammasome is a multiprotein intracellular complex that detects microorganisms and cell damage–related mediators and acts to activate pro-inflammatory cytokines such as IL-1β and IL-18. Hyperactivation of the inflammasome leads to classically recognized inflammasome disorders such as familial Mediterranean fever (MEFV), familial cold autoinflammatory syndrome 1 and 2 (*NLRP3* and *NLRP12*), and neonatal onset multisystem inflammatory disease (NOMID, due to *NLRP3* mutations).
- *Non-inflammatory-related conditions*, including PAPA syndrome (pyogenic sterile arthritis, pyoderma gangrenosum, acne, due to *PSTPIPI* mutations) and DIRA syndrome (deficiency of IL-1 receptor antagonist, due to *IL1RN* mutations).

A typical oral manifestation for many of the autoinflammatory syndromes is recurrent oral ulcers during periods of disease activity and inflammation (most prominent in periodic fever, aphthous stomatitis, pharyngitis, and adenitis [PFAPA] syndrome).[23]

Complement Deficiencies

The complement arm of the immune system protects the body from bacterial pathogens by opsonizing bacteria and leading to their phagocytosis and destruction. Additionally, complement proteins also play a role in clearance of apoptotic cell debris, which is necessary for the resolution of inflammation. Defective clearance of apoptotic cell debris is linked to persistent inflammation and autoimmunity. As such, patients with complement deficiencies can be predisposed both to bacterial infection and to autoimmunity. Interestingly, early classic complement component deficiencies (*C1q*, *C1r*, *C1s*, *C2*, *C4*, *C3*) present with systemic lupus erythematosus (SLE) and susceptibility to infections from encapsulated bacteria. Specific types of complement defects (*C1R*, *C1S*) are associated with severe periodontal disease. Terminal classic complement component deficiencies (*C5*, *C6*, *C7*, *C8*, *C9*) present with a unique susceptibility to recurrent *Neisseria* meningitis. Similar to terminal complement deficiency, alternative complement pathway defects due to properdin or factor D present with recurrent meningitis. Complement defects have not been clearly linked to oral phenotypes to date.

Phenocopies of Primary Immunodeficiencies

Phenocopies of PIDs include autoimmune lymphoproliferative diseases such as ALPS (mutations in *TNFRSF6*) and RAS-associated autoimmune leuko-proliferative disease (GOF mutations in *KRAS* and *NRAS*), associated with splenomegaly, lymphadenopathy, and cytopenia. Diseases in which autoantibodies target immune response mediators are also part of this category. Examples include APECED (also mentioned under diseases of immune deregulation) and thymoma (Good syndrome).

AUTOIMMUNE DISEASES

Autoimmune diseases represent a diverse family of conditions characterized by an immune-mediated response against self. Over 100 distinct autoimmune diseases have been described, showing a wide spectrum of manifestations from organ-specific autoimmunity (such as primary biliary cirrhosis) to organ-specific with systemic manifestations (such as Sjögren syndrome) to multiorgan systemic disease

(such as SLE). A common pathogenetic mechanism in all these disorders is the breakdown of immune tolerance. Following a break in tolerance, autoreactive T lymphocytes and/or autoantibodies trigger autoimmunity in one target organ or in multiple tissues. However, while a combination of genetic susceptibility and environmental triggering is thought to underlie the pathogenesis of all autoimmune disorders, triggering and pathogenesis of specific autoimmune diseases are generally incompletely understood.

Autoimmune diseases demonstrate considerable diversity regarding their clinical manifestations and molecular and pathophysiologic features. While some disorders lead to organ-specific damage, others exhibit widespread systemic autoimmunity. Similarly, while disease is mediated by autoantibodies with well-defined specific roles in some cases (such as pemphigus), others may be characterized by diverse autoantibodies with unclear roles and/or T cell–mediated immune damage.

The orofacial area, and in particular the oral mucosa and the salivary glands, is affected by multiple autoimmune diseases, either directly as a manifestation of their clinical phenotype, or indirectly due to possible comorbidities or adverse effects of the medications used for treatment. Identification of oral clinical manifestations can be key in the overall disease diagnosis and assessment. Additionally, dental or surgical management of autoimmune patients may be challenging due to the occasional immunocompromised status or their distinct clinical features. In this part of the chapter, selected autoimmune diseases and their clinicopathologic features and management are presented (Table 19-3), with an emphasis on identification of oral manifestations. However, other autoimmune disorders with oral manifestations (such as those affecting salivary glands and dermatologic diseases) are included in subsequent chapters.

Sjögren Syndrome

Sjögren syndrome is an autoimmune disorder in which immunocytes damage the salivary, lacrimal, and other exocrine glands and is thus termed an autoimmune exocrinopathy. Dry mouth and dry eyes are seen with lymphoid infiltrates in these and other exocrine glands and serum autoantibodies, as discussed in more detail in Chapter 9. Sjögren syndrome has two major clinical forms: primary Sjögren syndrome (SS-1), in which dry eyes and dry mouth are seen in the absence of a connective tissue disease, and secondary Sjögren syndrome (SS-2), which is more common, in which eyes and dry mouth are seen together with other autoimmune diseases, usually of connective tissue—most usually rheumatoid arthritis (RA), SLE, polymyositis, scleroderma, or mixed connective tissue disease. However, Sjögren syndrome shows a wide spectrum of clinical manifestations and new diagnostic criteria tend not to distinguish between the two clinical forms.

Systemic Lupus Erythematosus

SLE is considered a prototypic autoimmune disease characterized by a wide spectrum of clinical manifestations and an often unpredictable relapsing–remitting course. Patients can present with variable clinical features ranging from mild joint and skin disease to multiorgan life-threatening renal, hematologic, and CNS involvement. The etiology and pathogenesis of SLE remain largely unknown; however, it is recognized that genetic predisposition combined with environmental and possibly hormonal factors ultimately predisposes to disease. Immune dysregulation is thought to result from the breakdown in tolerance to self-antigens, leading to excessive inflammation, autoantibody production, and destruction of end organs. In fact, immunologic anomalies, particularly production of antinuclear antibodies (ANA) such as those against double-stranded (ds) DNA, are a hallmark of lupus. Diagnosis and management of lupus are particularly complex. Oral manifestations are a prominent feature that can aid in the diagnosis and should be taken into consideration during management of SLE. This section will review basic information on SLE pathogenesis, clinical manifestations, and diagnostics, with a focus on the oral features of the disease.

Epidemiology

SLE has an incidence of 23.2/100,000 person-years and a prevalence of 241/100,000 people in North America, based on a recent systematic review of epidemiologic studies. There is unequal distribution between sexes (females are affected 1.2–15 times more than males) and among different ethnic groups (people of African descent have the highest prevalence and Caucasians the lowest). The peak ages of prevalence are 45–69 for females and 40–89 for males.[24]

Genetic Susceptibility and Pathogenesis

SLE is considered a chronic inflammatory autoimmune disorder that is characterized by insufficient immune tolerance to nuclear antigens and pathologic production of nonspecific autoantibodies, eventually resulting in tissue damage. Even though its etiology remains unclear, complex pathogenetic mechanisms involving various distinct components of the immune system have been implicated. The role of genetic susceptibility in SLE is evident from the high heritability (43.9%) and the relative risk (5.87%) in first-degree relatives of patients with SLE. Although the disease can develop from a single-gene deficiency, such as of complement component 1q (*C1q*), three-prime repair exonuclease 1 (*TREX1*), or deoxyribonuclease 1-like 3 (*DNASE1L3*), in most cases it results from a combination of multiple gene variant effects.

Table 19-3 Summary of salient features for select autoimmune disorders with orofacial involvement.

Disease	Target Organ(s)	Main Autoantibodies	Histopathologic Findings (in the Orofacial Area)	Other Laboratory Findings	Orofacial Manifestations
Lupus erythematosus	SLE: Multiple organs	SLE: ANA (>95%) anti-ds-DNA (43–92%) anti-nucleosome (59–62%) anti-Sm (15–55%) anti-Ro (36–64%) anti-La (8–33%) anti-U1-RNP (23–49%) anti-phospholipids (30–40%)	Subepithelial and perivascular lymphocytic infiltrate with degeneration of the basal cell layer Direct immunofluorescence shows IgG, IgM, and complement deposition in the basement membrane SLE: Positive lupus band test	SLE: Anemia, leukopenia, thrombocytopenia, elevated ESR, hypocomplementemia	Ulcerative, atrophic/erythematous and/or white striated/radiating lesions of the oral mucosa (discoid lesions) Lupus cheilitis (rare malignant transformation) Butterfly rash or other erythematous lesions affecting the facial skin
Systemic sclerosis	Multiple organs, including skin	ANA (up to 96%) anti-Scl70 (up to 41%) ACA (up to 37%) anti-RNA polymerase III (up to 19%) anti-Th/To (up to 3%) anti-Pm/Scl (up to 13%)	Extensive dense collagen deposition in connective tissue	Various hematologic abnormalities (e.g., elevated ESR, hypergammaglobulinemia)	Mask-like face, reduced mouth opening (microstomia), telangiectasias, temporomandibular disorders, resorption of posterior mandible, diffuse widening of periodontal membrane, other comorbidities (periodontal disease, xerostomia)
Rheumatoid arthritis	Joints	Anti-CCPs (ACPAs) (up to 70%) RF (up to 70%) ANA (up to 60%)	Hyperplasia of the synovial cell lining Dense subacute inflammation of the synovial membrane Rheumatoid granulomas in skin lesions	Elevated ESR and CRP	TMD, TMJ radiographic abnormalities, periodontal disease, xerostomia (in cases of secondary Sjögren syndrome)
Dermatomyositis	Skeletal muscles and skin	ANA (up to 80%) Anti-MI2 anti-NXP2 anti-TIF1 anti-Jo1	Perifascicular atrophy Interface mucositis/dermatitis in mucocutaneous lesions	Elevated creatine kinase, aldolase, alanine aminotransferase, aspartate aminotransferase, lactate dehydrogenase	Dental and periodontal disease, TMD, telangiectasias, lichenoid lesions
Mixed connective tissue disease	Multiple organs	ANA (up to 100%) anti-U1 RNP (up to 100%) RF (up to 50%)	Overlapping with other connective tissue diseases	Anemia, leukopenia, thrombocytopenia	Trigeminal neuropathy and other overlapping manifestations
Granulomatosis with polyangiitis	Multiple organs (mainly upper and lower aerodigestive tract and kidneys)	ANCA including: PR3-ANCA (c-ANCA) (up to 95%) MPO-ANCA (p-ANCA)	Small-vessel necrotizing vasculitis with granulomatous features	Anemia, leukocytosis, eosinophilia, elevated ESR and CRP	Oral ulcerations, gingival involvement ("strawberry gingivitis"), destructive lesions (palatal perforation), salivary gland enlargement

ACA, anticentromere antibody; ACPA, antibodies to citrullinated proteins; ANA, antinuclear antibody; ANCA, antineutrophil cytoplasmic antibodies; CCP, cyclic citrullinated peptides; CRP, C-reactive protein; ds, double stranded; ESR, erythrocyte sedimentation rate; Ig, immunoglobulin; RF, regulatory factor; SLE, systemic lupus erythematosus; Sm, Smith antigen; MPO, myeloperoxidase; PR3, proteinase 3; RNP, ribonucleoprotein; TMD, temporomandibular disorders; TMJ, temporomandibular joint.

Gene loci associated with common non-Mendelian SLE susceptibility have been described, mostly for intronic regulatory regions of genes involved in *immune pathways*. Examples of specific immune pathways involved in the genetics are (1) genetic loci associated with antigen presentation, such as the human leukocyte antigen (*HLA*) locus, which have shown a strong association with SLE development; (2) gene loci associated with mechanisms of apoptosis and clearance of apoptotic cell debris (such as *TREX1*, *DNASE1*, autophagy-related 5 (*ATG5*), and *RAD51B*), where it is thought that defects in apoptosis or clearance of cellular debris are related to release of self-proteins and nucleic acids, which are a common source of autoantigens in SLE; (3) gene loci involved in nucleic acid sensing and type I interferon (IFN) production, such as interferon-regulatory factor 5 (IRF5), IRF7, toll-like receptor 7 (TLR7), TLR8, and TLR9; and (4) other SLE-associated loci code for proteins involved in T- and B-cell function, such as ELF1, BANK1, BLK, and CD3Z.

These genetic loci reveal pathways deregulated in lupus. Excessive inflammation, deregulated IFN-I production, defective clearance of apoptotic debris, and T-cell/B-cell activation and autoantibody production with immune complex deposition are hallmarks of lupus. In fact, *immune complex deposition* underlies tissue destruction in lupus. Specific autoantibodies found to contribute to disease-related injury include anti–blood cell antibodies causing cytopenia, anti-dsDNA antibodies causing nephritis, and anti-phospholipid antibodies causing, through various pathologic mechanisms, fetal resorption.

Environmental factors triggering disease in susceptible individuals are poorly understood, yet viral and other microbiome triggering has been extensively hypothesized. Additionally, hormonal deregulations and other environmental triggers, such as ultraviolet radiation, tobacco consumption, and physiologic factors, have been investigated.

Clinical Features

SLE may be difficult to diagnose, especially in the early stages, when nonspecific signs and symptoms (constitutional symptoms), such as fatigue, headache, arthralgias, lymph node enlargement, fever, and significant weight loss, occur, causing diagnostic dilemmas with other autoimmune connective tissue diseases as well as neoplastic processes or infections. Besides constitutional systemic manifestations, SLE may be characterized by the involvement of various specific organs. *Renal disease*, which affects approximately 40–70% of patients, is considered one of the major causes of morbidity and mortality in SLE. The term lupus nephritis, which has been used to describe kidney involvement in lupus patients, ranges from mild clinical and histopathologic manifestations to severe renal failure, which is considered a prognostic factor and a determinant of the selected treatment.

The *musculoskeletal system* is also commonly affected (in up to 93% of SLE cases). Arthritis and arthralgias are a dominant feature of SLE. Arthritis, with demonstrable inflammation, occurs in 65–70% of patients and tends to be migratory, polyarticular, and symmetric. The arthritis is moderately painful, usually does not cause erosion, and is rarely deforming.

Cardiovascular manifestations are also common in SLE and typically include vasculitis and pericardial effusions. Additionally, rare occasions of myocarditis or endocardial involvement, such as Libman–Sachs endocarditis, have been described. Atherosclerosis, valvular heart disease, and defective coagulation mechanisms (related to antiphospholipid syndrome) can cause significant morbidity and demand specific medications.

Involvement of the *central or peripheral nervous system* in SLE also presents diverse features and may be associated with poor prognosis. Anxiety, mood disorders, psychosis, seizures, headaches, and myelin defects are examples of CNS manifestations in SLE, while various types of peripheral neuropathies have also been described.

Finally, pulmonary involvement (especially pleuritis, interstitial lung disease, pulmonary embolism), gastrointestinal disease (abdominal pain with nausea and vomiting, peritonitis, pancreatitis, enteritis, mesenteric vasculitis with intestinal infraction), genitourinary disorders (abortions associated with antiphospholipid syndrome), and ocular manifestations (retinal involvement with a "cotton-wool" appearance upon ophthalmoscopy, keratoconjunctivitis especially in patients with simultaneous Sjögren syndrome) can further describe the multisystemic phenotype of SLE.

Mucocutaneous Manifestations

Most lupus patients will develop cutaneous and mucosal lesions during their disease. There is tremendous variability in the type of skin involvement in SLE. The most common lesion is a facial eruption that characterizes acute cutaneous lupus erythema (also known as the "butterfly rash"), presenting as erythema in a malar distribution over the cheeks and nose (but sparing the nasolabial folds) that appears after sun exposure. Some patients may develop discoid lesions, which are more inflammatory, and tend to scar. Photosensitivity is also a common theme for skin lesions associated with SLE (Figure 19-6).

Oral Manifestations

The oral cavity is commonly affected during both systemic and cutaneous involvement in SLE. A wide spectrum of clinical manifestations may be observed that depend on the type of lupus and possible comorbidities.

Figure 19-6 Extraoral cutaneous lesions in systemic lupus erythematosus (SLE). (A) Diffuse discoid lesions on the skin of a patient with SLE with development of squamous cell carcinomas on the vermillion border of the lower lip. Right lower lip presents with exophytic mass and ulcerations. (B–C) Discoid lesions on the facial skin of another patient with SLE.

Figure 19-7 Intraoral lesions in systemic lupus erythematosus. (A) Nondescript widespread white coating on dorsal surface of tongue, with erythematous regions. (B) Central erythematous area surrounded by radiating white striations, mimicking lichen planus on buccal mucosa. (C) Nondescript white and red lesions on hard palate.

Typically, oral lesions in SLE occur in approximately 5–40% of patients, include nonspecific ulcerations and erythematous or discoid lesions, and predominantly affect the palatal mucosa, buccal mucosa, and gingiva (Figure 19-7). Due to their significant prevalence, oral ulcerations are included among the classification criteria of SLE. However, there are various disorders in the oral cavity manifesting as oral ulcerative lesions, hence this criterion should be supported by histopathologic examination and direct immunofluorescence. The vermillion border of the lower lip can be characteristically involved (lupus cheilitis). The temporomandibular joint (TMJ) can also be affected, with significant differences in reported symptoms and objective findings of SLE patients related to healthy controls. Finally, in addition to direct lupus-related lesions, some indirect manifestations of SLE may arise in the oral cavity and are discussed later in this chapter (See "General Considerations for Dental Management of Patients with Immune-Mediated Diseases").

The oral manifestations of the cutaneous forms of lupus erythematosus (CLE) closely mimic those of oral lichen planus, with characteristic central erythematous (erosive or atrophic) areas surrounded by white radiating striations (Figure 19-7), and may also be encountered in SLE patients (see Chapter 4). Even though this radiating pattern as well their asymmetric distribution are characteristic features that differentiate discoid lesions from lichen planus, diagnosis cannot be based solely on clinical features and necessitates clinicopathologic correlation. The most common sites of involvement are the lips (vermillion border and labial mucosa) and the buccal mucosa. Interestingly, a correlation between specific oral lesions (such as discoid plaques, cobblestone, or macules) and disease activity in CLE was recently reported; a similar association was seen between gingivitis in CLE, as well as gingival telangiectasias in SLE, and systemic inflammation. On rare occasions, squamous cell carcinoma may arise in discoid lesions affecting the lips[25] or even intraoral sites (Figure 19-6A), for which it is considered an oral, potentially malignant disorder based on the World Health Organization (WHO) classification.

Laboratory Findings

Pathologic values in complete blood count (CBC) are common and can be the initial sign leading to subsequent

diagnosis of SLE. Main manifestations include anemia (mainly related to chronic disease, iron deficiency, or hemolysis), leukopenia (lymphopenia and/or neutropenia), and thrombocytopenia (autoimmune or related to hypersplenism or hemolysis) and their extent correlates with disease activity. Erythrocyte sedimentation rate (ESR) is usually elevated along with normal C-reactive protein (CRP), which is a characteristic feature of SLE.

Regarding the serologic features of SLE, several autoantibodies have been studied as biomarkers for diagnosis of the disease. Certain markers are extremely sensitive but lack specificity; in particular, ANAs are positive in more than 95% of SLE patients and, despite their lack of specificity (being detected in several other autoimmune diseases and in healthy subjects), can be used as a reliable screening test. Other markers, despite being disease specific, are only detected in a subset of patients; for example, anti-double-stranded DNA (anti-dsDNA) and anti-Smith antigen (anti-Sm) antibodies are positive in approximately 50–70% and 30–40% of SLE patients, respectively. Additionally, their expression is correlated with specific clinical features and prognostic factors (e.g., antiphospholipid antibodies are associated with thrombocytopenia, thrombosis, atherosclerosis, and abortions, while antiphospholipid syndrome and anti-Sm are associated with higher mortality and morbidity). Another serologic finding is the decrease in complement markers (hypocomplementemia), especially CH50, C3, and C4.

Histopathologic Features of Mucocutaneous Lesions

Histopathology plays a crucial role in the diagnosis of SLE. Besides renal biopsy, which is included among the diagnostic criteria of SLE, mucocutaneous involvement should also be investigated in the majority of cases with histopathologic examination and immunofluorescence studies. Cutaneous and oral mucosal lesions, even though showing some minor differences, have been described as exhibiting similar features. A superficial (subepithelial or in proximity with the dermo-epidermal junction) lymphocytic infiltrate, associated with vacuolar degeneration of the basal cells of the epithelium (or epidermis) and thickening of the basement membrane, is usually observed. These features may cause diagnostic confusion with lichen planus; however, in lupus erythematosus the lymphocytic infiltrate may also display a deep perivascular location, edema in the connective tissue is more commonly present, while civatte bodies are rarely observed. Cutaneous lesions may present the characteristic follicular plugging, while, depending on the type of lesion, lupus erythematosus may exhibit an ulcerated, atrophic, or hyperplastic surface. Finally, rare types of CLE may present histopathologic findings that may cause confusion even with malignant neoplasms (lupus erythematosus panniculitis and subcutaneous panniculitis-like T-cell lymphoma).

Direct immunofluorescence may also offer important information leading to diagnosis in lupus patients with mucocutaneous involvement. Subepithelial (or dermo-epidermal) immunoglobulin and complement deposition (IgG, IgM, and C3) at the basement membrane zone can be found in most lupus erythematosus lesions. Occasionally, these findings may be observed even in clinically normal skin, especially in SLE patients, known as a positive lupus band test.

Diagnosis/Disease Classification

The wide spectrum of clinical manifestations, as well as laboratory findings, is suggestive of the diagnosis of lupus erythematosus. To date several criteria have been proposed that classify SLE and facilitate diagnosis, including clinical signs and symptoms from multiple organs as well as immunologic findings. The most recent classification criteria for SLE have been initiated by the European League Against Rheumatism and the American College of Rheumatology (Table 19-4).[26]

Management

Treating SLE is challenging and depends on the extent of manifestations, the type of target organ(s), and the severity of disease as well as possible morbidities. As a result, medications used to treat lupus may range from topical therapy for exclusive cutaneous lesions or nonsteroidal anti-inflammatory drugs for mild musculoskeletal involvement to systemic immunosuppressive therapy.[25] In addition, possible side effects of the selected medications should be prevented accordingly.

Corticosteroids remain the main choice during management of SLE, due to their effectiveness in limiting disease and flares. However, because of common complications after their long-term use (such as diabetes, infections, osteoporosis, hypertension, and avascular necrosis of bone), other immunosuppressants have been proposed. Alternative options include cyclophosphamide, mycophenolate mofetil, and azathioprine, which should also be used with caution due to their toxic effects. Less commonly used immunosuppressive drugs for SLE include tacrolimus, cyclosporine, and methotrexate. Hydroxychloroquine, an antimalarial used in a variety of autoimmune diseases, has demonstrated effectiveness in managing cutaneous lesions as well as constitutional manifestations. Finally, biologic agents affecting the B-cell component of the immune system, including belimumab, rituximab, ofatumumab, and atacicept, are recently used drugs that present efficacy in limiting disease activity. In addition to directly managing the manifestations of lupus, comorbidities should be prevented appropriately. To date there are no clear guidelines regarding management of oral complications of lupus erythematosus and treatment options presented in the literature are similar to the therapeutic protocol of cutaneous involvement. Topical or intralesional administration of corticosteroids seems to be the first treatment option.

Table 19-4 Classification criteria for Systemic Lupus Erythematosus (SLE).

Entry criterion	
Antinuclear antibodies (ANA) at a titer of ≥1:80 on HEp-2 cells or an equivalent positive test (ever)	
If absent, do not classify as SLE	
If present, apply additive criteria	
↓	
Additive criteria	
Do not count a criterion if there is a more likely explanation than SLE	
Occurrence of a criterion on at least one occasion is sufficient	
SLE classification requires at least one clinical criterion and ≥10 points	
Criteria need not occur simultaneously	
Within each domain, only the highest-weighted criterion is counted toward the total score.§	
Clinical domains and criteria Weight	**Immunology domains and criteria Weight**
Constitutional	***Antiphospholipid antibodies***
Fever 2	Anti-cardiolipin antibodies OR Anti-β2GP1 antibodies OR Lupus anticoagulant 2
Hematologic	***Complement proteins***
Leukopenia 3 Thrombocytopenia 4 Autoimmune hemolysis 4	Low C3 OR low C4 3 Low C3 AND low C4 4
Neuropsychiatric	***SLE-specific antibodies***
Delirium 2 Psychosis 3 Seizure 5	Anti-dsDNA antibody* OR Anti-Smith antibody 6
Mucocutaneous	
Nonscarring alopecia 2 Oral ulcers 2 Subacute cutaneous OR discoid lupus 4 Acute cutaneous lupus 6	
Serosal	
Pleural or pericardial effusion 5 Acute pericarditis 6	
Musculoskeletal	
Joint involvement 6	
Renal	
Proteinuria >0.5 g/24 h 4 Renal biopsy class II OR V lupus nephritis 8 Renal biopsy class III OR IV lupus nephritis 10	
Total score:

§Additional criteria items within the same domain will not be counted.

Systemic Sclerosis (Scleroderma)

The word "scleroderma," originating from the Greek *scleros* and *derma* meaning hard skin, is considered an umbrella term characterizing a diverse group of disorders that exhibit excessive cutaneous fibrosis. Major disease subsets (also considered by many separate disease entities) include localized scleroderma (LSc), which is limited to skin involvement, and systemic sclerosis (SSc), a heterogenous disease, which affects a wide range of organs in addition to the skin, leading to significant morbidity.[28]

SSc presents with diverse manifestations and is subclassified into multiple subsets of disease. *Limited cutaneous SSc* refers to skin lesions in distal areas. In contrast, *diffuse cutaneous SSc* involves the proximal limbs or trunk, with a short history of Raynaud's phenomenon and frequent renal or cardiac involvement as well as lung fibrosis. *Sine scleroderma* is an entity that exhibits clinical and serologic evidence of SSc without skin sclerosis. *SSc overlap syndrome* refers to one of the aforementioned subsets in addition to manifestations from other autoimmune diseases.

Epidemiology

Both LSc and SSc are considered rare entities. More specifically, SSc exhibits a measured incidence that ranges between 4 and 43/million person-years, which is similar to that of LSc (3–30 cases/million person-years). In both entities, women are more commonly involved than men and a racial predisposition for Caucasian populations has been reported.

Pathogenesis

The pathogenesis of SSc is incompletely understood. Immune activation, vascular damage, and excessive synthesis of extracellular matrix are all well-appreciated features of the condition. Most hypotheses of the pathogenesis of SSc focus on the interplay between early immunologic events and vascular changes, which result in the generation of a population of activated fibroblasts generally considered to be the effector cell in the disease. There is no doubt that vascular and immunologic processes are central to the pathogenesis of scleroderma, although it is unclear what the initial events are and how different processes respectively trigger, amplify, and facilitate the development of the skin- and organ-based fibrosis with vasculopathy that is the hallmark of the disease.[28] The heterogeneity in the clinical features of patients with SSc is most likely a reflection of the variable contributions from each of these pathogenic factors. Incomplete understanding of the pathogenesis of the disease has rendered management very challenging, with the majority of trials of immunosuppressive agents showing limited promise.

Clinical Features

Cutaneous Manifestations

Skin thickening is the hallmark of cutaneous involvement in SSc. Skin involvement may be of acute onset in diffuse SSc or more slowly growing in limited SSc. The extremities and especially the fingers may be affected, causing a "puffy" appearance; progressively, the thin overlying skin becomes prone to ulceration and,in advanced stages, deformities may occur ("sclerodactyly") (Figure 19-8A). On rare occasions, calcifications of the skin may occur with the clinical presentation of multiple subcutaneous nodules. Additionally, hypo- or hyperpigmented areas as well as telangiectasias may be observed.

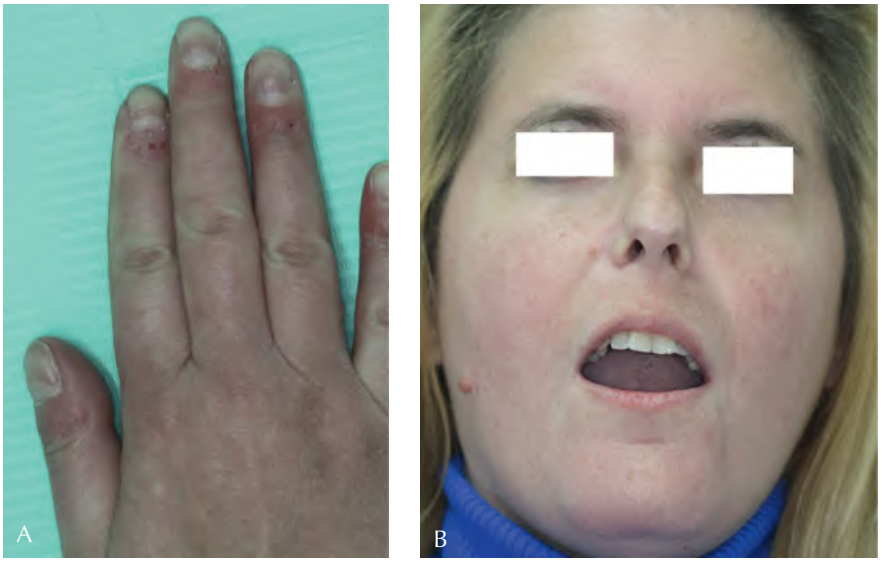

Figure 19-8 Extraoral manifestations in systemic sclerosis (SSc). (A) Finger involvement in SSc with thin, tense skin prone to ulceration. (B) Mask-like appearance of the face in a patient with SSc.

Skin lesions of SSc may occasionally be confused with those of LSc, especially of generalized morphea. In contrast, other subsets present distinct features, including dermal induration with a linear pattern involving the limbs or face (linear scleroderma) or circumscribed cutaneous plaques (circumscribed or plaque morphea), while even rarer manifestations may be present.

Other Manifestations

SSc is characterized by multiorgan involvement manifesting with various signs and symptoms and occasionally significant morbidities. Raynaud's phenomenon is the most common initial sign, developing simultaneously or prior to cutaneous involvement. Musculoskeletal involvement takes the form of generalized arthralgias and morning stiffness resembling RA. Myopathy is also common and is accompanied by elevated serum muscle enzymes. The upper or lower gastrointestinal tract may be affected with dysfunction in motility or gastroesophageal reflux, while, during late stages, fibrosis of the gastrointestinal tract may result in malabsorption. Pulmonary complications including interstitial lung disease and pulmonary hypertension are also common and associated with morbidity and mortality. Inflammatory processes may involve the heart, causing arrhythmias, hypertension, pericardial effusions, conduction defects, or "patchy fibrosis" of the myocardium. Finally, renal involvement is common and, before the initiation of angiotensin-converting enzyme inhibitors, was the most common cause of death in SSc patients. Renal crisis is most commonly encountered in patients with early onset of diffuse scleroderma, exhibits an acute course, and is associated with diverse manifestations, including malignant arterial hypertension, hyperreninemia, and progressive renal failure.

Oral Manifestations

The orofacial area may be involved in a similar pattern to other anatomic areas of SSc patients.[29] The lips become rigid, which, in addition to the generalized skin sclerosis, results in a mask-like appearance of the face (Figure 19-8B). Mouth opening is significantly decreased (microstomia) and the tongue becomes hard, leading to difficulties in speech and swallowing. Telangiectasias are also frequently present. If a biopsy of the affected mucosa is performed, diffuse deposition of dense collagen is seen in the connective tissue.

Temporomandibular disorders are also commonly encountered.[29] Mandibular movement may be limited secondary to muscular fibrosis. Additionally, myofascial pain, especially involving the masseter and posterior belly of the digastric muscle, feeling of locked jaw, and arthralgia are common symptoms in SSc patients.

The jaw bones exhibit clinical and radiographic findings in SSc patients. Mandibular resorption, either at the angle of the mandible, condyles, coronoid processes, or digastric region, is a result of masticatory muscle involvement (Figure 19-9). Additional radiographic signs include widespread widening of the periodontal membrane, especially around the posterior teeth (Figure 19-9), or soft tissue calcifications mimicking intraosseous lesions.

Other morbidities manifesting in the oral cavity of SSc patients include periodontal disease, xerostomia, and susceptibility to local infections. The high prevalence of periodontitis has been speculated to be related either to vasculopathy or to reduced mouth opening, along with limited manual dexterity that compromises dental hygiene in these patients. Xerostomia, related to fibrosis of the salivary glands, secondary Sjögren syndrome, or medications, may predispose to dental and periodontal disease as well as candidiasis.

Figure 19-9 Radiographic findings in scleroderma. (A) Widening of periodontal ligament space on periapical radiograph. (B) Marked resorption of the angle, ramus, and coronoid process of the mandible, bilaterally. Courtesy of Professor Tsiklakis.

Laboratory Findings

The following routine laboratory tests are recommended in patients with suspected SSc:

- CBC and differential, which may reveal anemia due to malabsorption of iron or gastrointestinal blood loss.
- Serum creatinine level, which may indicate renal dysfunction.
- Creatine kinase (CK), which may be elevated in patients with myopathy or myositis.
- Urinalysis.

The following serologic tests may support the diagnosis if positive:

- Antinuclear antibody (ANA).
- Anti-topoisomerase I (anti-Scl-70) antibody.
- Anticentromere antibody (ACA).
- Anti-RNA polymerase III antibody.

Diagnosis

The most recent classification criteria for SSc were published in 2013 by the American College of Rheumatology in association with the European League Against Rheumatism. These criteria help clinicians classify patients as having SSc. Diagnosis is made upon exclusion of similar entities that could justify the clinical manifestations, including generalized morphea. Skin sclerosis of the fingers of both hands extending proximal to the metacarpophalangeal joints is by itself sufficient for classification as SSc, while other clinical or serologic features are helpful classification criteria.

Management

Treatment of SSc aims at limiting the inflammatory process that characterizes its clinical phenotype as well as managing the distinct clinical manifestations involving separate organs. The selected treatment is also based on the stage of disease and possible morbidities. Based on the most recent recommendations, immunosuppressants including methotrexate have been used for SSc treatment, especially for diffuse skin manifestations or lung disease. Additionally, hematopoietic stem-cell transplantation may be the treatment of choice in selected patients with progressive disease.

Even though oral complications of SSc may respond to systemic therapy, especially with early intervention, management of specific manifestations may be essential. Patients with limited mouth opening should undergo several stretching exercises that have been reported to be effective. Additionally, morbidities associated with disease (such as periodontitis or dry mouth and its sequelae) or adverse effects of treatment should be managed appropriately.

SSc exhibits a variable prognosis that depends on the extent and severity of organ involvement. Additionally, demographic parameters may be associated with a poorer prognosis (black race or male sex). Early treatment is considered essential to reduce mortality, since the progression of disease during the first three years is fast.

Rheumatoid Arthritis

RA is a chronic inflammatory autoimmune disease that is characterized by symmetric involvement of joints in a progressively destructive manner, which can cause significant disability if not properly treated. Besides musculoskeletal disease, other extraskeletal manifestations, as well as constitutional symptoms, may be observed.

Epidemiology

RA is considered among the most common autoimmune diseases, presenting a reported incidence of 0.5–1%. Even though not as evident as in SLE, slight differences between ethnic groups (Native Americans are more commonly involved) or topographic areas (northern hemisphere and urban areas present a higher incidence) may be observed. RA involves patients in their middle age with a female predominance (2:1 to 3:1).

Pathogenesis (Genetics and Environment)

The cause of RA remains unknown. As with other autoimmune diseases, a combination of host genetic and environmental factors is thought to underlie disease triggering. In RA immune cell infiltration of the synovial membranes of joints with T cells, B cells, monocytes, and neutrophils leads to inflammation of synovial membranes, "pannus" formation, and subsequent bone and cartilage erosion. Inflammatory mediators such as tumor necrosis factor (TNF) and IL-6 as well as Janus kinase (JAK)-STAT cytokine-mediated immune responses are clearly involved in disease activity, as blockade of relevant pathways has been effective for therapeutic intervention. One interesting aspect of the disease is that autoantibodies often develop 1–10 years prior to disease onset. Specifically, antibodies to citrullinated proteins (ACPA) develop 5–10 years before disease onset.

A genetic predisposition has clearly been defined in RA. Most significantly associated with RA are HLA class II antigens, such as *HLA-DRB1*01* and *HLA-DRB1*04*, containing a "shared" epitope—a stretch of five amino acids in the region responsible for antigen presentation to T lymphocytes. Also associated with RA are genetic loci relevant to T-cell function (*CTLA4*, *PTP22*), cytokine signaling (*TNF*, *IL2RA*, *IL2RB*), and B-cell activation (*CD4*), suggesting a role of these pathways in disease. In addition to genetic susceptibility, epigenetic modifications may be observed including modified DNA methylations, histone acetylation, as well as microRNA differential expression. Finally,

environmental triggers including smoking, alcohol consumption, socioeconomic level, and infectious agents, such as periodontal pathogens, have been associated with the development of RA.

Clinical Presentation

The most common and significant manifestation of RA is the development of symmetric polyarthritis with a migratory character and gradual increase of disease. The inflammatory process primarily involves the wrists and metacarpophalangeal, metatarsophalangeal, and proximal interphalangeal articulations. Accompanying morning stiffness lasting from 30 minutes to several hours is also common. The fingers are affected in a fusiform pattern, mainly around the joints, in contrast to psoriatic arthritis where the whole digit is swollen ("sausage digit").

If RA is insufficiently treated, extraskeletal manifestations may develop. The occurrence of firm masses called rheumatoid nodules, especially in subcutaneous areas in proximity to bony prominences, is the most frequent finding. Severe complications may also develop, such as necrotizing vasculitis of the small and medium-sized arteries, interstitial lung disease, or cardiovascular disease, with the latter being the most common cause of mortality among RA patients.[32]

Intra- and Extraoral Manifestations

The TMJ is involved in almost every patient with RA according to the Helkimo index. Various clinical signs or symptoms of TMJ involvement, such as pain (frequently elicited by pressure on the joint), crepitation, reduced mouth opening, and impaired movement, have been described in RA patients. In advanced stages, progressive condylar destruction may cause malocclusion and anterior open bite, joint ankylosis, and facial asymmetry. Additionally, radiographic signs may be observed (on routine TMJ radiographs, CT or cone-beam CT (CBCT) scans, and other imaging modalities), including modifications in cortical integrity, erosions, diminished joint spaces, condylar asymmetry, flat condyles, and subcortical cysts (Figure 19-10).

Besides affecting the TMJ, RA may show several other manifestations in the orofacial area.[31] Cases of simultaneous (secondary) Sjögren syndrome are associated with hyposalivation, causing the subjective symptom of xerostomia and susceptibility to local infections (primary dental caries and candidiasis). The relationship of RA with dental and periodontal disease has been widely studied. Increased prevalence and severity of periodontal disease have been documented in RA patients, even in those newly diagnosed. Susceptibility to periodontal disease has been associated with various factors, including common disease mechanisms underlying both periodontitis and arthritis and impaired ability of RA patients to perform hygiene. Additionally, periodontitis has been hypothesized as a disease trigger for RA development. Finally, oral side effects of systemic medications used to treat RA have been reported.

Diagnosis

Diagnosis is primarily made by evaluation of the clinical and immunologic findings. Although to date there are no diagnostic criteria for RA, diagnosis may be facilitated by the classification criteria proposed by the American College of Rheumatology and European League Against Rheumatism (Table 19-5). If a patient presents with clinical features of synovitis, in the absence of an alternative diagnosis that can better explain the synovitis, four different parameters are assessed and, if the total score is greater than or equal to 6, definite classification as RA is accomplished.

Laboratory Findings

Typically, the main laboratory findings in patients with RA include acute-phase reactants and autoantibodies. CRP and ESR are the most significant markers used to detect inflammatory responses, with the former being more specific in measuring disease activity due to its association with inflammatory cytokines expressed in RA. The main autoantibodies used for diagnosis of RA are cyclic citrullinated peptides (anti-CCP) and rheumatoid factor. Both are specific markers, even though they are occasionally expressed in other diseases. Additionally, antibodies that may be detected in other autoimmune diseases, including ANA and anti-dsDNA, may also be positive in RA, despite the fact that biologic therapies may cause a reactive expression of these markers.

Management

A critical element in RA treatment is early diagnosis and treatment by a specialist. Due to significant progress in understanding of the disease, irreversible joint damage can be prevented today in 90% of patients. Initial-phase treatment for RA typically involves methotrexate (used as monotherapy or in combination with corticosteroids), which is considered an efficient treatment for RA and is associated with few and easily controllable adverse effects.[32] Symptomatology may also be improved by other drugs including nonsteroidal anti-inflammatory drugs (NSAIDs), which however do not inhibit disease development and should be used as supplementary therapy before a definite diagnosis of RA is established. Subsequent treatment typically involves disease-modifying antirheumatic drugs (DMARDs), such as TNF inhibitors, IL-6 inhibitors, and small-molecule inhibitors of JAKs involved in cytokine signaling.[30]

Figure 19-10 Temporomandibular joint (TMJ) imaging abnormalities in rheumatoid arthritis (RA). Cone-beam computed tomography of the TMJ of a patient with RA reveals (A) a flat condyle on the right side and (B) erosions of the condyle and diminished joint space on the left side. Courtesy of Professor Tsiklakis.

Oral manifestations of RA should also be treated accordingly. Even though oral manifestations may respond to the aforementioned systemic treatments, management of specific disorders is essential. When the TMJ is affected, treatment ranges from conservative (NSAIDs, physiotherapy, occlusal splints, as well as local injections of corticosteroids or anesthetics) to surgical reconstructive therapy in cases with significant defects. Finally, possible comorbidities (Sjögren syndrome, periodontal disease, or oral complications of systemic therapy) should be managed appropriately.

Mixed Connective Tissue Disease

Mixed connective tissue disease (MCTD), an entity that highlights the overlapping character between autoimmune inflammatory disorders, was first described almost five decades ago. More specifically, this term is used for cases presenting clinical manifestations in the spectrum of SLE, Sjögren syndrome, as well as inflammatory myopathies (IMs). Even though extensively described, its recognition as a separate entity is still a subject of controversy, with some authors believing that it represents an initial phase of another well-characterized connective tissue disease.

Table 19-5 Classification criteria for rheumatoid arthritis.

Rheumatoid arthritis score-based algorithm: a score of categories A–D ⩾6 out of 10 is required for definite classification as rheumatoid arthritis	Score
A. Joint involvement*	
1 large joint	0
2–10 large joints**	1
1–3 small joints (with or without large joints)	2
4–10 small joints *** (with or without large joints)	3
>10 joints (at least one small joint)	5
B. Serology (at least 1 test result is needed for classification)	
Negative RF and negative ACPA	0
Low-positive RF or low-positive ACPA	2
High-positive RF or high-positive ACPA	3
C. Acute-phase reactants (at least 1 test result is needed for classification)	
Normal CRP and normal ESR	0
Abnormal CRP or abnormal ESR	1
D. Duration of symptoms	
<6 weeks	0
≥6 weeks	1

*Joint involvement refers to any swollen or tender joint on examination, which may be confirmed by imaging evidence of synovitis. Distal interphalangeal joints, first carpometacarpal joints, and first metatarsophalangeal joints are excluded from assessment. Categories of joint distribution are classified according to the location and number of involved joints, with placement into the highest category possible based on the pattern of joint involvement.
**Large joints refers to shoulders, elbows, hips, knees, and ankles.
***Small joints refers to the metacarpophalangeal joints, proximal interphalangeal joints, second to fifth metatarsophalangeal joints, thumb interphalangeal joints, and wrists.
ACPA, antibodies to citrullinated proteins; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; RF, regulatory factor.

Epidemiology

Few data can be retrieved from the literature regarding the epidemiologic features of MCTD; however, females seem to be more frequently involved compared to males and the disease could show an early onset. Overall, it is considered a rare disease with a measured prevalence ranging from 0.8 to 3.8 per 100,000 adults in Northern European populations.[33]

Pathogenesis

The cornerstone in the pathogenesis of MCTD is the presence of the anti-ribonucleoprotein (RNP) antibodies, albeit the exact biologic mechanisms are to date unspecified. A proposed hypothesis is that a genetic predisposition and especially the presence of distinct subsets of HLAs may play a key role. More specifically, several studies have linked MCTD with the presence of HLA DRB1*04, which seems to generate anti-U1-RNP expression.[33]

Clinical Features

Clinical manifestations identical to various connective tissue diseases are present, including Raynaud's phenomenon and "puffy" or swollen hands, myositis, arthritis, interstitial lung disease, pulmonary hypertension, cutaneous lesions and alopecia, esophageal dysmotility, neurologic symptoms, as well as renal disease. Insufficient data comparing adult patients and juveniles are available in the literature, although slight differences are described, such as the increased severity of lung disease in adults.

Orofacial involvements of MCTD have rarely been reported. Among them, trigeminal neuropathy is the most common manifestation. However, since this disease overlaps with other autoimmune diseases, signs or symptoms characterizing the phenotype, including xerostomia, lymphadenopathy, or lichenoid lesions, may be observed. Additionally, patients receiving high-dose immunosuppression could develop oral mucosal lesions as an adverse effect.

Laboratory Findings

Autoantibodies against the U1 small nuclear ribonucleoprotein autoantigen (U1-snRNP) are considered specific markers for an MCTD diagnosis, even if their expression has been observed in other autoimmune diseases. ANAs are also expressed in almost every case. Other hematologic findings include anemia, leukopenia, and thrombocytopenia.

Diagnosis

MCTD has a complex nature and, as already mentioned, its characterization as a distinct entity is still under debate; hence, diagnosis is typically difficult. Additionally, alterations in diagnostic criteria of other autoimmune diseases render the classification of certain patients problematic. To date, various diagnostic (and/or classification) criteria have been proposed for MCTD, which, as in every other connective tissue disease, includes immunologic (anti-U1-RNP detection) as well as clinical parameters.

Management

No randomized trials have been conducted regarding treatment protocols in MCTD. Management mainly includes immunosuppressants, especially corticosteroids, as well as steroid-sparing medications, such as methotrexate, cyclosporine, and azathioprine. Further, specific manifestations (including Raynaud's phenomenon) should be treated accordingly (e.g., with calcium-channel blockers). MCTD presents a measured mortality rate of 8–36%, with common causes of death being related to pulmonary hypertension and interstitial lung disease.

Dermatomyositis and Other Inflammatory Myopathies

IMs are a complex group of diseases falling under the term "myositis," generally characterized by inflammatory processes involving the muscles in addition to extramuscular manifestations. Myositis may involve adults or juveniles and may present heterogeneous manifestations, justifying its subclassification into various separate entities. Dermatomyositis (DM) is one of the main disease subsets characterized by skin involvement accompanying the progressive muscle weakness. DM is also the most prevalent myopathy in young patients (juvenile DM), while occasionally amyopathic forms may develop, which are considered by some authors as separate disorders (amyopathic DM).[34] IMs presenting distinct demographic, clinical, or pathologic features are inclusion body myositis and immune-mediated necrotizing myositis. As observed in other autoimmune diseases, IMs may also exhibit accompanying features shared with other connective tissue diseases, for which the term overlap myositis is used. Myositis may be associated with malignant neoplasms (cancer-related myositis), as supported by the high incidence of cancer in DM patients. However, it has not been clarified whether muscle involvement is a paraneoplastic phenomenon or myopathy precedes cancer development. Other uncommon types of myopathy have also been described, while cases of muscle involvement that do not exhibit specific features observed in other myopathies fall under the term polymyositis (PM).

Epidemiology

IMs are considered rare, with estimated prevalence rates ranging from 9 to 33 cases per 100,000 individuals; women and African Americans are more frequently affected. Inclusion body myositis is the only exception affecting males more commonly than females. Even though the prevalence and incidence of IMs as a whole may be easily counted, calculating the epidemiologic features of specific subsets of disease may be problematic due to the modifications that occasionally occur in the classification of these entities.

Pathogenesis

IMs are generally characterized by immune and nonimmune events initiated in a context of genetic predisposition as well as environmental triggers. Inflammatory cells of the immune system accumulating in lesions of IMs include T cells (mostly $CD4^+$, $CD8^+$, and $CD28^{null}$ populations), B cells secreting autoantibodies, and cells of the macrophage-dendritic lineage. Additional mechanisms that do not implicate the immune system have been proposed, including hypoxia, endoplasmic reticulum (ER) stress, and autophagy, all of which are mutually connected. However, their heterogeneous clinicopathologic manifestations may reflect different underlying pathologic mechanisms. Muscle involvement in dermatomyositis is believed to be a result of autoimmune attack against endomysial capillaries, leading to ischemia and atrophy of the muscle fibers. On the contrary, PM displays endomysial $CD8^+$ T cells that identify an endogenous peptide, resulting in myofiber necrosis via secretion of perforin-1 and granzyme B.

Genetic as well as environmental factors have also been widely accepted to be related to disease development. The role of certain class 2 HLA alleles and especially HLA DRB1*0301 has been described and may be associated with specific autoantibody expression. Additionally, exogenous parameters including infections (e.g., of the respiratory tract) or ultraviolet radiation may trigger disease.

Clinical Features

Dermatomyositis is characterized by varying amounts of proximal muscle weakness with symmetric distribution and cutaneous involvement. Muscle involvement may range from mild to severe causing serious disabilities. The most pathognomonic clinical sign in DM is the presence of a papular violaceous rash affecting the metacarpophalangeal and interphalangeal joints, also known as Gottron's papules. A highly characteristic cutaneous manifestation is the so-called heliotrope rash (discoloration of the periorbital area), while other typical lesions include the Gottron sign (erythematous lesions of the elbows, knees, knuckles, or ankles), the V sign (erythema in the face, neck, and chest area), and the shawl sign (affecting the neck and shoulders).[34] Juveniles more commonly develop febrile illness as well as calcinosis of the skin. Besides other more uncommon cutaneous signs, DM may develop extramuscular and extracutaneous manifestations, especially cardiac involvement as well as interstitial lung disease. Noteworthy is that muscle involvement is almost identical between different types of IMs and difficult to differentiate solely on the basis of clinical manifestations. Diagnosis is usually made upon correlation of the clinical phenotype with the pathologic and laboratory findings.

Few data can be retrieved from the literature regarding oral manifestations of patients with IMs.[34] An increased number of decayed, missing, or filled teeth has been attributed to poor oral hygiene. Additionally, a decrease in masticatory forces and increased incidence of temporomandibular disorders (TMDs) has been reported. Mucosal involvement is also reported in patients with PM and DM, most frequently in the form of telangiectasia. Specific gingival lesions have been described in patients with juvenile DM, described as having a "bushy loop" appearance. However, histopathologic examination was not performed in these cases to exclude other well-known entities with a similar clinical appearance. Lichenoid lesions have also been reported to affect patients with DM. Nevertheless, there is insufficient data on whether these manifestations could belong to the

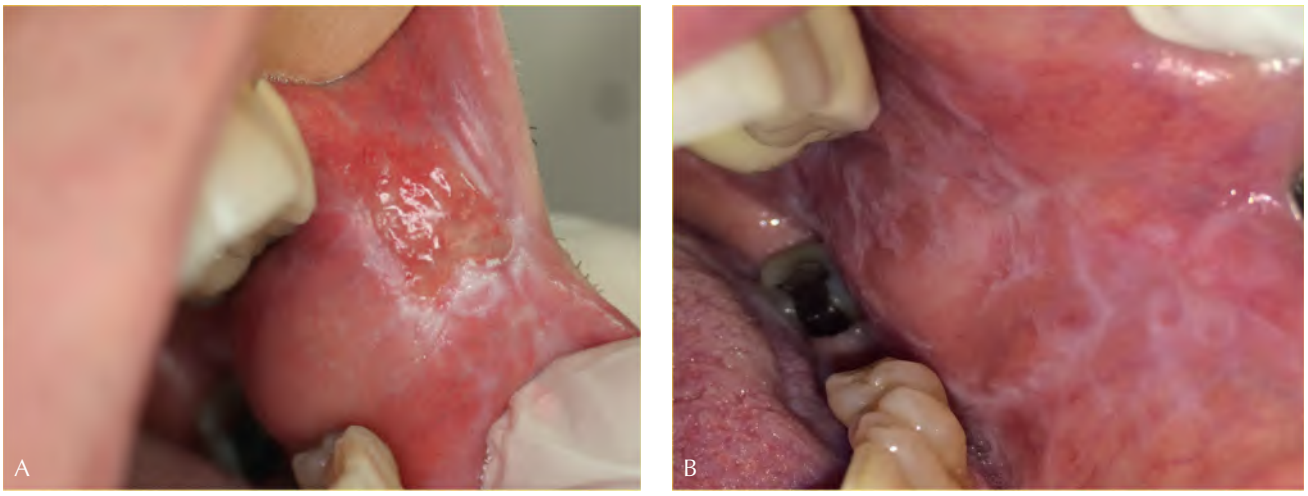

Figure 19-11 Intraoral (buccal mucosal) lesions in a patient with dermatomyositis. The appearance of lesions can change over time from (A) ulcerative to (B) striated.

spectrum of DM, represent lichen planus that coexists/interacts with DM, or are merely coincidental (Figure 19-11). As already mentioned, malignant neoplasms may be associated with DM and oral cancer cases have been reported in patients with DM, even though an exact causal relationship cannot be established. Fibrosis of the salivary glands is a common finding, while calcinosis of the soft tissues in juveniles can affect the head and neck region and be radiographically detectable.

Pathologic Features

Histopathologic examination of muscular tissue in patients with IMs may be helpful in establishing the diagnosis and categorizing patients, as different microscopic features may be observed in separate subsets of disease. Perifascicular atrophy is observed upon biopsy in addition to endomysial, perimysial, or perivascular inflammation and occasional necrotic muscle fibers.

Biopsy of cutaneous or mucosal lesions may be helpful for diagnosis in patients with DM. In acute phases, microscopic features may be similar to those in lupus erythematosus and include a hyperkeratotic and commonly atrophic epithelium/epidermis with hydropic degeneration of the basal cell area and perivascular inflammation along with interface dermatitis/mucositis. These histopathologic features may be characterized as exhibiting lichenoid features, highlighting the loss of sufficient data on whether previously reported intraoral lesions are manifestations of lichen planus or DM. Other cutaneous signs of DM may present distinct histopathologic features (e.g., Gottron papules show hyperacanthosis and papillomatosis). Direct immunofluorescence could facilitate diagnosis in equivocal cases exhibiting a granular deposition of immunoglobulins and complement in the dermo-epidermal junction.

Laboratory and Other Findings

The main laboratory feature in IMs is the presence of elevated muscle enzymes, especially CK, which also helps determine disease activity in individual patients. Electromyographic examination is a routine test that facilitates diagnosis, showing features of myopathy. Autoantibodies play an important role in the diagnostic process, as their detection is associated with discrete subsets (e.g., DM associated with anti-MI2 as well as anti-NXP2 antibodies, while anti-Jo1 antibodies are found in overlap myositis) and specific manifestations (e.g., anti-TIF1 in DM is strongly associated with cancer involvement).

Diagnosis

Diagnosis of IMs is made upon correlation of clinical, laboratory, and histopathologic manifestations. More specifically, in 2003 a classification was introduced and approved by the Myositis Study Group and the 119th European Neuromuscular Centre workshop, facilitating the classification of IMs except inclusion body myositis. Patients meeting these criteria may further be subclassified into different subsets based on their specific manifestations.

Management

Treating IMs may be a challenge due to their low prevalence rates as well as heterogeneous manifestations and subtypes, which render the establishment of specific protocols impossible for the time being. First-line treatment of these patients mainly includes corticosteroids in addition to reinforcement of physical exercise, followed by steroid-sparing immunosuppressive agents (including azathioprine and methotrexate). Intravenous immunoglobulins and biologic agents may be used in severe cases, while in patients exhibiting dysphagia invasive management or injection of botulinum toxin is

proposed. Plasmapheresis may also be performed in patients with interstitial lung disease.

Oral manifestations of DM should also be managed accordingly.[34] Dental, periodontal conditions, and TMD require appropriate treatment, while appointments should be short for patients with muscle weakness of the neck. Since mucosal involvement in DM has not been fully clarified, there are no specific guidelines regarding the management of lesions arising in these patients and biopsy and histopathologic examination should be performed. Follow-up of these patients is essential to control dental and periodontal health as well as to identify early signs of cancer.

IMs exhibit variable prognosis that depends on the onset of treatment and severity of organ involvement. Patients with cancer development, esophageal involvement, cardiovascular disease, or pulmonary dysfunction have a poor prognosis, while the main causes of death include respiratory or cardiac complications, infections, and cancer.

Granulomatosis with Polyangiitis

Granulomatosis with polyangiitis (GPA), formerly known as Wegener's granulomatosis, is an autoimmune disease classified under the broad category of ANCA-associated vasculitis (AAV) due to the pathogenetic association with antineutrophil cytoplasmic antibodies (ANCAs).[35] The hallmark of the disease is the presence of small-vessel necrotizing vasculitis with granulomatous features, resulting in multisystemic manifestations with significant morbidity and mortality. Although generally considered a distinct entity, recent reports suggest a more unifying classification of AAV due to the significant overlapping features of GPA with microscopic polyangiitis (MPA), as well as their similar pathogenetic characteristics. Other studies emphasize the genetic differences between these two entities (with GPA being more commonly associated with proteinase 3 ANCA (PR3-ANCA]) and support a classification of AAV into PR3-ANCA-associated vasculitis and myeloperoxidase (MPO) ANCA-associated vasculitis, depending on their underlying genetic abnormalities.

Epidemiology

GPA is considered a rare disease with a prevalence between 2 and 13 per 100,000 individuals and an inpatient prevalence of approximately 30 patients per 100,000 admissions. Older patients with a mean age of more than 60 years are typically affected, Caucasians are more susceptible and equal distribution between the two sexes is observed.

Pathogenesis

The exact etiology of GPA development has not yet been fully elucidated. As observed in other autoimmune diseases, environmental and genetic factors have been implicated as responsible for immune response deregulation. Exposure to external triggers, such as dust or silica, is included among the most frequent exogenous factors associated with GPA. Additionally, infectious agents, such as *Staphylococcus aureus* of the upper aerodigestive tract, have been suggested to play a role in triggering the disease. Drugs may also cause AAV-like phenomena with distinct features (i.e., resolution after discontinuation of the agent), while they may also trigger disease in already genetically predisposed GPA patients. Responsible agents for drug-induced AAV include antibiotics, antithyroid medications, and anti-TNF agents. A genetic predisposition has been highlighted by some GPA cases reported in siblings, as well as from recent findings in genome-wide association studies of AVA. More specifically, vasculitis with anti-PR3 ANCA (which most commonly exhibits phenotypic features of GPA) was associated with the gene encoding for proteinase 3, *HLA-DP*, as well as the gene encoding for α1-antitrypsin. In contrast, cases of vasculitis with antimyeloperoxidase ANCA (most commonly MPA) exhibited association with the *HLA-DQ* gene. Regarding the immune mechanisms participating in AVA pathogenesis, the role of neutrophils in facilitating loss of tolerance to the antigens recognized by ANCA has been underlined. Patients with GPA exhibit high frequency of long-lived plasma cells secreting ANCA. After interacting with ANCA, neutrophils and monocytes release cytokines, proteases, and ROS, while neutrophil extracellular trap products (NET-derived products) are secreted, resulting in activation of dendritic cells and eventually compromising Treg function.[36]

Clinical Features

A wide spectrum of manifestations has been described in GPA with varying degrees of organ involvement. While the upper aerodigestive tract is the predominant site of involvement in limited disease, generalized forms have been associated with major organ dysfunction as well as deteriorating general health. Additionally, nonspecific constitutional signs and symptoms including fever, fatigue, and weight loss are commonly encountered (in approximately half of cases) in generalized GPA. The ear, nose, and throat (ENT) region is considered the most commonly involved, especially in limited disease. Signs may include rhinorrhea with hemorrhagic crusts, deformities of the nose (scooped-out or depressed appearance), perforation of the nasal septum, sinusitis, chronic otitis media, and tracheal or subglottic stenosis. Nasal–sinus involvement is very characteristic of GPA and may be the only sign, while nasal obstruction with olfactory dysfunction is commonly the first manifestation. Other target organs are commonly affected. More specifically, the lungs are frequently involved, with alveolar hemorrhage as well as parenchymatous nodules being the most significant

pulmonary lesions in GPA. Pauci-immune necrotizing glomerulonephritis is a characteristic renal sign that is associated with microhematuria and proteinuria; noticeably, the severity of renal dysfunction is associated with prognosis in these patients. The nervous system may also be affected, usually with peripheral neuropathy (mononeuritis multiplex or sensorimotor neuropathy), while CNS involvement (pachymeningitis) is considered rare. Necrotizing nodular episcleritis is considered the most common ocular sign in GPA, while corneal ulcerations, scleritis, and retinal vasculitis may also be observed. Less common but characteristic signs of disease include the involvement of the eye socket with a granulomatous retro-orbital pseudotumor or dacryoadenitis. Cardiac manifestations may be a result of the necrotizing vascular changes characterizing the disease, with variable levels of severity. Finally, the gastrointestinal tract is commonly affected by ulcerative lesions, often resulting in perforation.

Mucocutaneous manifestations may be present and include oral manifestations. Purpura, leuco-cytoclastic vasculitis, cutaneous ulcerations, subcutaneous nodules, and pyoderma gangrenosum are common cutaneous manifestations, albeit to a variable extent. Oral mucosal involvement also exhibits heterogeneous manifestations that may vary depending on the clinical course of the disease.[37] Acute and rapidly progressing lesions are observed in widespread disease, including oral ulcerations with occasional necrotic features, while more chronic lesions with gradual deterioration and destruction of hard and soft tissues are observed in localized disease. Perforation of the palate may be observed, while involvement of the gingiva may exhibit a characteristic vegetating or granular appearance, called "strawberry gingivitis," which may occasionally be the first manifestation of the disease (Figure 19-12). The salivary glands may be involved in GPA showing enlargement, with the parotid being the most commonly affected major salivary gland, sometimes preceding involvement of other organs.

Figure 19-12 Diffuse gingival involvement in granulomatosis with polyangiitis (GPA), assuming a characteristic "strawberry gingivitis" appearance. Courtesy of Professor Kolokotronis.

Pathologic Findings

Biopsy is essential for the diagnosis of GPA. In some organs, including the kidney, the histopathologic features are considered prognostic factors. The microscopic characteristics in mucocutaneous GPA lesions include necrotizing vasculitis and granulomatous inflammation, with occasional palisading features (epithelioid histiocytes and multinucleated giant cells surrounding a central area of necrosis). Occasionally, however, nonspecific findings may be encountered, including acute or chronic inflammation, scattered multinucleated giant cells, increased vascularity, and pseudo-epitheliomatous hyperplasia, especially in biopsies retrieved from the gingiva of GPA patients. Nevertheless, even these features could suggest the diagnosis, which may be further substantiated after correlation with the clinical characteristics of the lesion as well as the possible involvement of other organs.

Laboratory Findings

Laboratory work-up is essential for GPA patients, facilitating diagnosis and occasionally determining prognosis. Anemia, leukocytosis, and eosinophilia may be observed in GPA. ESR and CRP may also be elevated, especially in active disease, while involvement of specific organs may be associated with respective laboratory findings (e.g., urine proteinuria in kidney involvement). The most important serologic marker for GPA is ANCA, although it is not necessary for diagnosis, which is primarily based on clinicopathologic correlation. Both indirect immunofluorescence, which may identify cytoplasmic c-ANCA (most common in GPA) or perinuclear p-ANCA, and enzyme immunosorbent assays (ELISA), which measure PR3-ANCA and MPO-ANCA titers, have been traditionally used with significant sensitivity and specificity. However, a recently published position paper proposes that high-quality immunoassays and not indirect immunofluorescence are sufficient to primarily screen patients with suspected AVA.

Diagnosis

Diagnosis of GPA is based on the clinical as well as histopathologic features, while ANCA serology may be indicative. Although no diagnostic criteria exist, classification criteria may simplify the diagnostic procedure. These criteria were proposed by the American College of Rheumatology in 1990 and include oral, nasal, pulmonary, and renal manifestations, in addition to histopathologic evidence of granulomatous inflammation.

Management

The major aim of treatment for patients with GPA is to achieve remission and survival by minimizing recurrences and fatal outcomes. The currently used recommendations were recently initiated by the European League Against Rheumatism in conjunction with the European Renal Association/European Dialysis and Transplant Association. They include guidelines about the first phase of treatment, consisting of immunosuppressive therapy (including cyclophosphamide and rituximab) in addition to glucocorticoids, and the second phase (remission maintenance). The initial therapeutic approach is usually individualized and depends upon the severity of disease and patient's general health. Although the aforementioned therapeutic approaches have minimized morbidity and mortality, GPA may be associated with relapses and life-threatening complications. Limited ENT involvement and granulomatous inflammation upon biopsy have been associated with recurrences, while the severity of renal involvement is a major prognostic factor. The most common causes of death are infections and kidney failure.

GENERAL CONSIDERATIONS FOR DENTAL MANAGEMENT OF PATIENTS WITH IMMUNE-MEDIATED DISEASES

Dental treatment and surgical procedures in the orofacial area in patients with immune-mediated diseases should be performed after consideration of multiple parameters and in close and continuous collaboration with the caring medical team. These disorders constitute a special category that should be managed with caution due to a variety of general and disease-specific complications that are related to the disease itself or the medications used to treat it.

Susceptibility to Infections

Dental and oral mucosal infections may pose an increased risk for systemic infection in immunocompromised patients. Most cases of oral microbiota leading to systemic infections in immunocompromised hosts are related to invasion in the presence of an existing dental infection (but not typically in the presence of oral health). In the presence of ongoing odontogenic infections, microbial translocation from the oral cavity has been considered a risk factor for distal infections, particularly during invasive dental procedures. Odontogenic infections have been associated most commonly with infectious endocarditis, but also with infections in the CNS and less commonly with distal skeletal infections. Cases of infections in the CNS have been reported in immunocompromised patients, and in a few cases the organism has been traced from the primary odontogenic infection. Septicemia from oral infections has also been reported in immunocompromised patients in multiple cases with the organism *Leptotricia buccalis*.

Patients with primary immunodeficiencies[38] may be at an increased risk for oral infections (as described in the earlier sections) as well as for dissemination of microbiota from dental infections from the mouth into the systemic circulation. To date, there are no specific guidelines for dental management and/or for use of antibiotic prophylaxis in patients with primary immunodeficiencies. Common recommendations include aggressive prevention to avoid and treat early oral and dental infections in such patients, close monitoring, and coordination of treatment with the medical team. Due to the severity of immunodeficiency in such patients, often dental treatment will be advised to be performed within the hospital setting.

Patients with autoimmune diseases are also often considered immunocompromised, either because of the disease itself or secondary to the use of immunosuppressive medications. Leukopenia is also a possible manifestation of autoimmune diseases or the medications used to treat them and is associated with susceptibility to infections; hence, procedures associated with bacteremia should be performed with caution. However, a recent study including patients with different levels of neutropenia concluded that extractions are safe and with few associated complications. Even though there are insufficient data about the use of antibiotics in these patients, perioperative treatment is generally proposed, especially in patients with moderate to severe neutropenia (<1000/μL). There is also no consensus regarding the use of antibiotics in patients under corticosteroid treatment. As a result, the main consideration is the potential modification of the dose of corticosteroids to prevent an adrenal crisis, which is discussed later in this chapter.

Besides exhibiting a higher risk of infection after dental procedures, patients with autoimmune diseases may develop specific infections with oral manifestations. Herpes zoster or HPV infection is considered common in patients with SLE and could manifest in the oral cavity. Oral candidiasis may also be frequently encountered in autoimmune disease patients as a side effect of corticosteroid or other immunosuppressive treatment or a consequence of reduced salivary flow, and should be managed accordingly.

Additionally, SLE and other autoimmune disorders lead to valvular disease, requiring prosthesis and increasing the risk for bacterial endocarditis following surgical procedures. Such patients will require antibiotic prophylaxis prior to surgical procedures, based on the most recent guidelines about patients with valvular disease from the American Heart Association and the American College of Cardiology. Prosthetic joints used to manage certain autoimmune diseases and especially RA exhibit a higher risk of infection,

even though this risk has not been associated with dental procedures. Patients with prosthetic joints do not require antibiotic prophylaxis prior to dental procedures to avoid infection of the prosthetic joints.

Risk of Bleeding

Coagulation is commonly impaired in autoimmune diseases for multiple reasons, including thrombocytopenia associated with the disease (e.g., in SLE), use of certain myelotoxic drugs, or treatment with anticoagulants or antiplatelet regimens (in patients with risk for thrombosis). Such patients may be at increased risk of bleeding subsequent to surgical interventions. Recent studies suggest that extractions in patients with thrombocytopenia are usually safe and complications are easily managed with local measures. However, patients exhibiting a platelet count under 50,000/μL require platelet transfusion, so cases with severe thrombocytopenia should be managed in a hospital environment. In patients with anticoagulant therapy, INR should be measured and if its value is between 2.0 and 3.5, minor interventions are allowed, while for more invasive procedures, replacement of the regimen with low molecular weight heparin should be considered. Insufficient data exist regarding the management of patients receiving novel direct anticoagulants. Discontinuation of antiplatelet therapy should be considered prior to intervention. Communication between the patient's dental and medical practitioners is necessary, especially for complex cases.

Adrenal Suppression

Corticosteroids are included among the most common medications used to treat autoimmune connective tissue diseases due to their significant efficacy in limiting disease activity. However, their side effects, including adrenal suppression, should be taken into consideration during dental treatment. To date, few cases of adrenal suppression following dental procedures have been reported. Adrenal suppression is considered to correlate with the dosage and duration of corticosteroid treatment.

Currently, confusing data exist in the literature regarding management of patients under corticosteroids. While some authors propose perioperative steroid cover for these patients, others support giving supplementary steroids only in cases treated under general anesthesia. As a result of the absence of specific guidelines, every case should be individualized, and treatment planned with the caring physician.

Cardiovascular Disease

As already described, several autoimmune diseases display a multisystemic clinical appearance, occasionally involving the cardiovascular system. More specifically, patients with SLE or SSc may exhibit hypertension, while SSc cases may also present with arrhythmias. Common atherosclerosis in SLE may also be associated with ischemic episodes and angina. The dental practitioner must always assess the general condition of these patients before starting any minor or invasive procedure and establish a communication with the patient's physician. Antianxiety techniques and pain control play a key role in the prevention of medical emergencies, appropriate management of which, should they happen, requires proper medical supplies and experience on behalf of the dentist.

Liver and/or Kidney Disease

Renal involvement is common in patients with autoimmune diseases (e.g., lupus nephritis), while nephrotoxicity or hepatotoxicity is included among the side effects of certain medications for connective tissue diseases. Renal and liver function should be monitored in these patients, as the doses of common medications prescribed by the dentist may be modified depending on the extent of disease and the type of drugs used. Additionally, dental procedures should be performed under appropriate conditions in patients under hemodialysis (treatment should be performed the day after dialysis).

Hyposalivation and Xerostomia

The salivary glands are a common site of involvement by several autoimmune diseases as a part of their phenotypic characteristics (e.g., fibrotic changes in SSc), a feature of secondary SS (e.g., in SLE or RA), or an adverse effect of certain medications for rheumatic diseases (e.g., drugs treating cardiovascular or musculoskeletal manifestations). Salivary gland involvement results in hyposalivation and the subjective feeling of xerostomia. Management of xerostomia and its etiologic factors is discussed in other chapters.

Dental and Periodontal Disease

Periodontal disease is more prevalent in patients with various autoimmune diseases. Appropriate periodontal treatment with frequent follow-up visits should be performed in these patients, in addition to control of the possible aggravating factors. Toothbrushes with customized handles and of special size are useful for patients displaying impaired manual dexterity (e.g., in patients with SSc or RA) or in cases of reduced mouth opening (e.g., in patients with SSc).

Oral Mucosal Involvement as an Adverse Effect of Immunosuppressive Therapy

Specific reactions to certain medications may affect the oral cavity with heterogeneous clinical manifestations.

Figure 19-13 Oral aphthous-like lesions associated with methotrexate treatment in a patient with rheumatoid arthritis: (A) tongue; (B) lip; (C) palate; (D) buccal mucosa.

Anemia, neutropenia, and thrombocytopenia induced by certain myelotoxic drugs (or by certain diseases, including SLE) may cause corresponding oral mucosal lesions in the oral cavity (such as atrophy, neutropenic ulcers, and petechiae, respectively). Systemic drug administration (e.g., methotrexate) may also cause occasional adverse mucosal reactions, which may vary from mucosal ulcers or erythema to lichenoid lesions (Figure 19-13). Other oral lesions related to medications for rheumatic diseases include pigmentation (e.g., related to hydroxychloroquine) or diffuse gingival enlargement (e.g., due to cyclosporine). The clinician should be aware and suspicious of these conditions, especially if their occurrence shows a chronological relationship with the administration of the offending drug.

ALLERGIC AND HYPERSENSITIVITY REACTIONS

The modern dentist uses a wide variety of drugs to treat patients, including antibiotics, hypnotics, and anesthetics. All practitioners who use these medications must know how to manage adverse reactions triggered by these agents.[39] A dental practitioner also uses a wide range of materials such as impression materials, adhesives, latex, and restorative and endodontic materials that contain potential allergens. These include preservatives, coloring agents, fixatives, binding agents, flavorings, and latex.

Hypersensitivity Reactions

Immunologic reactions may be of several different types: type 1 IgE-mediated (anaphylactic), type 2 antibody-mediated, type 3 (immune complex–mediated), and type 4 (cell-mediated or delayed hypersensitivity). Type 1 reactions are acute (e.g., penicillin, latex, or peanut allergy) and require immediate recognition and action. Type 2 reactions are not usually found in response to dental materials or drugs, but are found in autoimmune conditions affecting the oral cavity, such as pemphigus. Such conditions are discussed in Chapter 3, "Ulcerative, Vesicular, and Bullous Lesions." Type 3 reactions can be seen in response to dental materials, but more commonly in response to viral infections such as recurrent herpes labialis, giving rise to erythema multiforme or Stevens Johnson syndrome (clinical manifestations are discussed in Chapter 3). Delayed hypersensitivity (cell-mediated or contact sensitivity) reactions to dental materials are very common and are usually seen in the oral cavity where an amalgam or gold restoration is in direct contact with the buccal or lingual mucosa. Stomatitis associated with allergy is discussed in Chapter 3. In this section, acute allergic reactions and their management are discussed.

Acute allergic reactions are caused by an immediate-type hypersensitivity reaction mediated by IgE and are the most serious of allergies.[40] Reactions can occur rapidly, and full-scale anaphylactic reactions may occur and be associated with local as well as systemic swelling. Type 1 reactions require the presence of mast cells with attached IgE. A patient previously exposed to a drug or other antigen has antibody (primarily IgE) fixed to mast cells. When the antigen (in the form of a drug, food, or airborne substance) is reintroduced into the body, it will react with and cross-link the cell-bound antibody. This causes an increase in intracellular calcium and the release of preformed mediators including histamine, proteases, and newly synthetized lipid-derived mediators such as leukotrienes and prostaglandins. Cytokines are also released, which attract eosinophils and augment the inflammatory response. These substances cause vasodilation and increased capillary permeability, ultimately leading to fluid and leukocyte accumulation in the tissues and edema formation. Constriction of bronchial smooth muscle results when IgE is bound in the pulmonary region. The anaphylactic reaction may be localized,

producing urticaria and angioedema, or may result in a generalized reaction, causing anaphylactic shock.

Localized Anaphylaxis

A localized anaphylactic reaction involving superficial blood vessels results in urticaria (hives). Urticaria begins with pruritus (itching) in the area where histamine and other active substances are released. Wheals (welts) then appear on the skin as an area of localized edema on an erythematous base. These lesions can occur anywhere on the skin or mucous membranes. There seems to be little doubt that the oral mucosa is well endowed with mast cells and that type 1 reactions can occur in the oral cavity. Urticaria of the lips and the oral mucosa occurs most frequently after food ingestion by an allergic individual. Common food allergens include chocolate, nuts, shellfish, and tomatoes. In the oral allergy syndrome (see later), it is thought that patients become sensitized by inhalation of allergens such as birch, and then react orally to cross-reactive foods, including apples. Drugs such as penicillin and aspirin may cause urticaria, and cold, heat, or even pressure may cause the reaction in susceptible individuals. Impression compounds, coloring agents, and preservatives, as well as ingredients of mouthwashes, may all cause local swelling or even anaphylaxis.

Angioedema is characterized by rapid development of edematous swelling, particularly of the head and neck, sometimes accompanied by urticarial rashes. It occurs when blood vessels deep in the subcutaneous tissues are affected, producing a large diffuse area of subcutaneous swelling under normal overlying skin. This reaction may be caused by contact with a known allergen, but a significant number of cases are idiopathic. Many patients have short-term disfiguring facial swelling, but if the edema involves the neck and extends to the larynx, it can lead to fatal respiratory failure.

Angioedema most commonly occurs on the lips (Figure 19-14) and tongue and around the eyes. It is temporary and not serious, unless the posterior portion of the tongue or larynx compromises respiration. The patient who is in respiratory distress should be treated immediately with 0.5 mL of epinephrine (1:1000) subcutaneously, or better intramuscularly. This can be repeated every 10 minutes until recovery starts. The patient should be given oxygen, placed in a recumbent position with the lower extremities elevated unless there is a danger of shortness of breath or vomiting, given fluids intravenously, and transported to hospital immediately. Patients may need intubation to maintain the airway. When the immediate danger has passed, 50 mg diphenhydramine hydrochloride (Benadryl®, Pfizer, Parsippany, NJ, USA) should be given four times a day until the swelling diminishes.

Figure 19-14 Immediate type 1 swelling of the lips after ingestion of peanuts in a patient with peanut allergy.

Hereditary angioedema (HAE) is another life-threatening condition that is not associated with allergens. It is a genetic disease with an autosomal dominant pattern of inheritance. The underlying defect is a failure to produce adequate levels of C1 esterase inhibitor (C1 inh), which normally acts as an inhibitor of the first component of complement and kallikrein. This inhibitor controls the degree of complement activation. Activation of kinin-like substances causes a sudden increase in capillary permeability. C4 is consumed and plasma levels fall, but C3 levels remain normal. An acquired form of angioedema in which antibody develops against C1 inh has also been described. Dental procedures can trigger attacks of HAE. These attacks do not respond well to epinephrine, and diagnosed patients are usually treated with the androgen danazol that increases C1 inh plasma levels. Fresh-frozen plasma may be given to patients before dental procedures until recombinant C1 inh is available for clinical use.

Generalized Anaphylaxis

Generalized anaphylaxis is an allergic emergency. The mechanism of generalized anaphylaxis is the reaction of IgE antibodies to an allergen, causing the release of histamine, bradykinin, and slow-reacting substance of anaphylaxis (SRS-A) from mast cells and later eosinophils. These chemical mediators cause the contraction of smooth muscles of the respiratory and intestinal tracts, as well as increased vascular permeability. Within dentistry, penicillin is a frequently encountered cause, but muscle relaxants, cephalosporins, sulfonamides, vancomycin, radiographic contrast media, and vaccines may also cause anaphylaxis.[41]

The following factors increase the patient's risk for anaphylaxis: history of allergy to other drugs or food, history of asthma, family history of allergy (atopy), and parenteral administration of the drug. Anaphylactic reactions may occur within seconds of drug administration or 30–40 minutes later, complicating the diagnosis. Symptoms of generalized anaphylaxis should be known so that diagnosis and

prompt treatment may be initiated. It is important to be able to differentiate anaphylaxis from syncope or a hypoglycemic event. The generalized anaphylactic reaction may involve the skin, the cardiovascular system, the gastrointestinal tract, and the respiratory system. The first signs often occur on the skin and are similar to those seen in localized anaphylaxis (e.g., facial flushing, pruritis, paresthesia, or peripheral coldness). Pulmonary symptoms include dyspnea, wheezing, and asthma. Gastrointestinal tract disease, such as abdominal pain and vomiting, often follows skin symptoms. Symptoms of hypotension (loss of consciousness, pallor, and a cold clammy skin) appear as the result of the loss of intravascular fluid. The pulse becomes rapid, weak, and faint. If untreated, this leads to shock. Patients with generalized anaphylactic reactions may die from respiratory failure, hypotensive shock, or laryngeal edema.

Management

The most important therapy for generalized anaphylaxis is the administration of epinephrine.[42] Clinicians should have a vial of aqueous epinephrine (at a 1:1000 dilution) and a sterile syringe easily accessible. For adults, 0.5 mL of epinephrine should be administered intramuscularly or subcutaneously; smaller doses from 0.1 to 0.3 mL should be used for children, depending on their size. If the allergen was administered in an extremity, a tourniquet should be placed above the injection site to minimize further absorption into the blood. The absorption can be further reduced by injecting 0.3 mL epinephrine (1:1000) directly into the injection site. The tourniquet should be removed every 10 minutes.

Epinephrine will usually reverse all severe signs of generalized anaphylaxis. If improvement is not observed in 10 minutes, readminister epinephrine. If the patient continues to deteriorate, several steps can be taken, depending on whether the patient is experiencing bronchospasm or edema. For bronchospasm, slowly inject 250 mg aminophylline intravenously, over a period of 10 minutes. Too rapid an administration can lead to fatal cardiac arrhythmias. Do not give aminophylline if hypotensive shock is a part of the clinical picture. Inhalation sympathomimetics may also be used to treat bronchospasm, and oxygen should be given to prevent or manage hypoxia. For the patient with laryngeal edema, establish an airway. This may necessitate endotracheal intubation; very rarely, a cricothyroidotomy may be necessary. Patients who have had an anaphylactic attack should carry self-injectable epinephrine.

Latex Allergy

Latex allergy associated with undesirable cutaneous and mucosal reactions has been noticed with increasing frequency over the last few years, possibly related to the greater use of protective gloves. While less than 1% of the general population is sensitized to latex, the US Occupational Safety and Health Administration estimates that over 8% of healthcare workers may be sensitized. Dental staff and students appear to be at high risk for latex sensitization and the overall prevalence of skin sensitization in dentists in a number of studies was about 10%, higher in those reporting asthmatic symptoms.[43] Much of the sensitization appears to have been by inhalation of the glove powder and the rate of sensitization is now falling, since gloves are mainly powder free.

The symptoms of latex allergy are usually those of type 1 hypersensitivity, but contact dermatitis to rubber chemicals is also well described. Sensitized individuals produce specific IgE antibody to at least 10 potent latex allergens, Hev b 1–Hev b 10, each of which differs in its structure, size, and net charge, but testing for them is not yet routine. Cross-reacting antigens are found in bananas, kiwi fruit, avocados, and chestnuts. The important concept that latex allergy can induce clinical symptoms to specific foods (food allergy) is reinforced by the demonstration of amino acid sequence homology between latex antigens and proteins in kiwi fruit, avocados, tomatoes, and potatoes. Cross-reacting IgE antibodies to 33kd and 37kd antigens shared between bananas and latex have been described.

Testing

Recently a skin prick test reagent that contains most of the known clinically significant allergens for diagnosis of type 1 latex allergy has been standardized. The protein content of the gloves correlates with immunoreactivity and the ratio of the IgE to IgG response correlated positively with the severity of symptoms. In most studies, a history of atopy was a significant factor in latex allergy. There seems to be a reasonable correlation between in vitro; IgE testing and in vivo; skin prick tests.

Management

Patients with latex allergy may also show high levels of positive responses to certain foods, so a good medical history is imperative.[43] Urticaria, rhinitis, and eyelid edema can be immediate manifestations of latex allergy. Severe systemic reactions (such as asthma and anaphylaxis) may result in permanent disability or even death. In the healthcare setting, the two major strategies for management are the safe care of the latex allergic patient and the prevention and treatment of occupational latex allergy in employees. In managing a patient with latex sensitivity, the distinction between an immediate hypersensitivity reaction to latex and allergic contact dermatitis due to other irritants must

be established. At initial evaluation, latex allergy status should be established by the history and documented clearly on the chart. Any history of an immediate hypersensitivity reaction to latex necessitates a latex-free environment for that person, including "hypoallergenic" latex gloves. Latex-containing products (such as blood pressure cuffs and disposable tourniquets) should not be worn *or used in the vicinity of* persons who are allergic to latex. Premedication with antihistamines, steroids, and histamine H2 blocking agents is sometimes carried out in operating rooms, but anaphylactic reactions have occurred despite such pretreatment.

Workers who are irritated by gloves should change the type of gloves worn or the type of soap used for scrubbing. In addition, the use of cotton liners and emollients may effectively prevent sensitivity reactions. In cases of true latex allergy, the avoidance of all latex products is the only measure that can avert a serious allergic reaction. All persons with latex hypersensitivity should carry an epinephrine autoinjection kit and wear MedicAlert identification. Acute systemic reactions to latex should be treated in the same manner as other anaphylactic reactions (see earlier; i.e., airway and circulation assessment, administration of oxygen, and administration of epinephrine and steroids as needed). In the course of resuscitation, all latex contact must be avoided.

Oral Allergy Syndrome

Swelling of the lips, tongue and palate, and throat, along with oral pruritis and irritation, sometimes associated with other allergic clinical features including rhino-conjunctivitis, urticaria, and even anaphylaxis, has been termed the oral allergy syndrome.[44] It seems to be precipitated by fresh foods, including apples, in people who have been sensitized to cross-reacting allergens in pollens, particularly birch.

Immune Complex Diseases: Serum Sickness and Erythema Multiforme

Serum sickness is named for its frequent occurrence after the administration of foreign serum, which was given for the treatment of infectious diseases before the advent of antibiotics. It is a type 3 immune complex–mediated disease. The reaction is now uncommon, but still occurs as a result of the susceptible patient being given tetanus antitoxin, rabies antiserum, or drugs that combine with body proteins to form allergens.

The pathogenesis of serum sickness differs from that of anaphylaxis. Antibodies (usually IgG) form immunocomplexes in blood vessels with administered antigens. The complexes fix complement, which damages vessels and attracts leukocytes to the area, amplifying direct tissue injury. Serum sickness and vasculitis usually begin 7–10 days after the administration of the allergen, but this period can vary from 3 days to as long as 1 month. Unlike other allergic diseases, serum sickness may occur during the initial administration of the drug.

Major symptoms consist of fever, swelling, lymphadenopathy, joint and muscle pains, and rash. Less common manifestations include peripheral neuritis, kidney disease, and myocardial ischemia. Serum sickness is usually self-limiting, with spontaneous recovery in 1–3 weeks. Treatment is symptomatic; aspirin is given for arthralgia, and antihistamines are given for the skin rash. Severe cases should be treated with a short course of systemic corticosteroids, which significantly shortens the course of the disease. Although serum sickness is rare, the dentist who is prescribing penicillin should be aware of the possibility of its occurring days or weeks after use of the drug. It is thought that penicillin binds to host proteins to form a recognizable antigen and, as antibodies form, they meet across vessel walls and give a localized vasculitis.

Oral erythema multiforme is thought to be an immune complex disease where 7–10 days after a herpes simplex infection, IgG antibodies are formed and bind to remaining residual tissue-located herpes antigen, giving rise to localized inflammation and ulceration. Similar oral appearances can sometimes occur after systemic therapy with antihypertensive drugs.

Delayed Hypersensitivity: Oral Lichenoid Reactions

Cell-mediated damaging immune reactions can occur in the oral cavity. Lichen planus is thought to be a cell-mediated autoimmune reaction against basal epithelial cells. Similarly, oral lichenoid reactions (OLRs) reflect cellular immunity to antigens found in dental restorations (Chapter 3). These are usually associated with contact sensitivity to amalgam fillings, but similar OLRs can be found with gold, composite, or glass ionomer materials. They are important to recognize, since there is increasing evidence of the malignant potential of such lesions. The lesions usually present as chronic, unilateral, mixed red and white lesions in direct proximity to a restoration, and histologically appear very similar to lichen planus with a predominantly lymphocytic infiltrate. The combination of history, clinical appearance, and histology usually leads to the diagnosis. Damaging immune-mediated reactions, including cell-mediated, can also occur to many other dental materials, including dentifrices, toothpastes, and mouthwashes.[45]

Transplantation Medicine

Sharon Elad, DMD, MSc
Marie Laryea, BSC, MDCM, FRCP (Int Med, GI)
Noam Yarom, DMD

INTRODUCTION

Transplantation is the treatment of choice for the restoration of function in end-stage organ disease. Innovative surgical techniques have played a major role in enhancing the success of organ transplants, leading to improved graft and patient survival. Advances in the biology of organ preservation have led to improved cold storage of the solid organs, improving the overall quality of the transplanted organs and diminishing the damage incurred by warm ischemia, allowing optimization of the medical conditions of the donor and the recipient. Furthermore, insights into the biology of immune responses to transplanted tissues have aided in the development of immunosuppressive techniques to prevent the rejection of the organ transplant while minimizing the morbidities associated with chronic immunosuppression. The main limitation to even greater use of transplantation as a treatment modality for end-stage organ damage remains the shortage of organ donors.

Burket's Oral Medicine, Thirteenth Edition. Edited by Michael Glick, Martin S. Greenberg, Peter B. Lockhart, and Stephen J. Challacombe.

Attempts at organ and bone marrow transplantation date back to the 1800s. Dr. Joseph Murray performed the first successful human renal transplantation between identical twin brothers in 1954. This procedure was well tolerated, as there was no rejection by the genetically identical recipient. The first successful allogeneic (not genetically identical) transplantation was a kidney transplant between fraternal twins performed in 1959, in which the recipient was "conditioned" (immunosuppressed to prevent rejection) by total body irradiation. In 1962, a successful cadaveric donor renal transplantation was achieved, and in 1966, a pancreas transplantation was successfully performed. In the following year, the first human liver transplantation was performed, resulting in a 13-month survival. In the same year, a heart was transplanted. In 1968, a genetically related bone marrow transplantation (today referred to as a hematopoietic stem cell transplantation [HSCT]) was performed, and in 1973, a genetically unrelated HSCT was performed. Lung transplantation has also been performed both as a single procedure and in combination with a heart transplantation. The first heart–lung transplantation in the United States was done in 1981, and the first ever single-lung transplantation was performed in Canada in 1983. Other organs that have been successfully transplanted include the small bowel, skin, various limbs, face, and components of the human eye.

In past decades, significant advances—including tissue typing and the development of immunosuppressive medications and medication regimens—have increased the success of transplantation. Overall, long-term patient survival has also significantly increased over the past 30 years, in both solid organ and HSCT recipients. Most transplant clinicians consider the discovery of the immunosuppressive agent cyclosporine (CSA) to be the most significant advance in transplantation medicine. This medication was approved for use in 1983. Both solid organ and non–solid organ transplantations are becoming more routine throughout the world. In November 2013, over 120,000 patients in the United States alone were waiting for a solid organ transplant. In 2012, 28,052 solid organs were transplanted, approximately the same number as was seen in 2005, and in 2019, 39,719 transplants were performed (Table 20-1).[1]

As the process of solid organ transplantation expands, there is a continued need to increase the supply of organs suitable for transplantation. The limitation of available donor organs will hopefully become less of an issue with increased awareness of organ donation and perhaps with collaborative sharing initiatives, alternative organ procurement methods, including xenografts or stem cell–derived tissue, or printed organs.

The likelihood of a dentist having to treat a transplanted patient is increasing, as many of these transplant recipients resume a normal life after transplantation and many achieve long-term survival beyond 10 years. This chapter reviews different aspects of transplant medicine pertinent for the oral health professional.

CLASSIFICATION

Most transplant clinical classification systems employ both the type of tissue transplanted and the genetic relationship of the tissue to the recipient. It is extremely important for the dental clinician to know exactly what type of transplantation was performed, as both the management and the prognosis are intimately related. This will become evident later in this chapter.

Some authorities broadly divide transplantations into solid organ/tissue transplant or HSCT. Virtually all solid organs/tissues have been transplanted, including heart, lung, kidney, liver, stomach, intestine, pancreas, skin, tendons, nerves, veins, and eye components, as well as composite tissue transplants, including the face and the limbs. HSCT is another type of transplantation frequently used to treat various hematologic and some nonhematologic malignancies, as well as other disorders. HSCT uses either an autologous "self" donor graft or a "nonself" donor (allogeneic graft).

Table 20-1 Waiting lists and transplanted solid organs (2019) in the united states.

Organ	Awaiting Transplants	Transplants Performed	Total Transplants Performed to Date
All*	112,402	39,719	804,607
Liver	12,698	8,896	174,582
Kidney	94,552	23,401	473,811
Lung	1,275	2,714	41,529
Heart	3,669	3,552	76,493

*Note that these numbers do not equal those cited in the text, since other organs, including the small intestine and pancreas, are not included in this table. All transplants up to end of 2019.

Source: Based on Organ Procurement and Transplantation Network (OPTN). https://optn.transplant.hrsa.gov/data/view-data-reports/national-data/#. Accessed March 24, 2020.

Classification of transplants can also be based broadly on the genetic relationship of the recipient to the donor. For the purpose of this chapter, the transplanted cell, tissue, or organ is referred to as the graft. A transplant to and from one's self (autograft) is known as an autologous transplant. A transplantation from an identical twin (identical genetic makeup) is known as an isograft, with the process of this type of transplantation known as isogeneic or syngeneic transplantation. Most transplants are from donors that are not genetically identical to the recipient (allografts). These types of transplants are known as allogeneic transplants. Finally, transplants from donors of one species to recipients of another species (xenografts) are known as xenogeneic transplants.

Due to the scarcity of isografts and the obvious limitations to autografts, allogeneic transplants are most commonly used today. The success of allogeneic transplantation relies on more or less sophisticated mechanisms for identifying and matching specific genetic markers between the donor and the recipient depending on the organ, as well as suppressing the recipient's immune system to prevent transplant rejection. These are concepts that serve as the basic foundation in transplantation medicine. In the future, these concepts may be extended and improved to allow transplantation across species. Tissue xenografts, which have been treated to reduce their immunogenicity, have been used as a successful treatment modality in some applications (i.e., porcine heart valves), but whole-organ xenografts have been unsuccessful. Research regarding genetically altered xenografts is ongoing. When the important immunologic barriers to xenogeneic transplantation are eliminated, the use of animal donors may possibly alleviate the relative paucity of available organs. Of course, significant ethical questions, as well as transplant longevity and transmissible infectious diseases from animals, are issues that must be addressed before these types of transplants become commonplace. Bioengineered tissues that have been fabricated in vitro and transplanted back into the patient have also been successful, including a trachea and a bladder.

TRANSPLANTATION IMMUNOLOGY

Transplantation immunology encompasses most aspects of the human immune response to alloantigens expressed by the recipient as well as the donor organ/tissue. When donor and recipient genetic disparities exist, the recipient mounts a specific immune response to the alloantigens expressed by the donor grafted organ/tissue. In addition, donor T cells contained within the transplanted graft or organ can recognize foreign tissue in the host and mount a "graft-versus-host" reaction. Transplantation medicine would be grossly unsuccessful if this concept were not appropriately appreciated and manipulated.

T lymphocytes are the primary, though not the only, cells that mediate graft rejection as well as graft-versus-host disease (GVHD). T cells can become activated shortly after transplant by recognizing foreign major and minor human leukocyte antigen (HLA) molecules. The major histocompatibility complex (MHC), a genetic region found on the short arm of chromosome number 6 of all mammalian cells, codes for HLA molecules that allow immune cells to identify self from nonself. Although there are many other gene products, from more than 30 histocompatibility gene loci, which can stimulate graft rejection, it is the HLA system that produces the strongest immunologic response.

MHC genes are inherited from each parent; every child has components of both the mother's and the father's HLAs on their cell surfaces. The MHC/HLA system is broadly divided into regions. MHC class I and class II regions are those significantly involved in rejection and GVHD (see later in the chapter). MHC class I regions include HLA-A, -B, -C, -E, -F, and -G. (The present role of the -E, -F, and -G regions in transplantation is not well understood.) MHC class II regions include HLA-DR, -DQ, -DP, -DO, and -DN. MHC class II genes have two chains, allowing for four different gene products for each locus.

The MHC has extensive polymorphism, allowing remarkable diversity among genes of the HLA system. There are over 180 different class I alleles in the HLA-B region alone and over 220 class II alleles in just one loci of the HLA-DR region that have been recognized in humans. Deoxyribonucleic acid (DNA)-based typing (see below) has led to a more specific and detailed classification of the transplantation genes, such that the HLA alleles are related to their DNA sequences.

HLA class I antigens are expressed on most nucleated cells and on red blood cells, whereas class II antigens are expressed only on certain cells known as antigen-presenting cells (APCs). APCs include macrophages, B cells, dendritic cells, and some endothelial cells. The expression of these MHC gene products (antigens) on a cell's surface is regulated by various cytokines such as interferon (IFN) and tumor necrosis factor (TNF).

In the setting of solid organ transplantation, the transplanted foreign MHC molecules activate the immune response by stimulating the recipient's T cells to respond to foreign antigens. The interaction of the MHC of the donor cells with the recipient's T-cell receptor initiates the immune reaction that can lead to rejection. T cells can be activated either by the donor's or the recipient's APCs, resulting in the expression and production of lymphokines and cytokines that promote activation of cytotoxic T cells, activation of B cells, and activation of natural killer cell activity, as well as promote enhanced expression of MHC and increased macrophage activity. This, in turn, causes further

immune reactions that result in direct tissue damage and damage to the vascular endothelium of the graft, which may ultimately result in graft rejection.

Despite the treatment of recipients with immunosuppressive drugs, the potential for immunologic rejection is not entirely eliminated. Rejection may be characterized as acute, a process evolving rapidly over days to weeks. Acute rejection can occur at any time, from hours after transplant to years later. This acute process is related to the primary activation of T cells and usually can be reversed by modifying or intensifying the immunosuppressive regimen.

Chronic rejection of the allograft is also a significant problem leading to organ failure. This type of rejection is slow and insidious and in most cases cannot be reversed by conventional immunosuppressive drugs. It likely occurs by continued, albeit muted, cell-mediated toxicity that results in vascular endothelial damage of the transplanted organ (as well as other actions, which have not been fully elucidated), leading ultimately to graft failure.

Another type of rejection is known as hyperacute rejection; this occurs within minutes to hours after a transplantation procedure. This pattern of rejection occurs in patients who have undergone previous transplantations, patients who have had multiple pregnancies, and patients who have had multiple blood transfusions. It is caused by the presence of preformed antidonor antibodies in the recipient that activate complement cascade, resulting in severe damage to the parenchymal constituents of the graft, which often cannot be reversed.

Transplant immunology is even more complicated in the setting of allogeneic HSCT. Without proper immune suppression, residual host lymphocytes can mediate graft rejection, leaving a patient aplastic. However, unlike solid organ transplant, a hematopoietic stem cell graft has large numbers of mature lymphocytes capable of reacting against nonself antigens in the host in inducing GVHD. Donor leukocytes tend to react against the skin, liver, and gastrointestinal tract. Occasional involvement of the lungs can be seen as well. GVHD varies from nonexistent in approximately 50% of patients to severe and life-threatening. GVHD remains one of the major limitations to successful HSCT. Intensive therapies designed to minimize GVHD have resulted in higher rates of relapse from loss of the potential "graft-versus-tumor" (GVT) effect and from higher rates of infection. Ultimately, therapies that may limit GVHD and retain the important GVT activity of the donor graft will be needed to improve the outcomes of HSCT, and several strategies are in clinical testing.

It should also be noted that in unusual cases after solid organ transplant, mature donor lymphocytes transplanted with the organ can engraft and likewise cause GVHD. This is particularly complicated and similar to "transfusion-associated GVHD" (TA-GVHD), which can lead to marrow aplasia without the support of a donor stem cell graft. Similar to TA-GVHD, the prognosis is often poor, and treatment requires early recognition and intensive intervention with immune suppression.

CLINICAL INDICATIONS

The clinical indications for transplantation vary, but the disease outcome can be fatal without the transplant. The more common indications for transplantation are listed in Table 20-2.

Other indications can be added to this list when quality of life can be improved by transplantation. For example, autologous HSCT may ameliorate the effects of systemic lupus erythematosus or other autoimmune disorders. HSCT has been performed as a treatment for the management of various metabolic disorders and solid tumors, germ cell tumors, and neuroblastoma.[2]

In recent years there has been a steady increase in vascularized composite allograft transplantations. These include facial, craniofacial, hand, limb, and genitourinary transplantations. Such transplantations prompt new ethical questions.[3]

MEDICAL MANAGEMENT

Medical management of the transplant candidate focuses on successfully preventing rejection. In solid organ transplantation, when the donor and recipient tissue are genetically identical (autologous or syngeneic), the outcome of the transplantation relies upon the surgical success of the procedure. For autologous HSCT, success is largely dependent on the high-dose chemotherapy or radiation used to eradicate residual malignant cells prior to HSCT. When tissue from genetically different sources is transplanted, a sophisticated means of preventing rejection must be instituted to ensure graft survival, and in the setting of allogeneic stem cell transplant, methods must be used to prevent both graft rejection and severe GVHD. Transplantation surgeons and oncologists have improved the surgical procedures for various transplantations. Medical management to achieve longer-term successful grafts and longer-term overall patient survival has been quite successful, yet it still is fraught with longer-term complications. The success of an allogeneic transplantation relies on the ability to identify and match certain genetic markers between the donor and the recipient while suppressing the recipient's immune system in order to prevent rejection.

Table 20-2 Major indications for transplantation*.

Type of Transplant	Indications
Kidney**	End-stage renal disease
	Diabetic nephropathy
	Glomerulonephritis
	Pyelonephritis
	Congenital abnormalities
	Nephrotic syndrome
Liver	Fatty liver disease (both alcohol and nonalcoholic fatty liver)
	Viral cirrhosis
	Autoimmune chronic liver disease
	Biliary atresia (children)
Pancreas	Severe diabetes
	Severe hypoglycemic unawareness
	Hypertensive nephrosclerosis
Isolated pancreatic islets	Severe hypoglycemic unawareness
Intestinal	Short bowel syndrome
	Functional bowel problems
Heart	Hypertrophic cardiomyopathy
	Dilated myopathy
	Valvular heart disease
	Severe coronary artery disease
	Congestive heart failure
	Congenital heart defect
Heart and lung	Multiorgan end-stage disease
	Congenital abnormalities
	Amyloidosis
Lung	Primary pulmonary hypertension
	Chronic obstructive pulmonary disorder/emphysema
	Pulmonary fibrosis
	Cystic fibrosis
Hematopoietic cell transplantation (autologous)**	Acute myelogenous leukemia
	Multiple myeloma and amyloidosis
	Lymphoma (Hodgkin and non-Hodgkin)
	Some solid tumors (germ cell, ovarian)
	Systemic lupus erythematosus/autoimmune disorders
	Ewing sarcoma
	Neuroblastoma
	Wilms tumor
	Osteosarcoma
	Medulloblastoma
	Juvenile rheumatoid arthritis

(*Continued*)

Table 20-2 (Continued)

Type of Transplant	Indications
Hematopoietic cell transplantation (allogeneic)**	Acute myelogenous leukemia
	Acute lymphoblastic leukemia
	Chronic myelogenous leukemia
	Multiple myeloma
	Aplastic anemia
	Primary immune deficiencies
	Hemoglobinopathies (sickle cell anemia, thalassemia)
	Myelodysplastic syndrome
	Multiple sclerosis
	Fanconi anemia
	Dyskeratosis congenital
	Blackfan–Diamond anemia
	Wiskott–Aldrich syndrome
	Lymphoproliferative disorder
	Chronic granulomatous disease
	Mucopolysaccharidoses (MPS-I and MPS-VI)
	Some metabolic diseases
	Osteopetrosis
	Globoid cell leukodystrophy (Krabbe)
	Metachromatic leukodystrophy
	Cerebral X-linked adrenoleukodystrophy
Face and/or craniofacial	Composite midface defects/mutilation
Limb	Upper-extremity disabilities
	Lower-extremity disabilities
Genitourinary transplantations	Absolute uterine-factor infertility (uterus)
	Genital loss (penile)

* Partial listing only. Additional specification on the Organ Procurement and Transplant Network webpage.[1]
** Per the specifications of the Guidelines from the American Society for Blood and Marrow Transplantation.[2]

BLOOD AND TISSUE TYPING

Standard ABO and Rh blood typing is performed to prevent hyperacute rejection of the transplant based on isoagglutinin incompatibility. ABO matching is mandatory for solid organ transplant and directly impacts short-term graft survival. ABO matching does not appear to impact graft survival after allogeneic HSCT; the impact on patient outcomes such as relapse is controversial, but is likely to be small and of unclear significance that may depend on graft source and disease.

Cross-matching (crossing recipient serum with donor lymphocytes) is usually done to prevent hyperacute rejection in allogeneic solid organ transplants. This is a basic serologic test that is regarded as necessary, particularly in those allogeneic transplant recipients who have previously experienced massive immune challenges such as a prior transplantation, multiple pregnancies, or multiple blood transfusions, and have developed preformed anti-HLA antibodies. The existence of preformed alloantibodies is detected by single HLA antigen bead technology. Since transplantation of solid organs (heart, lung, liver) often requires some expediency, time-consuming complex cross-matching or tissue typing cannot be performed. Instead, absence of antibodies to a panel of cells (defined in advance and known as panel-reactive antibodies) is usually adequate for heart and lung transplantation. Interestingly, MHC compatibility in liver transplantation seems negligible in achieving better outcomes. This is fortunate, because the timing of liver transplantation often precludes HLA typing.

The most critical matching criterion for allogeneic HSCT is tissue typing to determine and match HLA. HLA molecules

are found on donor and recipient cells, and in the setting of HSCT are critical for determining engraftment and complications such as GVHD. HLA typing is much less critical in renal transplantations and for graft survival in liver or heart transplantations. Tissue typing can be performed by serologic assays, but more commonly, most typing is performed using rapid DNA-based testing methods. Polymorphisms in HLA antigens are common, and it is now practical and routine to test not just for HLA antigens but for HLA alleles. In the setting of allogeneic HSCT, it is clear that allele level matching improves outcomes. Matching at class I HLA-A, -B, -C, and class II (HLA-DR) is critical in all cases. The role of matching at the HLA class II molecule DQ is less clear and a single DQ mismatch does not seem to impact the outcome after HSCT.

IMMUNOSUPPRESSION

Immunosuppressive regimens vary among transplant centers and according to organ type (intestines, liver, etc.). Since tissues in allogeneic transplants are not genetically identical, medications used to control the immune response are essential for graft survival. All allogeneic transplantations initially require immunosuppression to prevent acute and hyperacute and/or acute cellular rejection. Furthermore, most allogeneic solid organ transplant recipients require lifelong maintenance immunosuppression and may require even more intensive immunosuppression should they develop rejection. Long-term immunosuppression is usually not required in allogeneic HSCT, and autologous HSCT generally requires no immunosuppression at all.

Most immunosuppressive medications are nonspecific and cannot prevent a specific component of the immune response. More sophisticated and directed agents are currently in development that will allow for graft tolerance while allowing the immune reaction to infection or other detrimental antigens to remain intact.

One of the most significant advances in transplantation has been made in pharmacotherapeutic immunosuppression. As mechanisms of graft rejection are better understood, agents become more specific in their mode of immune modulation.

Immunosuppression in solid organ transplant can be divided into induction (used at the time of implantation of the graft or soon after) and maintenance (to prevent rejection long term) (Figure 20-1). The most frequently used contemporary medication classes are discussed in this chapter (see Table 20-3), with a brief review of some key formulations.

Calcineurin Inhibitors

Calcineurin activates a nuclear component of T cells that is thought to initiate gene transcription for the formation of interleukin (IL)-2. The development of calcineurin inhibitors (known as CNI), specifically cyclosporine A (CSA) in 1981, was a watershed moment in solid organ transplantation and immediately lead to drastically lower rates of rejection.

Cyclosporine

CSA is a cyclic polypeptide macrolide medication derived from a metabolite of the fungus *Tolypocladium inflatum*. It specifically and reversibly inhibits immunocompetent lymphocytes in the G0 and G1 phase of the cell cycle by binding with the intracellular protein cyclophilin, and inhibiting calcineurin, which is presumed to inhibit IL-2 by preventing gene expression. CSA also reduces the expression of IL-2 receptors. This medication has some effect on humoral immunity but not on phagocytic function, neutrophil migration, macrophage migration, or direct bone marrow

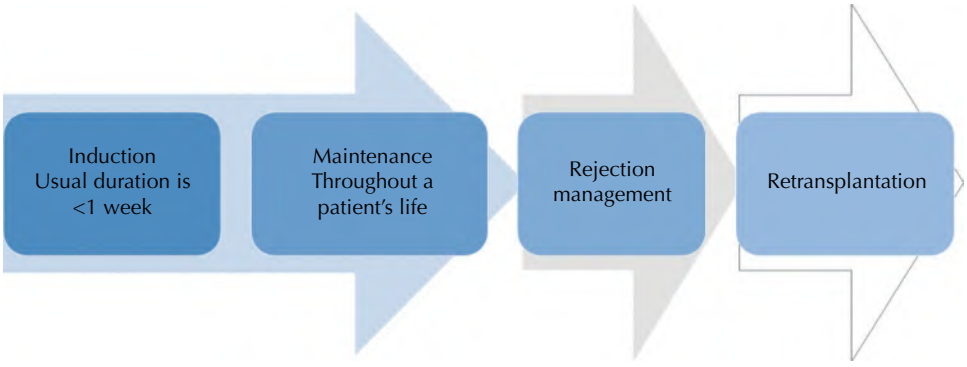

Figure 20-1 Phases of immunosuppression in solid organ transplantation. During the induction phase, the goal is to prevent early rejection. During the maintenance phase, the goals are to prevent acute/chronic rejection, to maximize immunosuppression, and to minimize toxicity. If rejection develops, the treatment goals are to increase immunosuppression, filter/remove/block offending immune components, and enable residual organ function. In some patients, retransplantation is needed in order to overcome the rejection.

Table 20-3 Major immunosuppressive agents*.

Drug	Type	Indications	Major Side Effects†	Implications in the Dental Office†
Cyclosporine	Calcineurin inhibitor	Maintenance IS	Nephrotoxicity Neurotoxicity Elevation of blood pressure Cosmetic side effects PTLD	Immunosuppression related‡ Drug–drug interaction (P-450 CYP3A)§ Vital signs monitoring Gingival overgrowth Risk of neoplasm
Tacrolimus	Calcineurin inhibitor	Maintenance IS	Nephrotoxicity Neurotoxicity Post-transplantation diabetes mellitus Elevation of blood pressure PTDM	Immunosuppression related‡ Drug–drug interaction (P-450 CYP3A)§ Vital signs monitoring Risk of neoplasm
Sirolimus	mTOR inhibitor Antiproliferative	Maintenance IS Potential treatment for chronic rejection Used in CNI-sparing IS	Delayed wound healing Hyperlipidemia Hypertriglyceremia Proteinuria Bone marrow suppression Interstitial pneumonitis	Immunosuppression related‡ Drug–drug interaction (P-450 CYP3A)§ Vital signs monitoring Risk of neoplasm
Everolimus	mTOR Inhibitor Antiproliferative	Maintenance IS Potential treatment for chronic rejection Used in CNI-sparing IS	Delayed wound healing Hyperlipidemia Hypertriglyceremia Proteinuria Bone marrow suppression	Risk for osteonecrosis of the jaws Risk of neoplasm
Azathioprine	Antimetabolite	Adjuvant to maintenance IS	Bone marrow suppression Hepatotoxicity	Immunosuppression related‡ Risk of neoplasm
Mycophenolate mofetil	Antimetabolite	Adjuvant to maintenance IS	Immunosuppressant‡ Leukopenia	Immunosuppression related‡ Absorption is altered by antibiotics, antacids, and bile acid binders Risk of neoplasm
ATG/ALG	Polyclonal antibody	Induction IS Treatment of very severe rejection	Leukopenia PTLD Pulmonary edema Renal dysfunction	Immunosuppression related‡ Risk of neoplasm
Basiliximab	Monoclonal antibody	Induction IS	Pulmonary edema Renal dysfunction	Immunosuppression related‡ Risk of neoplasm

Corticosteroids	Nonspecific immunosuppressant	Induction IS Maintenance IS Treatment of acute rejection	(see Box 20-1)	Immunosuppression related‡ Peptic ulcer related (avoid NSAIDs) Vital signs monitoring Poor wound healing Risk of neoplasm Steroid supplement may be needed with stressful procedures As applicable for diabetes, if develops Possible history of bisphosphonates

ASA, acetylsalicylic acid; ATG/ALG, antithymocyte globulin/antilymphocyte globulin; CNI, calcineurin inhibitor; CV, cardiovascular; IS, immunosuppression; mTOR, mammalian target of rapamycin; NSAIDs, nonsteroidal anti-inflammatory drugs; PTDM, post-transplantation diabetes mellitus; PTLD, post-transplantation lymphoproliferative disorder.

* Major mechanisms of action are outlined in the text.

† Partial listing only.

‡ Use of an immunosuppressant results in an increased risk of infection.

§ Dental/oral pharmacotherapeutics that are metabolized by the liver's cytochrome P-450 CYP3A system alter this drug's serum levels. This group of medications includes, but is not limited to, erythromycin, clarithromycin, azole antifungals, benzodiazepines, carbamazepine, colchicine, prednisolone, and metronidazole.

suppression. Absorption of this drug is variable, and blood levels must be drawn 2 hours after dosing to ensure that the drug is in the therapeutic range.

Tacrolimus

Tacrolimus (FK-506; Prograf) is a macrolide immunosuppressant produced by *Streptomyces*. Similar to CSA, it suppresses cell-mediated reactions by suppressing T-cell activation. Tacrolimus inhibits calcineurin by interacting with an intracellular protein known as the FK-binding protein. Consequently, T cells are not activated, and cell-mediated cytotoxicity is impeded. There may be a lower incidence of rejection with the use of tacrolimus compared with the use of CSA in liver, kidney, and lung transplantations. Overall graft and patient survival rates in kidney transplantations do not seem to differ significantly with the use of this medication, although the safety profiles do differ and seem to favor tacrolimus.[4]

Inhibitors of Mammalian Target of Rapamycin

Sirolimus (rapamycin; Rapamune) and everolimus (Afinitor) are other macrolide immunosuppressive agents. Sirolimus is produced by *Streptomyces hygroscopicus*. These mammalian target of rapamycin (mTOR) inhibitors are used for prophylaxis against acute rejection of solid organ transplants and may be appropriate for use in chronic rejection. They inhibit the activation of a particular cellular kinase (target of rapamycin [TOR]), which then interferes with the intracellular signaling pathways of the IL-2 receptor, thereby preventing lymphocyte activation. Everolimus is more selective for mTORC1 and may have less impact on glucose homeostasis. Both sirolimus and everolimus lead to inhibition of T-cell response to IL-2 and other cytokines. The overall effect is interference of T-cell activation during the cells' G1 to S phase. Sirolimus and everolimus are used in conjunction with CNIs. Their antiproliferative effects lead to potential inhibitory effects on neoplasia and fibrosis as well, but can impair wound healing.[4] They can also be associated with significant toxicity. Sirolimus has been shown to reduce acute rejection when azathioprine (AZA) is used.

Inhibitors of Purine and Pyrimidine Synthesis

Azathioprine

AZA is an antimetabolite that inhibits ribonucleic acid and DNA synthesis by interfering with the purine synthesis that results in decreased T- and B-cell proliferation. It does not interfere with lymphokine production, but has significant anti-inflammatory properties. AZA can be bone marrow suppressive, leading to pancytopenia, and it can also cause hepatotoxicity, usually mild but potentially severe. Therapeutic response is delayed, normally taking 3 months but occasionally requiring up to 6 months in some patients.[5] In addition, polymorphisms in the *TPMT* gene that codes for an enzyme involved in AZA metabolism are associated with severe bone marrow toxicity, including aplastic anemia. For these reasons, AZA has lost favor with the advent of mycophenolate mofetil (MMF).

Mycophenolate Mofetil

MMF, an ester of mycophenolic acid, is an antimetabolite used for prophylaxis against graft rejection, and may have some action in reversing ongoing acute rejection. It inhibits inflammation by interfering with purine synthesis. Both T cells and B cells, which are dependent on this synthesis for their proliferation, are prevented from reproducing. Additionally, MMF interferes with intercellular adhesion of lymphocytes to endothelial cells. It does not inhibit IL-1 or IL-2. MMF is used as an adjunct to CNI-based immunosuppression and is commonly used in all solid organ transplants.

Corticosteroids

Corticosteroids are consistently used in all allogeneic transplantations for prophylaxis against graft rejection and for reversal of acute rejection. The mechanism of action of this medication is nonspecific, as it affects the immune system in many complex ways. Steroids have anti-inflammatory effects and are able to suppress activated macrophages. They also interfere with antigen presentation and reduce the expression of MHC antigens on cells. Steroids reverse the effect of IFN-γ and alter the expression of adhesion molecules on vascular endothelium. These medications also have significant effects on IL-1 activity and block the IL-2 gene and its production.

Antibody-Based Immunosuppression

Antithymocyte and Antilymphocyte Globulin

Polyclonal antilymphocyte sera, antilymphocyte globulin (ALG), and antithymocyte globulin (ATG) are part of the same medication class. These agents are produced by immunizing animals with human lymphoid cells; the animals produce antibodies, which then reduce the number of circulating T cells after infusion into transplanted recipients. Individually, these agents affect lymphocyte immunosuppression by reacting with common T-cell surface markers and then coating (opsonizing) the lymphocyte—marking it as foreign for phagocytosis. Polyclonal antibodies are used as conditioning agents prior to transplantation as well as for reversal of steroid-resistant rejection.

Basiliximab

Basiliximab (Simulect) is made of synthetic monoclonal antibodies used in some centers for induction immunosuppression. These monoclonal antibodies bind the CD25 receptor (IL-2 receptor) on the surface of activated T cells (IL-2 receptor antagonists), preventing the expansion of CD4 and CD8 lymphocytes. They may be effective in conjunction with MMF and corticosteroids to eliminate the need for CNI use in the early post-transplantation period. Anti-CD25 agents have also been reported to be efficacious in treatment of corticosteroid-resistant GVHD.

Alemtuzumab

Alemtuzumab (previously known as Campath-1; currently, Lemtrada) is a monoclonal antibody that binds to and depletes CD52, which is expressed on the surface of mature lymphocytes. It is used for the treatment of chronic lymphocytic leukemia, and in some conditioning regimens for bone marrow, kidney, and islet transplantation.

Conditioning in Hematopoietic Stem Cell Transplantation

Unlike solid organ transplant, HSCT requires "conditioning" of the patient with cytotoxic chemotherapy. Traditional conditioning regimens were designed to take advantage of the dose–response activity against cancer cells. High doses of chemotherapy or radiation are used to eradicate residual tumor prior to infusion of the hematopoietic stem cell product. Typical myeloablative agents include cyclophosphamide in combination with busulfan, etoposide, fludarabine, or often total body irradiation (TBI). A complication of the conditioning regimen is myeloablation, requiring the need to transplant additional donor hematopoietic stem cells. The conditioning therapy must also be sufficiently immunosuppressive to prevent graft rejection, or patients would be left aplastic and die from complications of cytopenias and infections. It has been recognized for years, however, that the success of transplantation is also related to the immunologic activity of the donor graft, independent of the conditioning therapy. Donor T cells have the ability to react against and kill residual tumor cells and induce a GVT effect. This observation led to the development of reduced-intensity conditioning (RIC) regimens designed primarily for immunosuppression to allow donor cell engraftment, and to take advantage of the GVT activity without the organ toxicity often associated with very high doses of chemotherapy and radiation. Typical regimens for RIC HSCT include similar drugs and TBI as used in myeloablative transplant, but, as the name implies, often at reduced doses. While treatment-related morbidity and mortality are less with these regimens, this is often offset by higher relapse rates. RIC HSCT results in significantly less organ toxicity, including mucositis.

Other Immune-Modulating Agents

Rituximab (Rituxan and Biogen) is a chimeric monoclonal antibody that binds to CD20 antigen of B cells. It depletes the level of mature B cells by various mechanisms such as mediation of antibody-dependent cellular cytotoxicity, complement-dependent cytotoxicity, and B-cell apoptosis.[6]

Bortezomib (Velcade) is a proteasome inhibitor. Proteasome inhibition can downregulate NF-κB activity; decrease cell proliferation/differentiation; induce apoptosis via cell cycle arrest, endoplasmic reticulum stress, and caspase induction due to the accumulation of unfolded or misfolded proteins; and downregulate antigen presentation, cell–cell interaction, and cell migration.[7] Bortezomib is approved in the United States for multiple myeloma and mantle cell lymphoma; however, based on its mechanism of action, it is used extensively for the management of rejection in transplantation.

Eculizumab (Soliris) is a humanized monoclonal antibody directed against the complement C5a component. It is currently being used in renal transplantation and HSCT.

Newer Immunosuppressive Strategies

A scientific breakthrough concept is the chimeric antigen receptor (CAR) T-cell therapy. The CAR is directed at a disease-specific antigen. During this process, the patient's leukocytes are collected via leukapheresis. These T cells are processed ex vivo using retrovirus or lentivirus to transduce expression of vector containing a gene coding the CAR construct. The CAR construct is a protein that has an extracellular domain that can identify the abnormal cell, and at least two intracellular domains. The intracellular domains have two roles: direct activation of the T cell and co-stimulation of the T-cell activation (CD28 or 4-1BB domains). Then the engineered CAR T cells are grown in culture to produce an appropriate quantity. Finally, the CAR T cells are infused into the patient, typically following a lymphodepleting conditioning regimen, such as fludarabine and cyclophosphamide. These CAR T cells identify the disease-specific abnormal cells and destroy them.

Two types of engineered T cells are approved by the US Food and Drug Administration: axicabtagene ciloleucel and tisagenlecleucel. The early indications were refractory lymphoid malignancies, especially diffuse large B-cell lymphoma (DLBCL) and acute lymphoblastic leukemia (ALL), which often express CD-19. Therefore, the CAR T cells are targeted at the CD-19. This technology is being expanded in other diseases. Promising results were reported in the

treatment of multiple myeloma, with CAR T-cell therapy targeting the B-cell maturation antigen.[8] This CAR T-cell therapy is also being explored with certain efficacy in clinical trials in solid malignancies such as glioblastoma, neuroblastoma, non-small-cell lung cancer, osteosarcomas, and Ewing sarcoma.[9,10] Therefore, the number of patients undergoing transplants of this type is expected to increase.

Although CAR T cells achieved complete remission in a large portion of the patients with relapse-free survival of up to 12 months, it is associated with severe toxicities, including cytokine release syndrome and neurotoxicity. Current research is aimed at improving the response rate and duration of remission and decreasing toxicity.[11]

Similar immunosuppressive therapies are used in patients undergoing HSCT. Immunosuppression in this setting is used not only to prevent graft rejection, but also to prevent GVHD. Approaches used for GVHD prevention and management include pharmacologic agents that inhibit T-cell function, antibody therapy directed against T cells, selection of stem cell grafts in ways that eliminate T cells prior to transplant, various approaches to inhibit T-cell trafficking to sites where GVHD can be initiated, enhancement of suppressive mechanisms that can limit T-cell activity (such as infusion of regulatory T cells and mesenchymal stem cells), and the use of other novel compounds that may modulate T-cell function and activity. More recently, tyrosine kinase inhibitors (TKIs) were attempted for steroid-resistant chronic GVHD (cGVHD). The first agent was imatinib (Gleevec) for sclerodermatous cGVHD, and more recently ibrutinib (Imbruvica) for second-line treatment for cGVHD.[12] Ibrutinib inhibits the Bruton tyrosine kinase, as well as the interleukin-2–inducible kinase (ITK), which initiates a cascade that ends with T-cell activation, cytokine release, and rapid proliferation.[13] The T-cell activation by ibrutinib inclines toward Th2, which is linked to cGVHD. The most promising therapies for cGVHD in early-phase trials include Janus kinase (JAK) inhibitors (ruxolitinib and bacritinib), immune checkpoint inhibitors (abatacept), monoclonal antibodies against integrin (natalizumab), proteasome inhibitors (ixazomib and carfilzomib), cytokines (IL-2 and IL- 22), CCR5 receptor antagonists (maraviroc), and cytokine modulators (alpha-1 antitrypsin).[14] This is a rapidly changing landscape and has been reviewed in detail.

ANTIMICROBIAL MEDICATION

In addition to immunosuppressive medication regimens, antimicrobial medication regimens are important in preventing infection in the transplant recipient. These regimens vary from center to center and from program to program. Transplant patients are typically profoundly immunosuppressed for months. Many factors affect the pace of immune reconstitution, but it is common to use prophylactic antibiotics for bacterial, protozoan, fungal, and viral infections. Antimicrobial medication coverage has proven to be effective in the prevention of common transplant-associated infections (Table 20-4).

The Centers for Disease Control and Prevention (CDC) have published updated guidelines for preventing opportunistic infections among HSCT recipients based upon the quality of the evidence supporting the recommendation.

Table 20-4 Most common pathogens requiring prophylaxis post liver transplantation.

Pathogen	Prophylaxis	Duration of Prophylaxis*
Cytomegalovirus (CMV)	Ganciclovir Valganciclovir	6 months
Pneumocystis jiroveci	TMP–SMX† Atovaquone Dapsone Aerosolized pentamidine Dapsone plus pyrimethamine	3–12 months
Candida Albicans	Fluconazole Itraconazole Echinocandins	3–6 months
Herpes simplex virus	Ganciclovir Valacyclovir Acyclovir§	3–6 months

* Varies according to transplant center.
† Trimethoprim–sulfamethoxazole.
§ Choice in patients that do not require concomitant CMV prophylaxis.

Prophylaxis is, however, very different from the empiric treatment required in febrile neutropenia.

COMPLICATIONS

Complications with transplantation are still common and require close evaluation and management. General complications can be broadly characterized into those caused by rejection, side effects from medication, and those induced by immunosuppression. Additionally, there are some organ-specific complications observed in certain types of transplantation.

Rejection

As previously mentioned, rejection of the transplanted organ remains a significant obstacle to long-term transplant graft and patient survival. Rejection is characterized by time course and mechanism of injury. Rejection leads to end-organ damage and can lead to allograft failure, often associated with reappearance of complications of organ failure. Clinically, rejection may manifest in many ways, including abnormal liver function such as bilirubin, albumin, and International Normalized Ratio (INR; liver failure); a decreased metabolism of medications (rejection of liver/kidney); or even complete organ failure and death (rejection of liver/lung/heart). In cases of end-organ disease (except those of kidney failure), retransplantation may be the only way to prevent death.

Rejection is continually screened for throughout the post-transplantation period. Most chronic rejections are insidious and are detected by laboratory analysis and by organ biopsy. Graft biopsy provides a reliable means to assess rejection. An alternative approach to monitoring rejection in a transplanted heart is the use of pacemakers to record changes in ventricular evoked response (VER). Subtle changes in VER have been correlated with rejection of heart transplants.

Complications of Immunosuppression Medication

Medications used to produce immunosuppression and prevent graft rejection have significant systemic side effects, which pose serious complications to the transplant recipient. Some of the major side effects are listed here (Table 20-3); however, complete drug information can be obtained through an appropriate medication reference source.

CSA, a mainstay in immunosuppression, is nephrotoxic and may alter renal function. It is also associated with hypertension and lowering of seizure threshold, as well as rare cases of hepatotoxicity. It also has cosmetic side effects such as gingival hyperplasia and hirsutism that can be quite concerning to patients. CSA is metabolized via the P-450 CYP3A system of the liver; therefore, it has many drug interactions, including interactions with drugs frequently used in dentistry, such as lidocaine and oxycodone.

Tacrolimus has been associated with hypertension and nephrotoxicity. In addition, it is neurotoxic and rare hepatotoxicity has been described.[4] There are many other side effects associated with the use of this medication, one of which is the development of insulin-dependent post-transplantation diabetes mellitus (PTDM). The incidence of PTDM appears to be higher with tacrolimus use than with CSA use in liver transplantation. Tacrolimus is metabolized by the P-450 CYP3A system in the liver. It is 99% protein bound and requires titration. Tacrolimus also has significant interactions with medications used in dentistry, such as ibuprofen and metronidazole.

Sirolimus causes or exacerbates proteinuria and may cause abnormal liver enzymes. It can cause stomatitis and oral ulceration and lead to interstitial pneumonitis in rare cases.[4] Sirolimus is also associated with a high incidence of hyperlipidemia owing to elevated triglyceride and cholesterol levels. Being a substrate for P-450 CYP3A, sirolimus interferes too with the metabolism of other medications.

AZA may cause bone marrow suppression, resulting in pancytopenia, which leaves the patient not only susceptible to opportunistic infections, but also at significant risk for bleeding. It also causes skin rash and pancreatitis in some patients.[4]

MMF has significant drug interactions that are particularly important to the dentist. One interaction commonly cited occurs as a result of antibiotic regimens that can alter gastrointestinal flora, leading to dramatic changes in MMF drug levels. For example, if a patient is taking a broad-spectrum antibiotic for a dentoalveolar infection, the possibility and probability of an abnormal MMF level do exist. Other medications, such as antacids (containing magnesium or aluminum) and bile acid binders, may also interfere with the absorption of MMF. MMF is usually well tolerated, without significant hepatotoxicity (although higher doses are associated with gastrointestinal symptoms of nausea, vomiting, and diarrhea) or nephrotoxicity, but hematologic alterations (mostly leukopenia) can be a side effect. It is also teratogenic.

Monoclonal and polyclonal antibodies can be associated with a severe reaction known as cytokine release syndrome. Cytokines (including TNF-α) are rapidly released, resulting in significant medical issues, including fever, chills, nephrotoxicity, vomiting, pulmonary edema, and, in a few instances, arterial thrombosis.

Both monoclonal and polyclonal antibodies have been associated with significant side effects (in addition to significant cytokine release), including a high risk of viral/fungal infection and an increased incidence of post-transplantation lymphoproliferative disorder (PTLD).

Corticosteroids, another mainstay used in transplantation immunosuppression, can have multiple detrimental side effects (Box 20-1).

Cytotoxic agents such as cyclophosphamide, busulfan, and TBI cause bone marrow suppression, resulting in pancytopenia.

Complications of Immune Modulation

Immunosuppression used to prevent rejection of a transplanted organ also can pose serious complications to the recipient, including life-threatening infections and cancer.

Infections after HSCT are a significant problem. The type of transplant and the time that has transpired since the transplantation often predict the specific infection. For example, patients who have had an HSCT usually have broad immunologic defects, either due to their underlying disease or more likely from a combination of immunosuppressive drugs and delayed immune reconstitution. This impacts all components of the immune system. These patients are at a significantly higher risk of infection than are those patients transplanted with solid organs. Additionally, transplants of certain organs are associated with a greater likelihood of a particular infection.

Box 20-1 Corticosteroid Adverse Effects

- Induces diabetes
- Induces muscle weakness
- Induces osteoporosis
- Alters fat metabolism and distribution
- Induces hyperlipidemia
- Induces electrolyte imbalances
- Induces central nervous system effects, including psychologic changes
- Induces ocular changes—cataracts, glaucoma
- Aggravates high blood pressure
- Aggravates congestive heart failure
- Aggravates peptic ulcer disease
- Aggravates underlying infectious processes (e.g., tuberculosis)
- Suppresses the hypothalamic–pituitary–adrenal axis, resulting in adrenal atrophy
- Suppresses the stress response

Timing following the transplantation may correspond with a specific infective process. Bacterial infections are usually seen in the early postoperative period (immediately after transplantation) in solid organ transplantations. The type of bacteria varies with each specific organ and may include both gram-positive and gram-negative bacterial species. Drug-resistant bacterial infections have been documented, such as staphylococcal infections associated with skin wounds, upper and lower respiratory infections (pneumonia), and tuberculosis. Infective endocarditis has also been seen in transplant recipients. In this population, endocarditis is often related to *Staphylococcus* infection or aspergillosis.

Systemic viral infections are a common problem in immunosuppressed patients. CMV and herpes simplex viruses (HSVs) are often the etiologic viral agents involved. Other viral agents, including adenovirus, respiratory syncytial virus (RSV), varicella-zoster virus (VZV), Epstein–Barr virus (EBV), and human parvovirus B19, are also common causes of disease in a transplant population. Viral infections may be related to time following transplantation. HSV infections usually occur at 2–6 weeks after organ transplantation, whereas CMV infections generally occur at 1–6 months after transplantation, and VZV infections typically occur between 2 and 10 months post transplantation.

Patients who are immunosuppressed are susceptible to local and systemic fungal infections that vary from those of *Candida* species to deep fungal infections caused by *Aspergillus*, *Cryptococcus neoformans*, *Fusarium*, and *Trichosporon*. Invasive fungal infections are usually seen later in the transplantation process. Systemic fungal infections are often difficult to treat in the immunosuppressed patient and require systemic antifungal agents. Some have considered the role for macrophage colony-stimulating factor, a cytokine used to stimulate macrophages and monocytes, in the treatment of patients with fungal infections.

Parasitic infections caused by *Toxoplasma gondii* and others can be seen in immunosuppressed transplant recipients, but are uncommon in the context of solid organ transplantation.

In addition to, and perhaps directly related to, infectious complications, immunosuppression renders the patient at higher risk for the development of secondary cancers. The immune system provides surveillance against antigens that may act as initiators or promoters of cancer. When the immune response is muted, so, too, is this surveillance system. Cancers most commonly associated with immunosuppression are squamous cell carcinomas of the skin, lymphomas (mostly B-cell lymphomas including PTLD), and Kaposi's sarcoma. Human herpesvirus 8 has been

implicated in Kaposi's sarcoma and EBV in PTLDs. The most important factors in the development of PTLD are the level of immunosuppression and the EBV serology status. Additionally, there seems to be a clinico-pathologic difference between those transplant recipients who are diagnosed with PTLD early (within the first year of transplantation, which are EBV + PTLD) versus those diagnosed after the first year.

Specific Complications of Transplantation

Solid Organ Transplantation

A significant medical complication seen in patients receiving solid organ transplants is accelerated advanced cardiovascular disease (CVD), including coronary artery disease (CAD). The cause of this rapid CVD is unknown, but some researchers postulate it could be either infectious (CMV), medication induced, or potentially both. In this population, CVD is likely multifactorial. For instance, many investigators have explored the etiologic role of immunosuppression in the development of CVD. Hypertension is a common side effect of CNIs. Steroids and CNIs are diabetogenic, CSA and sirolimus cause hyperlipidemia. All these medical complications are part of the metabolic syndrome and recognized as risk factors for CVD.

In many transplantation facilities, hypertension is treated by calcium-channel blockers (CCBs). Some clinicians note that this group of medications may raise serum levels of CSA, thus decreasing the cost of immunosuppression. Caution must be exercised with any drug affecting CSA metabolism; for this reason, most clinicians prefer to prescribe medications that do not alter CSA levels. Non-dihydropyridine CCBs are often first line, but can have adverse oral effects, such as gingival overgrowth (see below).

PTDM is another significant condition frequently seen post transplant. Experimental and clinical observations both suggest that this phenomenon is related in some part to immunosuppressive agents. PTDM may cause both macro- and microvascular changes, which affect both graft and patient survival.

Neuropsychiatric complications, such as anxiety, seizures, and neuropathies, can also be noted in transplant recipients.

More specifically in lung transplant, the second most common long-term cause of morbidity and mortality (infection being the first) after transplantation is bronchiolitis obliterans. This disorder is caused by inflammation and constriction in bronchioles. It may be related to chronic rejection and infection and perhaps altered microvasculature.

Heart transplantation can also be associated with particular complications. As previously mentioned, post-transplantation CAD is common in all transplants, including heart transplants. Additionally, early after transplantation the heart is denervated, such that symptoms of angina may be absent and the heart may have diminished vagal response. There is, however, evidence of sympathetic and possibly parasympathetic nerve regeneration later in the post-transplantation period, suggesting that angina and heart-rate changes from stress are regained. Care of patients with cardiac transplants must recognize these cardiac abnormalities. Mitral and tricuspid regurgitation has also been observed after heart transplantation (see Chapter 14 on Cardiovascular Disease).

Hematopoietic Stem Cell Transplantation

Perhaps the most significant complications are those observed after an allogeneic HSCT. Allogeneic transplantation often involves both administration of intensive chemotherapy and/or radiation, as well as the administration of immunosuppressive therapy. The major complications of allogeneic HSCT include (1) end-organ damage from pretransplantation conditioning therapy; (2) GVHD; (3) infections.

Major complications occur after HSCT that are directly related to the conditioning regimen. Unlike solid organ grafting, HSCT requires intensive chemotherapy and/or radiation to "condition" the recipient to accept the graft. The conditioning regimen must provide deep immunosuppression to prevent rejection and typically has cytotoxic effects to kill any residual malignant cells. Direct organ toxicity can occur with all types of HSCT, but appears higher after myeloablative conditioning than after nonmyeloablative or reduced-intensity conditioning. One major complication is sinusoidal obstructive syndrome (SOS), previously known as veno-occlusive disease of the liver. SOS is felt to be initiated by endothelial injury that leads to nonthrombotic sinusoidal occlusion, with an increase in sinusoidal pressures. This leads to cholestasis and ultimately can result in portal hypertension. It is associated with renal abnormalities and increased capillary permeability. SOS can ultimately lead to multisystem organ failure, encephalopathy, and even death. Clinical manifestations of SOS include jaundice, hepatomegaly, and fluid retention. Treatment for this process is supportive, and severe SOS is associated with high mortality rates. Another major complication is pulmonary toxicity, manifested as interstitial pneumonitis or alveolar hemorrhage. Pulmonary complication of both solid organ transplantation and HSCT has been reviewed in detail. The use of RIC for allogeneic transplantation appears to minimize direct organ toxicity and nonrelapsed mortality.

Perhaps the most frequently cited complication uniquely associated with HSCT is GVHD, which is a complex immunologic phenomenon that occurs when immunocompetent cells from the donor are given to an immunodeficient host. The host possesses antigens foreign to the transplanted graft that stimulate an immune response by the newly engrafted immune cells. GVHD affects the entire gastrointestinal system, including the mouth, as well as the skin and the liver. Other organs that may be involved in GVHD are the eyes, vagina, joints, lungs, and musculoskeletal tissues. This reaction can be lethal and requires therapy with intensive immunosuppression. Mucosal ulceration seen in GVHD may serve as an entry port for other infectious pathogens. This graft-versus-host reaction can attack the host's hematologic cancer cells as well, leading to an antitumor effect that may be protective against relapse.

LONG-TERM PROGNOSIS POST TRANSPLANT

Transplantation outcomes have improved over the past several decades. Outcomes of solid organ transplants are summarized in Table 20-5. Clinical outcomes of solid organ transplantation are reported as graft survival and patient survival.

The number of patients on waiting lists for solid organ transplants continues to increase. The deaths of patients awaiting kidney transplants increased in 2019 to 3,759 while the death rates for patients awaiting heart and liver transplants in 2019 was 224 and 1,200, respectively. Since 2015, there has been a consistent reduction in number of deaths of heart transplant candidates (from 406 in 2015 to 224 in 2019). This may be due to adoption of new medical innovations such as ventricular assistance device.

Current estimates of HSCTs performed annually are greater than 50,000 worldwide. The annual rate of growth of this procedure has been estimated to between 40% and 50%. Improved HSCT-related healthcare has resulted in less morbidity and lower mortality rates. Historically, HSCTs for hematologic malignancies were undertaken as salvage therapy for refractory cancers, but outcomes are actually better for patients who are treated with HSCT soon after diagnosis or in remission, rather than after multiple relapses of hematologic disease. Outcomes have improved in both autologous and allogeneic HSCTs. There are various reasons that the success of HSCT has improved. In the setting of autologous HSCT, changes in conditioning regimens, hematopoietic growth factors, and the use of peripheral blood stem cells rather than bone marrow stem cells have been credited in part with improving mortality by shortening the duration of neutropenia (and incidence of severe infections) after intensive chemotherapy or radiation. In addition, better supportive care, antibiotic use, and blood product support have all improved outcomes for autologous HSCT. For allogeneic HSCT, CSA was introduced in the 1980s as an immunosuppressive agent limiting the severity of GVHD, making allogeneic donor HSCT practical. Decrease in severe GVHD has improved outcomes in allogeneic HSCT. Additionally, CMV accounted for high rates of mortality seen in patients treated with an allogeneic HSCT. Viral transmission can be limited by using screened "CMV-free" blood products for CMV-negative patients or using leukocyte-reduced blood products for transfusions. CMV-positive patients are treated with a

Table 20-5 Patient survival rates for transplants performed 2008–2015.

	Type of Transplant			
Type of Survival	**Renal (Living Donor)**	**Renal (Cadaveric Donor)**	**Liver (Cadaveric Donor)**	**Lung (Cadaveric Donor)**
1-year graft survival (%)	97.5	93.2	89.1	86.7
5-year graft survival (%)	85.6	74.4	71.9	52.5
1-year patient survival (%)	98.8	96.3	91.2	87.4
5-year patient survival (%)	92.1	83.3	75.0	55.0

prophylactic or, more recently, "preemptive" strategy using new high-sensitivity assays for CMV reactivation. These procedures have decreased the mortality associated with CMV interstitial pneumonitis. Post-transplantation cell growth factors have also been cited as improving outcomes in allogeneic HSCT patients. In allogeneic HSCT, advances have led to a decrease in overall mortality. The introduction of nonmyeloablative HSCT with RIC regimens allows for faster recovery of blood lineages and fewer complications post transplant. There are many patients who have survived HSCT for 5 years or more, and the future holds even greater promise as various transplantation techniques become further refined.

Outcomes of recipients who have received both bone marrow and solid organ transplantation have also been reviewed. There are many clinical and immunologic considerations that are highlighted by reviewing this unique patient population. Further research regarding the concept of immunologic tolerance/chimerism in patients who have had both a solid organ and an HSCT transplant may provide clues for future studies or for consideration of routine treatment regimens, including HSCT with the transplanted solid organ. Close monitoring of these patients will allow a better understanding of the concept of chimerism and tolerance.

ORAL HEALTH SEQUELAE IN TRANSPLANTATION

Oral complications post transplantation may affect the patient at any time. Some may subside and others may become chronic and be detrimental to patient quality of life. The following section will extend on each oral complication (Box 20-2).

Infections

Following transplantation, patients are more susceptible to bacterial, viral, and fungal infections, to include the oral cavity. Signs of oral infection may be muted by a decreased inflammatory response, or occasionally signs of infection may be exaggerated. Oral infection is often related to the level of immunosuppression and the patient's ability to mount an immune response. Oral infections must be diagnosed and aggressively treated, as these localized infections can spread quickly. Furthermore, systemic infections can present as changes in the oral tissues and it is important to remember that in severely immunocompromised patients, infections could be caused by opportunistic microbes that are not usually associated with oral infection. Laboratory tests such as culture, polymerase chain reaction (PCR), and sensitivity testing are prudent to target the therapy to the source of the infection.

Box 20-2 Oral Complications in Transplant Patients

1) Infections - viral, fungal, deep fungal, bacterial
2) Dental caries
3) Periodontal and gingival complications
4) Oral ulcerations due to medications
5) Dysgeusia and dysphagia
6) Malignancy - lymphoma, Kaposi sarcoma, basal cell carcinoma
7) Graft-versus-host disease
8) Soft tissue overgrowth (nongingival)
9) Oral mucositis
10) Salivary gland dysfunction
11) Developmental tooth defects and dentofacial growth alterations
12) Neurologic complications
13) Vitamin deficiency–related oral lesions

Viral infections occur frequently in immunosuppressed patients. Recurrent HSV is the most common viral pathogen cultured from oral infections in HSCT patients. Recurrent HSV infections can be labial or intraoral (Figures 20-2, 20-3, and 20-4). Whereas in immunocompetent individuals HSV typically presents on keratinized mucosa, in immunocompromised patients the nonkeratinized mucosa may also be affected. Recrudescence intraoral herpes may be chronic and difficult to diagnose based solely on clinical appearance, and is associated with decreased mortality at 2 years post HSCT.[15]

VZV, EBV, and CMV have been implicated in oral disease, although they are much less common than HSV. VZV may affect the oral or extraoral tissues, and its unilateral presentation is often diagnostic. Oral CMV has a nonspecific

Figure 20-2 Recurrent herpes labialis in an immunocompromised patient.

Figure 20-3 Recurrent herpes labialis in an immunocompromised patient.

Figure 20-4 Kaposi sarcoma in a patient post hematopoietic stem cell transplantation.

presentation and it is critical to test for this potentially fatal virus. It is unclear whether human herpesvirus 6 infection is associated with oral lesions, although it has been detected in the saliva.[16]

Oral hairy leukoplakia related to EBV has been reported in transplant recipients not infected with the human immunodeficiency virus (HIV). Whereas in the past this pathology was typically observed in HIV patients, and to a lesser extent in patients post solid transplant, it has been reported in immunocompetent individuals.

Before transplantation, viral serologic tests are performed, and patients are immunized according to the recommended protocols.[17–19] Antiviral prophylaxis is often used and strategies for preemptive treatments are recommended. Treatment of viral infections requires administration of the appropriate antiviral agent. Occasionally, HSV is not responsive to acyclovir, valacyclovir, or famciclovir, therefore requiring foscarnet or cidofovir. If the disease has disseminated, the antiviral treatment will be delivered IV in an inpatient

Figure 20-5 Pseudomembranous candidiasis in a transplant recipient.

Figure 20-6 An everolimus induced oral ulcer in a patient post cardiac transplant.

setting. For CMV the first line of treatment is ganciclovir, valganciclovir or letermovir. New antiviral agents and strategies are being developed such as brincidofovir (CMX001), as well as virus-specific T-cell infusions.

Immunosuppressed patients are more susceptible to fungal infections such as *candidiasis*, as well as deep fungal infections such as aspergillosis, cryptococcosis, mucormycosis, and blastomycosis (Figures 20-5 and 20-6). There are various oral

Figure 20-7 Atrophic candidiasis.

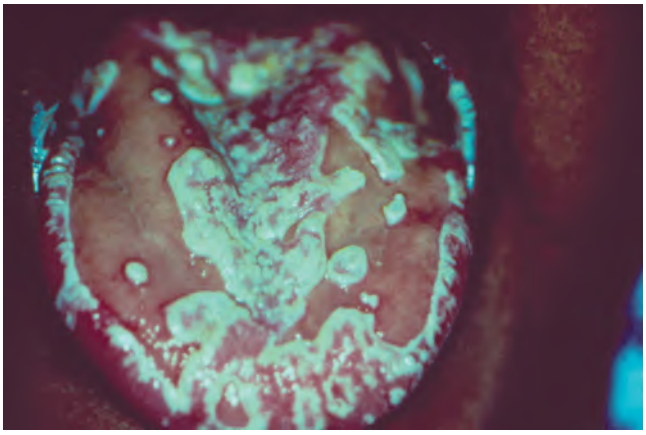

Figure 20-8 Hyperplastic candidiasis in a kidney transplant recipient. This infection did not respond to fluconazole.

presentations to these infections. Candidiasis can occur in the classic, pseudomembranous form, or it can be atrophic or even hyperplastic (Figures 20-5, 20-7, and 20-8). Occasionally candidiasis is not responsive to standard antifungals and may need treatment with IV antifungal agents.

Deep fungal infections involving the upper respiratory tract/sinuses may present as necrotic plaques on the palate of recipients of HSCT (Figure 20-6). Rarely, deep fungal infections may present in other sites in the oral cavity. These fungal infections are very difficult to treat and often require IV antifungal agents and surgical debridement. In severely neutropenic patients, these infections may be fatal, with the patient ultimately succumbing to a disseminated deep fungal infection.

Bacterial infections frequently affect the oral mucosa in patients undergoing HSCT. The main causative bacterial species are gram-negative bacilli (*Pseudomonas aeruginosa*, *Klebsiella pneumoniae*) and gram-positive cocci (*Staphylococcus aureus*, *Staphylococcus epidermidis*, and *Streptococcus pyogenes*), typically presenting as a painful ulceration. The clinical signs may be deceiving, as immunosuppression masks the full scale of the local inflammation.[20,21] Treatment is based on antibiotics and basic oral care. In HSCT, the protocol usually includes a combination of two or three types of antibiotics. Culture and antibiotic sensitivity are critically important if the empiric choice of antibiotic(s) is ineffective.

Dental Caries

An increased incidence of caries in the post-transplantation period has been reported. Children who have undergone HSCT for ALL have a higher incidence of caries and a higher decayed, missing, and filled teeth (DMFT) index. An age and gender, case-control matched study reported a significant increase in the prevalence of caries and periodontal disease in patients post liver transplantation compared to controls. Other studies describe a relative decrease of salivary immunoglobulin A (IgA) levels and increased salivary pH in children post liver transplantation, and altered dental development post HSCT. A retrospective study in a cohort of patients who developed chronic GVHD after allogeneic transplantation showed that more than 50% developed extensive cervical caries 2 years after transplantation. These studies highlight the importance of dental caries as a late complication of GVHD post transplantation.

Periodontal and Gingival Complications

Periodontal health in the transplant population is often compromised. Medical necessities including the long-term use of steroids and immunosuppressants contribute to the high rate of periodontal problems.[22,23] Side effects of transplant-related medications have been associated with periodontal disorders, particularly gingival overgrowth. The medication-induced gingival overgrowth seen in the transplant recipient in Figure 20-9 appears to be related to the immunosuppressive agent CSA. Furthermore, CSA-associated

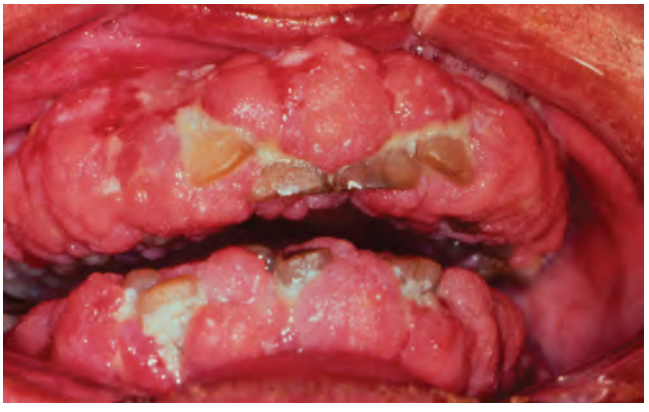

Figure 20-9 Gingival overgrowth in a kidney transplant recipient taking cyclosporine and nifedipine who also had poor oral hygiene.

gingival overgrowth may be amplified by the coadministration of nifedipine, a calcium-channel blocker often used to treat hypertension in this patient population. Nifedipine is frequently the drug of choice because it does not alter plasma levels of CSA. Administration of tacrolimus instead of CSA has significantly reduced the incidence and severity of gingival hyperplasia.[24]

A biopsy/histopathologic analysis should be performed on the overgrown gingival tissue if malignancy is suspected. Impeccable oral hygiene can prevent gingival overgrowth. Partial reversal of CSA-induced overgrowth has been reported upon discontinuation of the medication. Although treatment of severe gingival overgrowth usually requires a gingivectomy, nonsurgical periodontal treatment (scaling, root planing, oral hygiene instructions) reduces bleeding on probing, plaque index, probing depth, and the hypertrophy index in some transplant patients.

Oral Ulcerations Due to Medications

With the introduction of novel immunosuppressant agents, new oral complications have been identified. Targeted therapy agents are reportedly associated with several types of oral lesions. Among the classes of targeted therapy prescribed in transplant patients, the following cause oral complications: mTOR inhibitors (everolimus, temsirolimus, and sirolimus), multikinase angiogenesis inhibitors (sorafenib, sunitinib, cabozantinib, pazopanib), human epidermal growth factor receptor inhibitors (dacomitinib, afatinib), and TKIs (imatinib).[25] Another group of drugs increasingly utilized in transplant medicine is the immune checkpoint inhibitors for post-transplant malignancies, including the PD-1/PD-L1 inhibitors (nivolumab, pembrolizumab).[26] Additional agents belonging to the targeted therapy or immune checkpoint inhibitors have reportedly induced oral lesions.

The most commonly reported oral complication of targeted therapy is mucositis or stomatitis. However, this description often includes many types of oral lesions presenting as erythema or ulceration. The more specific description includes aphthous-like ulcers appearing either as a single small elliptic ulcer ("minor"), a polygonal ulcer larger than 10 mm ("major"), or simultaneous numerous ulcers. The agents causing the aphthous-like ulcers are sirolimus, everolimus, temsirolimus, and to a lesser extent sunitinib. These lesions may be severe, causing pain, limiting oral intake, and leading to discontinuation of the drug. The treatment is frequently dose adjustment and topical steroids.

Another unique oral mucosal lesion associated with targeted therapy is lichenoid changes in the form of white striations with erythema or ulceration, which was reported in association with sunitinib, nivolumab, and imatinib.[25,26]

Interestingly, some of these agents have been reported to induce geographic tongue (bevacizumab, sorafenib, and sunitinib), grayish-bluish hyperpigmentation of the palate (imatinib), and reactional hyperkeratotic plaques (dabrafenib, sorafenib).[25–28]

Dysgeusia and Dysphagia

Taste changes are common post HSCT, and have also been documented post solid organ transplant. These changes can appear in the days following the HSCT conditioning regimen and usually resolve within 2.5 months,[29] but may linger for years.[30] In pediatric patients these changes reportedly resolve in about 6 months.[31] Immediate hypogeusia was reported in 66% of patients during the neutropenic phase, and the bitter taste commonly described seems to be related to the cytotoxics, and not to the presence of oral mucositis or to reduced salivary flow.[32] Late taste change may be related to cGVHD.[33]

After liver and kidney transplants, dysgeusia was reported in 11%–24% of patients.[23,34]

Taste changes after solid organ transplant are usually associated with polypharmacy and the medications administered during the course of immunosuppression.[26] Targeted therapy and immunotherapy are also associated with altered taste.[26,30] Additionally, vitamin deficiency and poor nutrition may contribute to taste loss.

Malignancy

Oral lesions in transplant recipients may be neoplasms, since these patients are at a higher risk of developing lymphoma, which is on the spectrum of PTLDs. PTLD develops in the presence of immunosuppression; it may manifest as a benign localized lesion, as a flu-like disease, or as a full-blown lymphoma. Often EBV is identified in malignant PTLD and in these cases the treatment includes acyclovir and a reduction of immunosuppression. However, not all lymphomas regress following this protocol. Oral manifestations of PTLD include a persistent localized ulcer or a mass.[35]

Patients post HSCT are considered high risk for squamous cell carcinoma of the oral mucosa.[36] This risk is associated with cGVHD, azathioprine in the conditioning regimen, or radiation at a young age.[37] Accordingly, the National Institutes of Health (NIH) consensus paper recommends thorough evaluation of oral tissues twice a year.

Post-transplant oral Kaposi sarcoma (OKS) is not as frequent as AIDS-associated OKS and overall is considered rare. OKS in the mouth and oropharynx accounted for about 2% of all post-transplant Kaposi sarcomas.[38] The median time to its development is 23.3 months.[39] When OKS develops, it most often affects the hard and soft palate, gingiva, and dorsal

tongue. When large OKS may be associated with pain and bleeding, and may become secondarily infected. The adjacent teeth may become mobile, and the OKS may interfere with oral function. Treatment for Kaposi sarcoma post transplant is by reduction of immunosuppression, conversion to mTOR inhibitors, chemotherapy, or a combination of these.[40]

Graft-versus-Host Disease

GVHD is usually considered a unique complication of HSCT, but has also been reported post colon transplant, face transplant, and blood transfusion.[41] In the oral cavity, cGVHD can manifest with a lichenoid appearance, erythema, or ulceration (Figure 20-10). These lesions are usually associated with pain and sensitivity to foods that are tolerated in non-cGVHD patients. The ulcerations may serve as a port of entry for pathogens. The gingivae are often atrophic and there may be desquamative gingivitis. cGVHD can affect the salivary glands, resulting in dry mouth or multiple mucoceles, which contribute to difficulty swallowing, oral candidiasis, and rampant caries. Additionally, cGVHD may affect the connective tissue and result in limited mouth opening and tongue movement. Taken together, these changes restrict oral intake and have a negative impact on the patient's quality of life. The latest version of the scoring systems for oral cGVHD was developed by the NIH and published in 2014 (Figure 20-11).[42] It refers to most of these oral manifestations and helps to communicate between clinicians, as well as to evaluate the response to treatment.

Figure 20-10 Graft-versus-host disease in a hematopoietic cell transplantation recipient.

Treatment goals are to relieve symptoms, control the activity level of the disease, and surveil for oral cancer. Oral cGVHD is challenging to treat and may require a change to the immunosuppressive regimen, and the implementation of systemic or topical mucosal therapy. When oral cGVHD is the only resistant site to systemic steroids, or when it is the sole site of the cGVHD, topical steroids are usually employed.[43] Topical tacrolimus, phototherapy, CO_2 laser, or topical CSA may be beneficial. Intra-lesional steroid injections may be applied in persistent isolated lesions. It is important to manage complications of oral cGVHD, such as caries and oral candidiasis.

Benign Soft Tissue Overgrowth (Nongingival)

Patients post HSCT may develop benign oral lesions such as pyogenic granuloma and verruciform xanthoma.[44,45] The evidence of these rare lesions is based on case reports. Nevertheless, it seems that chronic inflammation associated with cGVHD releases lipids that are phagocytosed by histiocytes, which is the first step in the development of a xanthoma, or induces capillary proliferation, which is the hallmark of pyogenic granuloma. Rarely, CSA may induce soft tissue overgrowth, unrelated to the gingivae, and these lesions have been seen in the buccal mucosa, alveolar mucosa, and elsewhere in the oral cavity (Figure 20-12).

There is an anecdotal report of tertiary hyperparathyroidism affecting the mandible.[46] Although the patient had a kidney transplant, the parathyroid glands functioned abnormally while the patient was in kidney failure, and parathyroid gland function did not return to normal, causing multiple brown tumors to develop in the mandible.

Oral Mucositis

Oral mucositis (OM) is defined as an inflammation of the mucosa accompanied by a burning or tingling sensation. It is

Erythema	None	0	Mild erythema or moderate erythema (<25%)	1	Moderate (≥25%) or Severe erythema (<25%)	2	Severe erythema (≥25%)	3
Lichenoid	None	0	Lichen-like changes (<25%)	1	Lichen-like changes (25–50%)	2	Lichen-like changes (>50%)	3
Ulcers	None	0			Ulcers involving (≤20%)	3	Severe ulcerations (>20%)	6
							Total score for all mucosal changes

Figure 20-12 Nongingival soft tissue growth.

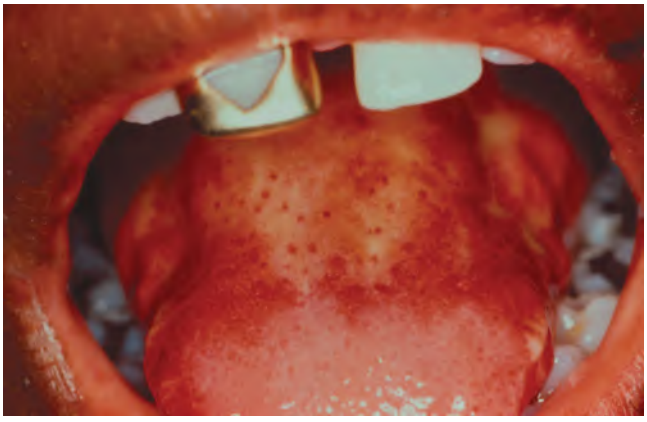

Figure 20-13 Mucositis shortly after induction chemotherapy for acute myelogenous leukemia.

characterized by atrophy of the squamous epithelium, vascular damage, inflammatory infiltration, and ulceration (Figure 20-13). It is common in patients who have had chemotherapy, radiotherapy to the head and neck, or HSCT. Mucositis is a diagnosis of exclusion, made by elimination of other etiologies, such as infection, topical drug chemical irritation, local trauma, or hypersensitivity reaction to a drug. OM in patients undergoing HSCT is associated with worse outcomes in terms of increased risk of significant infection, additional days of fever, total parenteral nutrition, injectable narcotic therapy, hospitalization, and an increase in 100-day mortality risk.[47]

The pathogenesis of mucositis involves simultaneous multistep molecular reactions that are outlined as a five-phase model: induction, upregulation and message generation, signaling and amplification, ulceration, and healing.[48] The understanding of the pathogenesis of mucositis has advanced over the years and the role of the microbiome in the development of mucositis has been noted.[49] There are numerous scales evaluating and measuring OM. The most commonly used are the World Health Organization (WHO) scale and the National Cancer Institute (NCI) Common Terminology Criteria for Adverse Events (CTCAE) scale. The Oral Mucositis Assessment Scale (OMAS) has been validated and is often used in research. In addition, measurements of oral pain are used routinely following HSCT.

There are several goals in the management of OM, specifically prevention, treatment, and pain relief. A plethora of interventions for OM have been studied, including photobiomodulation; anti-inflammatory agents; vitamins, minerals, and nutritional supplements; growth factors and cytokines; antimicrobials; mucosal coating agents; anesthetics; analgesics; cryotherapy; natural and miscellaneous agents; and protocols categorized as basic oral care.[50] The Multinational Association of Supportive Care in Cancer/International Society for Oral Oncology (MASCC/ISOO) developed evidence-based guidelines for the management of mucositis.[51–58] The 2019 MASCC/ISOO guidelines are presented in Table 20-6.

A detailed description of the oral complications associated with oncologic treatment and their management can be found in Chapter 9.

Salivary Gland Dysfunction

Salivary gland dysfunction is common in patients after HSCT and may be related to the toxic effects of the conditioning regimens. Additionally, cGVHD may cause salivary dysfunction. The pathogenesis of salivary gland cGVHD is similar to the process reported in Sjögren's syndrome (Figure 20-14).

Xerostomia affects up to 48% and up to 30% of liver and kidney transplant recipients, respectively.[23,59] The risk of xerostomia correlates with the number of medications taken by the patient. The targeted therapy and immunotherapy agents sunitinib, everolimus, sorafenib, pazopanib, cabozantinib, bevacizumab, and imatinib reportedly cause xerostomia.[60,61]

Developmental Abnormalities

Developmental tooth defects affect up to 55% of survivors of childhood cancer.[62] Younger age at treatment and intensive chemotherapy increase the risk of long-term dental abnormalities among those treated with HSCT.[63] In particular, children conditioned with TBI and high-dose chemotherapy before HSCT are at high risk for dental developmental abnormalities.[63] The most common dental anomaly is microdontia, followed by tooth agenesis (20.4%), V-shaped roots (14.8%), and taurodontism (Figure 20-15). Dentofacial growth alterations have been reported in children post

Table 20-6 The MASCC/ISOO clinical practice guidelines for the management of oral mucositis.

Section	Intervention		LoE	Category	Guideline statement	Comment*
BOC	Multiagent combination	1	III	Suggestion	• The panel suggests that implementation of **multiagent combination** oral care protocols is beneficial for the prevention of OM during CT	New in 2019
		2	III	Suggestion	• The panel suggests that implementation of **multiagent combination** oral care protocols is beneficial for the prevention of OM during H&N RT	New in 2019
		3	III	Suggestion	• The panel suggests that implementation of **multiagent combination** oral care protocols is beneficial for the prevention of OM during HSCT	New in 2019
	Professional oral care	4	III	NGP/ expert opinion	• No guideline was possible regarding the use of **professional oral care** for the prevention of OM for patients with hematologic, solid, or H&N cancers due to limited and inconsistent data • An expert opinion complements this guideline. Although there was insufficient evidence to support the use of professional oral care for OM prevention, the panel is of the opinion that dental evaluation and treatment as indicated prior to cancer therapy is desirable to reduce risk for local and systemic infections from odontogenic sources	New in 2019
	Patient education	5	III	NGP/ expert opinion	• No guideline was possible regarding the use of **patient education** for the prevention of OM in hematologic cancer patients during HSCT or CT due to limited and inconsistent data • An expert opinion complements this guideline. The panel is of the opinion that educating patients about the benefits of BOC strategies is still appropriate as this may improve self-management and adherence to the recommended oral care protocol during cancer treatment	New in 2019
	Saline or sodium bicarbonate	6	III	NGP/ expert opinion	• No guideline was possible regarding the use **of saline or sodium bicarbonate** rinses in the prevention or treatment of OM in patients undergoing cancer therapy due to limited data • An expert opinion complements this guideline. Despite the limited data available for both saline and sodium bicarbonate, the panel recognizes that these are inert bland rinses that increase oral clearance which may be helpful for maintaining oral hygiene and improving patient comfort	New in 2019
	CHX	7	III	Suggestion against	• The panel suggests that **CHX** not be used in the prevention of OM in patients undergoing H&N RT	Confirmed in 2019

(*Continued*)

Table 20-6 (Continued)

Section	Intervention		LoE	Category	Guideline statement	Comment*
Anti-inflammatory agents	Benzydamine	8	I	Recommendation	• The panel recommends **benzydamine** mouthwash for the prevention of OM in patients with H&N cancer receiving a moderate dose RT (<50 Gy)	Confirmed in 2019
		9	II	Suggestion	• The panel suggests the use of **benzydamine** mouthwash for the prevention of OM in patients with H&N cancer receiving RT-CT	New in 2019
PBM (laser/light therapy)	PBM	10	I	Recommendation	• The panel recommends the use of intra-oral **PBM** therapy using low level laser therapy for the prevention of OM in adult patients receiving HSCT conditioned with high-dose CT, with or without total body irradiation using one of the selected protocols;** it is recommended that the specific PTPs of the selected protocol will be followed for optimal therapy	New in 2019
		11	II	Recommendation	• The panel recommends the use of intra-oral **PBM** therapy using low level laser therapy for prevention of OM in adults receiving RT to the H&N (without CT);** the specific PTPs of the selected protocol should be followed for optimal therapy • Safety considerations unique to patients with oral cancer should be considered	New in 2019
		12	I	Recommendation	• The panel recommends the use of intra-oral **PBM** therapy using low level laser therapy for the prevention of OM in adults receiving RT-CT for H&N cancer (LoE I);** the specific PTPs of the selected protocol should be followed for optimal therapy • Safety considerations unique to patients with oral cancer should be considered	New in 2019
Cryotherapy	Cryotherapy	13	II	Recommendation	• The panel recommends using oral **cryotherapy** to prevent oral mucositis in patients undergoing autologous HSCT when the conditioning includes high-dose melphalan	Confirmed in 2019
		14	II	Recommendation	• The panel recommends using 30 minutes of oral **cryotherapy** to prevent oral mucositis in patients receiving bolus 5-FU CT during the infusion of the CT	Confirmed in 2019
Antimicrobials, coating agents, anesthetics, analgesics	Morphine rinse	15	III	Suggestion	• Topical **morphine** 0.2% mouthwash is suggested for the treatment of OM-associated pain in H&N cancer patients treated with RT-CT	Confirmed in 2019
	Sucralfate	16	II	Recommendation against	• **Sucralfate** (combined topical and systemic) is not recommended for the prevention of OM-associated pain in H&N cancer patients treated with RT	Confirmed in 2019
		17	II	Recommendation against	• **Sucralfate** (combined topical and systemic) is not recommended for the treatment of OM-associated pain in H&N cancer patients treated with RT	Confirmed in 2019
		18	II	Recommendation against	• **Sucralfate** (combined topical and systemic) is not recommended for the treatment of OM-associated pain in solid cancer patients treated with CT	Confirmed in 2019

Growth factors & cytokines	KGF-1	19	I	Recommendation	• The use of **KGF-1** intravenously is recommended for prevention of OM in patients with hematological cancer undergoing autologous HSCT with a conditioning regimen that includes high dose chemotherapy and TBI	Confirmed in 2019
	GM-CSF	20	II	Suggestion against	• The evidence suggests that topical **GM-CSF** should not be used for the prevention of OM in patients undergoing HSCT	
Natural & miscellaneous	Glutamine	21	I	Recommendation against	• The panel recommends against the use of **glutamine** (parenteral) for the prevention of OM in patients undergoing HSCT	Confirmed in 2019
		22	II	Suggestion	• The panel suggests **glutamine** (per os) for the prevention of OM in patients with H&N cancer receiving RT-CT • The suggestion is with caution due to the higher mortality rate seen in HSCT patients treated with parenteral glutamine	New in 2019
	Honey	23	II	Suggestion	• **Honey** is suggested for the prevention of OM in H&N cancer patients treated with either RT or RT-CT	New in 2019
	Chewing gum	24	III	Suggestion against	• **Chewing gum** is not suggested for the prevention of OM in pediatric patients with hematological or solid cancer treated with CT	New in 2019
Antimicrobials, coating agents, anesthetics, analgesics	Patient-controlled analgesia with morphine	1	**II**	Recommendation	• The panel recommends that **patient-controlled analgesia with morphine** be used to treat pain due to oral mucositis in patients undergoing HSCT	Rolled over to 2019
	PTA or BCoG	2	**III**	Recommendation against	• The panel recommends that **PTA** and **BCoG** antimicrobial lozenges and PTA paste not be used to prevent OM in patients receiving RT for H&N cancer	Rolled over to 2019
	Iseganan	3	**II**	Recommendation against	• The panel recommends that **iseganan** antimicrobial mouthwash not be used to prevent OM in patients receiving high-dose chemotherapy, with or without total body irradiation, for HSCT	Rolled over to 2019
		4	**II**	Recommendation against	• The panel recommends that **iseganan** antimicrobial mouthwash not be used to prevent OM in patients receiving RT or RT-CT for H&N cancer	Rolled over to 2019
	Pentoxifylline	5	**III**	Suggestion against	• The panel suggests that **systemic pentoxifylline**, administered orally, not be used to prevent OM in patients undergoing bone marrow transplantation	Rolled over to 2019
Natural & miscellaneous	Pilocarpine	6	**III**	Suggestion against	• The panel suggests that **systemic pilocarpine**, administered orally, not be used to prevent OM in patients receiving RT for H&N cancer	Rolled over to 2019
		7	**II**	Suggestion against	• The panel suggests that **systemic pilocarpine**, administered orally, not be used to prevent OM in patients receiving high-dose CT, with or without TBI, for HSCT	Rolled over to 2019

HSCT.[64] The mean area of the mandibular central incisor, first, and second molar was significantly smaller in individuals post HSCT, and the vertical growth of the face was significantly reduced, especially in the lower third, compared to healthy controls.[65] Children undergoing HSCT had significantly more growth reduction in vertical craniofacial variables compared to healthy children.

Positive correlations were found between discoloration of the deciduous teeth and liver transplantation, between enamel hypoplasia and kidney transplantation, and between treatment with CSA and its dose and blood concentration.[66] Additionally, pulp stones were present in 13% of kidney versus 8% of liver recipients, more often in those treated with CSA than with tacrolimus. The presence of pulp stones correlated with the administration of glucocorticoids. Jawbone abnormalities affected 30% of kidney recipients and 12% of liver recipients, including foci of density and reduced bone density. Jaw abnormalities were also associated with glucocorticoid treatment.[66]

Neurologic Complications

Patients treated with targeted therapy and immunotherapy may report oral mucosal sensitivity (dysesthesia) without any abnormal clinical findings. This dysesthesia was most frequently associated with sunitinib and sorafenib.[61] It is unclear what analysis was done to eliminate known factors that contribute to oral burning; however, the literature refers to the condition as burning mouth syndrome.

Face transplant requires a long period for the establishment of reliable neurologic connections, and during this recovery time numbness in the trigeminal branches that were reconnected is expected. There are a limited number of reports on face transplantation, but the range of time for regaining sensation is 3–24 months.[67,68] This also applies to tooth vitality. Interestingly, an abnormal vitality test in which a stimulus to an upper premolar evoked a response in the upper incisors was reported.[68]

Vitamin Deficiency–Related Oral Lesions

Iron deficiency is common in patients with end-stage renal disease. Anemia improved within 1 year of kidney transplant, although iron deficiency increased.[69] The extent of the role of iron deficiency in post-transplant oral mucosal atrophy is unclear.

Intestinal transplant recipients may experience long-term intestinal insufficiency with pan-vitamin deficiency. The dentist may encounter the oral manifestations of malnutrition, including hypovitaminosis. The effect of vitamin deficiency is reviewed elsewhere.[70]

DENTAL TREATMENT

There are several principles in the approach to dental treatment for transplant patients, in particular the timing of the dental treatment relative to the transplant procedure: pre transplant, during transplant, and post transplant. Additionally, there are considerations specific to certain types of transplants. These considerations will be presented separately.

Pre-transplantation Considerations

General

The main consideration before the transplant is to eliminate dental infections that may impede transplantation. The process of evaluation and treatment planning prior to transplant is often referred to "clearance," and this process requires coordination with the transplant team. The concern is that sites of asymptomatic infection may flare up while the patient is immunosuppressed or hospitalized for the transplant procedure. Clearance involves a thorough evaluation of the dentition, periodontium, and oral mucosa. Controversy exists regarding the optimal radiographic examination for these patients. Some dentists feel that a full mouth series is necessary and others prefer a panoramic film and bitewings. There is consensus, however, on the importance of having access to recent dental radiographs.

Considering dental management goals, the treatment plan differs significantly to that of a routine treatment plan for a healthy patient. While eliminating foci of infection, sites of acute infection are prioritized, particularly if these sites are symptomatic. The treatment plan needs to be definitive and eliminate these foci as quickly as possible. Occasionally, chronic dental infections may be considered a priority as well. However, it is often clear that not all dental needs can be addressed before transplant, and elective dental treatment in patients with life-threatening end-stage disease should be postponed until the medical condition permits.

Although immunosuppression for solid organ transplants is not associated with neutropenia, the approach used in cancer patients prior to chemotherapy highlights the types of dental conditions considered as potential sites of infection. A list of dental conditions that put patients at risk for infection during times of immunosuppression includes nonrestorable teeth (e.g., those with severe periodontal disease, gross decay that involves the pulp), symptomatic teeth, and partially erupted third molars with a history of pericoronitis.[71] Furthermore, teeth posing risk for food impaction should be considered as high priority.

The more severe the immunosuppression, the more definitive dental treatment should be. Therefore, in patients undergoing HSCT, treatment decisions are determinative. On the other hand, in patients undergoing solid organ transplantation with a relatively short period of immunosuppression, dental needs that are not categorized as high priority may be postponed. In such cases, the patient should be informed about these unmet dental treatment needs and advised to follow up with their primary dentist post transplant when routine dental treatment has been approved.

During dental clearance, the patient should be advised to follow up with the dental team periodically, since there may be an extended waiting period until the actual date of transplant. Periodic dental checkups and hygiene visits are important during this time, and the low-priority dental needs may be addressed if the medical condition permits.

Specific organ dysfunction poses unique challenges. Transplant-specific considerations are detailed below. Occasionally multiorgan transplants are performed, to include heart–lung, lung–kidney, lung–liver, and kidney–pancreas transplants. In such cases, aspects related to each transplanted organ need to be followed.

Liver Transplant

The main concern in patients with end-stage liver disease is bleeding. In liver transplant candidates, the potential for bleeding is unpredictable. On top of the coagulopathy there is secondary portal hypertension that leads to destruction of platelets in the spleen, and patients may be resistant to platelet transfusions. The complexity of hemostasis impairment is driven also by the presence of anemia, reduced thrombopoietin production, and vitamin K deficiency, which may be seen in this patient population. Furthermore, preoperative coagulation tests may not correlate with the level of bleeding during an operation. Specifically, in the Model for End-Stage Liver Disease (MELD), preoperative prothrombin time (PT), preoperative partial thromboplastin time (PTT), preoperative INR, and preoperative platelet count were not statistically significant in predicting postoperative bleeding.[72]

A major bleeding episode following a dental extraction has been reported.[73] This type of bleeding may develop despite preoperative systemic coagulation-promoting medication and fresh plasma preoperatively, and may be life-threatening.[73]

A preoperative tool to assess bleeding risk pre liver transplant has been proposed.[72] In this study, patients were placed into three risk groups (minimal, moderate, high) based on the number and complexity of teeth to be extracted as well as any planned adjunctive preprosthetic procedures. The study found a relatively high rate of severe bleeding (6%, 12.5%, and 50% for low, moderate, and severe risk groups, respectively). Despite a more aggressive preoperative management protocol for the high-risk patients, 5/10 (50%) experienced prolonged postoperative bleeding, with 3/5 (60%) requiring hospital admission, and 1/5 (20%) experienced a significant prolongation of their inpatient stay.

More recently a few cohorts showed only minor bleeding when platelet transfusions were administered preoperatively. However, most of the studies reported no correlation

between the preoperative platelet count or INR and the risk for bleeding, highlighting the unpredictable nature of this bleeding risk. Notably, all these studies were conducted in Europe or Brazil; therefore, the availability of local hemostatic agents varies.[74–76] One study suggested a low risk of bleeding following tooth extraction in patients with liver cirrhosis, INRs of 2.5 or less, and platelet counts of 30,000/mm^3 or greater, and bleeding was controlled with local hemostatic measures.[77] Nevertheless, the unpredictability of the bleeding risk remains an issue. A lab test named thromboelastography (TEG) may be used in this patient population to guide the decisions about platelets and other blood products transfusions in order to reduce the bleeding risk.[78]

While risks associated with oral infection are well known, there is no consensus regarding the level of inflammatory disease that would hamper the transplant procedure and scope of dental therapy required in the pre/post-transplant patient to prevent oral infection.[79] Accordingly, although many publications support a minimal approach, the cutoff between minimal dental treatment and avoiding dental treatment is unclear.

Accordingly, the current view is that a dental examination before transplantation is essential, and that the nature of dental treatment may have to be modified according to patient health status. Importantly, infections from dental sources in the immediate term following transplantation appear to be rare or have not been reported because they were managed.[80] Therefore, the risk for dental treatment–related bleeding before liver transplant may outweigh the risk of infection in the period immediately after a liver transplant.

Consequently, a selective approach is needed for foci of infection when one of the following exists: acute dental infection that manifests as pain, fever, lymphadenopathy, extraoral swelling, intraoral swelling, and vestibular tenderness together with tenderness to percussion. These signs likely indicate an acute dentoalveolar abscess and justify extraction of the involved tooth. Risk for aspiration is another indication for dental intervention prior to liver transplant. For signs of low- to moderate-level infection, the transplant team and the patient should be informed, but the extraction may need to be postponed until after liver transplant (approximately 3 months). Although this empiric approach seems to be a reasonable inference from the literature, there are few data from clinical trials to support it.

Another concern in patients with end-stage liver disease is the ability to metabolize medications. Medications are often adjusted pre transplant because of altered hepatic metabolism (Table 20-7). These changes may be either dose reduction, longer intervals between doses, or complete avoidance of certain drugs. The dentist should be familiar with the available tools to identify medications that need to be altered in this population. There are several open databases that offer this information (e.g., ePocrates, UpToDate).

The necessity for antibiotic prophylaxis in patients pre liver transplant has been discussed in the literature, including whether prophylaxis is needed due to the vulnerability of these patients and risk for peritonitis, or whether an antibiotics is harmful to the failing liver.[81] Furthermore, considering that spontaneous bacterial peritonitis caused by *Streptococcus viridans* has only been noted in patients with multiple dental infections, it is possible that a surgical procedure on an infected site will cause a bacteremia.[82] A cohort study in 346 liver transplant candidates reported that routine extractions without antibiotic prophylaxis can be performed safely, 86% of patients had no complications, and 14% had minor complications.[74] This dilemma indicates that each patient should be assessed individually, and a consultation with an infectious diseases specialist may be needed.

Kidney Transplant

Kidney transplantation is the optimal modality of treatment for patients with end-stage kidney disease (ESKD). It is associated with improved quality of life, lower medical costs, and improved survival.[83] The shorter the period of time on dialysis, the better the results achieved by transplantation, and the best results are seen with preemptive transplantation.[84]

Some medical complications in patients with ESKD may influence pretransplantation dental clearance. Hypertension and congestive heart failure may develop due to fluid retention and production of vasoactive hormones via the renin-angiotensin system.[85] Therefore, vital signs should be measured prior to the dental exam, and monitored continuously if the values are elevated. Blood pressure readings above 180/110 mm Hg are an indication to postpone dental treatment and refer for medical evaluation.

Reduced synthesis of erythropoietin can lead to anemia. Uremia might increase bleeding tendency due to a qualitative platelet dysfunction (decreased platelet aggregation and impaired platelet adhesiveness). Therefore, invasive dental procedures should be delivered gradually and hemostasis should be achieved between treatment steps (for example, scaling in segments to confirm hemostasis prior to moving to the next segment). Hemostatic agents should be available to minimize postoperative bleeding.

Altered cellular immunity associated with uremia may put patients with ESKD into an immunocompromised state.[86] It is important to educate patients about unique considerations and stress the importance of oral hygiene to prevent infection.

The distribution, metabolism, bioavailability, and rate of excretion of many drugs are altered, and dosage adjustment of dose or frequency is required. Potentially nephrotoxic agents should be considered carefully, for example nonsteroidal anti-inflammatory drugs (NSAIDs), acetaminophen, acyclovir, and tetracycline (Table 20-7).

Table 20-7 Medication considerations in patients with liver or kidney failure*.

	Dose Change Advised	
Drug	**Renal Dosing**	**Liver Dosing**
Acetaminophen**	CrCl 10–50: give q6h CrCl <10: give q8h HD: usual dose q8h; no supplement after dialysis PD: usual dose q8h; no supplement	(Not defined) Hepatic impairment: consider decreasing dose
Acyclovir (per os)	CrCl <10: 200 mg PO q12h (for usual dose of 200 mg x5/d) (for usual dose of 400 mg x3/d) HD: 200 mg PO q12h, on dialysis days admin. after dialysis; give additional dose as supplement PO after dialysis PD: not defined	(Not defined) Hepatic impairment: caution advised
Amoxicillin**	CrCl 10–30: 250–500 mg q12h CrCl <10: 250–500 mg q24h; info: do not use 875 mg tab for CrCl <30 HD: 250–500 mg q24h, on dialysis days administer after dialysis; consider supplement during and after dialysis if next maintenance dose not due right after dialysis PD: 250 mg q12h; no supplement; info: do not use 875 mg tab for CrCl <30	(Not defined)
Cephalexin	CrCl 50–90: give usual dose q6–8h CrCl 10–50: give usual dose q8–12h CrCl <10: give usual dose q12–24h HD: give usual dose q12–24h, on dialysis days administer after dialysis; consider supplement if next maintenance dose not due right after dialysis PD: give usual dose q12–24h; no supplement	(Not defined)
Clavulanic acid with amoxicillin**	CrCl 10–30: 250 mg/125–500 mg/125 mg q12h CrCl <10: 250 mg/125–500 mg/125 mg q24h; info: do not use 875 mg/125 mg tab for CrCl <30 HD: 250 mg/125–500 mg/125 mg q24h, on dialysis days administer after dialysis; consider supplement during and after dialysis if next maintenance dose not due right after dialysis PD: 250 mg/125 mg q12h; no supplement; info: do not use 875 mg/125 mg tab	Hepatic impairment: caution advised; amoxicillin/clavulanate-associated hepatic impairment Hx: contraindicated
Clindamycin	(No adjustment)	(No adjustment)
Codeine sulfate	CrCl 10–50: decrease dose by 25%, titrate slowly CrCl <10: avoid use HD/PD: avoid use	(Not defined) Severe impairment: caution advised

CrCl, creatinine clearance; HD, hemodialysis; Hx, history; PD peritoneal dialysis.
Source: Adapted from ePocrates, https:// online.epocrates.com/home, accessed February 2020.

As kidney disease progresses, hemodialysis is life-saving. The efficiency of hemodialysis is much lower than a functioning kidney, therefore ESKD patients on hemodialysis are in a constant state of kidney failure and uremia. The risk for bleeding is increased from the use of heparin during hemodialysis. Infective endocarditis (IE) occurs more frequently in hemodialysis patients due to the vascular access. About 2%–6% of chronic hemodialysis patients develop IE and the incidence is 50–60 times higher than in the general population.[87] IE is usually related to bacteremia associated with repeated manipulation of the vascular access, particularly central venous catheters. According to the American Heart Association (AHA) statement regarding patients with nonvalvular-cardiovascular device, including hemodialysis, antibiotic prophylaxis is recommended for patients with these devices if they undergo incision and drainage of infection at other sites (e.g., abscess).[88] Additionally, if the patient has a history of IE, the AHA guidelines for the prevention of IE should be followed.[89]

Considering that the fistula is a life port for patients on hemodialysis, it is critical when measuring blood pressure not to place the cuff on the arm used for the dialysis access. Since fluid is restricted to avoid volume overload, attempts should be made to minimize water from the dental handpiece (high-speed, ultrasonic scaler) and manual instrumentation is preferred. Likewise, rubber dam and power suction will reduce water intake.

Hemodialysis patients with poor electrolyte balance are at risk for arrhythmia and overvolume complications. This is most noticeable after a weekend interval between hemodialysis sessions. Therefore, special consideration should be made if an emergency dental visit occurs on the morning following the weekend or a similar prolonged period without dialysis.

Patients with kidney failure develop changes in bone metabolism, termed renal osteodystrophy. Dentists should be aware that manifestations of renal osteodystrophy include tooth mobility, malocclusion, pulp stones, enamel hypoplasia, bone demineralization, decreased trabeculation of cancellous bone, decreased thickness of cortical bone, radiolucent giant cell lesions, and jaw fracture (spontaneous or after dental procedures). If giant cell tumors are present in the jaws, the transplant team should be informed, and the patient should be followed up to ensure that the lesions

resolve spontaneously when kidney function returns to normal. Likewise, osteodystrophy may result in abnormal bone healing after extraction, therefore extractions should be as atraumatic as possible and wound healing post extraction should be confirmed.[85]

Kidney failure may be a complication of an underlying chronic disease, such as diabetes. These comorbidities should be addressed concomitantly.

As home hemodialysis is becoming more common, it has a marked impact on the patient's vitality, quality of life, and independence from the hemodialysis unit. These factors indirectly influence dental care.

Heart Transplant

Patients awaiting a heart transplant are usually poor candidates for outpatient dental treatment. The majority of these patients have severe CAD or congestive heart failure. Both conditions can progress to life-threatening complications during invasive dental treatment. The sole effect of stress and/or pain can cause adverse outcomes in these patients. The cardiovascular reserve of these patients is small and they are therefore much better candidates for elective dental treatment after transplantation. Some patients awaiting heart transplant may not leave the hospital until they receive their new heart.

For urgent dental problems, individually tailored treatment includes adequate anxiolysis, close monitoring, and profound local anesthesia. In a cohort of 32 patients with refractory heart failure receiving dental treatment in a specialized hospital department, adverse systemic effects were reported as arrhythmias (25%) and pulmonary congestion (19%), of whom five required medical treatment.[90] Both adverse reactions were seen in patients undergoing dental extraction or periodontal treatment. Therefore, pre–heart transplant patients undergoing dental clearance should be monitored closely. The preferred position for dental treatment is semi-supine in order to avoid pulmonary congestion. Measures to avoid unintended fluid intake should be used, such as a rubber dam and power suction. Dentists should be certified in basic life support and have a routine in place for medical emergencies (see Chapter 14 regarding congestive heart failure).

Some pre–heart transplant patients have a left ventricular assist device (LVAD). LVAD offers patients a therapeutic option that provides circulatory support while awaiting transplantation, or it may be a permanent alternative to transplantation (i.e., "destination therapy").[91] Most patients have LVADs with a nonpulsating continuous-flow pump and therefore blood pressure does not fluctuate and there is no practical way to measure blood pressure and heart rate in the conventional fashion. In these cases, dentists can get an impression about patient vitality by assessing clinically adequate perfusion by skin color, capillary refill following light pressure, and mentation status.

In addition, LVAD patients are maintained on a consistent anticoagulation regimen, and therefore have an increased bleeding tendency and risk of thromboembolic events.[92] Unfortunately, there are no robust data regarding dental treatment complications in patients with LVAD. In a retrospective review of charts of 29 patients with LVAD who underwent oral surgical procedures, bleeding as defined in this study was documented in 17 patients and bleeding correlated with the INR level.[93] In a retrospective study of 32 LVAD patients undergoing dental extractions who were monitored for bleeding complications, several approaches were applied preoperatively, including holding warfarin treatment, changing to heparin drip, or continuing with warfarin.[94] The average postoperative change in hemoglobin level was -0.79 $\pm$ 1.45 g/dL. Only 1 patient (3%) required a postoperative blood transfusion and there were no surgical interventions due to bleeding. The authors concluded that minor oral surgical procedures can be performed safely in patients being supported on LVAD therapy.

Although data to support the practice are lacking, many of those managing these patients prefer to have them covered with prophylactic antibiotics prior to invasive dental procedures.

Lung Transplant

The common indications for a lung transplant are chronic obstructive pulmonary disorder (COPD), interstitial lung disease, pulmonary hypertension, and cystic fibrosis. The disease-specific modifications to dental treatments are described elsewhere in this book. Most patients awaiting lung transplant are on oxygen therapy and have difficulty breathing. Combustible sources near patients on oxygen therapy must be avoided. This may be relevant for some types of laser therapy in the dental office. Narcotic medications that cause respiratory depression should be considered carefully. These chronic conditions may result in extrapulmonary complications, which should also be addressed.

Mechanical ventilation and/or extracorporeal life support (ECLS) have advanced and are being used more often prior to transplant. Considering the proximity of the lines to the endocardium in the right atrium, antibiotic prophylaxis should be considered prior to dental treatment manipulating the gingiva, periapical area, or oral mucosa. The principles outlined in the 2007 AHA guidelines for prevention of IE may be applied in this scenario, although no specific data are available to demonstrate ECLS-associated risk for IE. These patients may be on anticoagulants, and protocols to establish hemostasis should be employed.

Intestinal Transplant

Intestinal transplantation is indicated for patients with gut failure due to life-threatening complications of parenteral nutrition or underlying gastrointestinal disease such as desmoid tumor, congenital mucosal disorders, and ultrashort bowel syndrome.[95] The 1-, 5-, and 10-year graft survival rates are 71%, 50%, and 40% and the patient survival rates are 77%, 58%, and 47%, respectively.[96] In some cases, other organs are transplanted simultaneously from the same donor. When advanced liver disease is present, the liver is replaced as well. The pancreas and duodenum are also often transplanted.[97]

Candidates for intestinal transplantation are severely malnourished.[98] Vitamins C, E, and K may be low in patients with short bowel syndrome. Theoretically, manifestations of vitamin C and K deficiencies may result in spontaneous gingival bleeding and excessive postoperative bleeding. Therefore, dentists should monitor coagulation tests and have local hemostatic agents available.

Normally, approximately 80% of immune cells reside in the gut. After transplantation, the gut is repopulated with recipient cells, whereas the genotype of the epithelium remains largely that of the donor, making the organ highly chimeric and immunogenic.[97] The large lymphoid load and the reaction due to this immunologic discrepancy between donor and recipient cells put the patient at risk for immunologic complications.[99] Therefore, relatively high doses of immunosuppressant are administered and the pretransplant dental clearance should be determinative.

Pancreatic Transplant

Patients awaiting pancreatic transplants have a significant glucose management challenge and therefore serum glucose levels must be considered before dental treatment. These patients may be poor wound healers and may have "brittle insulin-dependent diabetes"; that is, they may experience sharp alterations in blood glucose levels and be prone to both ketoacidosis and insulin shock (see Chapter 16 on diabetes mellitus and endocrine diseases). Pancreatic dysfunction may be accompanied by hepatic failure. Hence, coagulation complications and medication and local anesthetic metabolism must be considered when performing dental procedures in these individuals.

Hematopoietic Stem Cell Transplant

Most HSCT patients have been through induction and have endured consolidation chemotherapy to treat a hematologic malignancy. Many of these patients are pancytopenic and prone to infections and bleeding. They are poor candidates for routine outpatient dental treatment. Other patients may have had a significant remission of their disease with normal blood counts, allowing emergency dental treatment before HSCT.

Blood counts should be addressed during the pretransplant clearance exam. It remains unclear if the bacteremia from periodontal probing alone can increase the risk of bacteremia and septicemia while a patient is neutropenic, although studies in patients with OM demonstrated an increased risk for septicemia.[100] If the patient is leukopenic (white blood cell $<1 \times 10^9$ cells/L) or neutropenic (neutrophil count $<0.5 \times 10^9$ cells/L), antibiotic prophylaxis is indicated for invasive treatments.[100] Ideally, invasive tests or treatments should be combined to maximize the benefit of each antibiotic prophylactic course. For example, probing of gingival depth, scaling, and elimination of advanced decay may be performed in one session. Most of the pre-HSCT patients will have a central catheter inserted before their dental evaluation. This alone is not an indication for antibiotic prophylaxis.

Anemia is rarely a limiting factor; however, extreme anemia may cause sudden hemodynamic changes, and the transplant team should be informed before dental treatment. Platelet count is a critical parameter prior to dental intervention. Uncontrolled bleeding may occur following simple dental procedures such as scaling, therefore measures to avoid bleeding should be applied. The decision about platelet transfusion prior to dental treatment is ambiguous, with no clear cutoff line. Generally speaking, a platelet count below 20,000/μL is a red flag and if invasive dental procedures are indicated, platelet transfusion should be considered. Severe bleeding may occur at higher platelet counts, especially in the presence of an additional coagulopathy, and clinician discretion is needed.

Since immunosuppression induced by the HSCT conditioning regimen may be severe, eradication of potential sites of infection should be determinative. Furthermore, often the timeline for delivering dental treatment is very short. Therefore, compromises may be needed regarding treatment, for example extractions may be prioritized over endodontic treatment.

Prompt consultation with the hem/oncologist is recommended and the discussion may address the need for blood product transfusion, the timeline to complete dental clearance, inclusion of sufficient time for postextraction wound healing, and potential foci of infection that will remain during HSCT. The transplant team may prefer to delay invasive dental procedures and proceed with the HSCT.

Face Transplant

Face transplantation is indicated for patients with severe facial damage and disfiguration, usually associated with trauma. Since it was first performed in 2005, a few dozen cases have been published in the literature, reporting impressive restorative ability and improved quality of life.[101] In many cases the oral soft and hard tissues are also damaged

by trauma and transplantation may include the jaws and dentition. Therefore, the role of the dentist is significant in surgical planning and follow-up, and is not limited just to dental clearance. Considering the mental status of the patient and limited intraoral access, compliance with oral hygiene should be stressed and hygiene aids adjusted to accommodate the altered anatomy.[102]

Presurgical evaluation of the donor dentition should be performed not only for treatment planning, but also to reduce the risk of odontogenic infection post transplantation.[68] The outcome of this complex surgical procedure relies on close attention to occlusal relationships, temporomandibular joint (TMJ) dynamics, dental health, and the intraoral donor–recipient soft tissue interface.[103] Maxillofacial prosthodontists may be involved in the fabrication of a prosthetic donor mask for the donor's remains.[104]

Post-transplantation Considerations

The post-transplantation period can be divided into the immediate period, the stable period, and the chronic rejection period. The patient is most susceptible to both rejection and severe infection in the immediate post-transplantation period, which extends to when the transplanted organ is functioning appropriately. No elective dental procedures should be performed at this time of immunosuppression, and emergency treatment should only be provided after consultation with the transplantation physician.

The stable post-transplantation period begins when the transplanted organ is functioning appropriately. It is during this time that problems relating to immunosuppression, and side effects of immunosuppressive medications may become apparent. Dental treatment planning must consider these factors. This stage lasts for a variable amount of time (patients may remain stable for years) and is considered the best period for elective dental treatment.

Patients post solid organ transplant may have numerous dental needs.[22] Considering immunosuppression, a dentoalveolar abscess may manifest atypically and a bacterial infection requires prompt antibiotic therapy. Culture and sensitivity testing are advised. It is extremely important to provide oral hygiene instruction and to discuss with the patient the importance of appropriate hygiene to prevent oral infections.

Antibiotic prophylaxis prior to dental treatment may be proposed by the transplantation physician. This is an empiric decision and the indications and contraindications require further evidence-based research. Considerations that support the use of antibiotic prophylaxis include the nature and degree of immunosuppression, history of infections, signs of rejection, and nature of the dental procedure (e.g., invasiveness). Given the nature of HSCT, immunosuppression is deeper and if an urgent dental procedure is needed, antibiotic prophylaxis will be required when the patient is neutropenic. If antibiotic prophylaxis is indicated, a consultation with an infectious disease specialist may help determine the best antibiotic(s) in light of the post-transplant oral flora and concurrent antibiotic exposure.

Corticosteroid supplementation may also be required due to adrenal suppression associated with high-dose chronic corticosteroid use. This supplementation may help avoid cardiovascular collapse during stressful procedures including general anesthesia, and it is recommended when the stress of the procedure or the patient's perception of the stress (pain) of the procedure is increased. Some have questioned the need for supplementation for limited surgical procedures, such as removal of gingival overgrowth via gingivectomy under local anesthetic. Steroid supplement for limited dental procedures is not needed as long as the patient's medical and emotional status are stable.

Another consideration during the stable post-transplantation period involves medication interactions, as several antirejection immunosuppressive agents interact with medications that a dentist may prescribe. For example, CSA levels are affected by anti-inflammatory drugs such as ibuprofen and naproxen, antifungals such as itraconazole and fluconazole, and antibiotics such as clarithromycin. Reviewing potential interactions between the transplant patient's medications and those the dentist intends to prescribe is prudent. As the development and use of immunosuppressive agents evolve, dentists will need to be familiar with the newer medications and the potential risk of interactions with medications used in dentistry.

It may be reasonable to offer dental implant–based restorations considering the improved life expectancy of transplant recipients. A clinical trial demonstrated that dental implants are feasible in patients post liver transplant.[105] Patients were followed for 8 years while treated with immunosuppressive agents. More research is warranted, however, in order to understand the determinants of complication-free implant procedures in patients post liver transplant, or any other solid organ transplant.

Given the high risk for malignant transformation in patients post HSCT and post solid organ transplant, any abnormal tissue should be assessed closely, including delayed postextraction wound healing.

Many HSCT and solid organ transplant patients are treated with bone-modifying agents, such as bisphosphonates and denosumab for steroid-induced osteoporosis. Additionally, multiple myeloma patients are treated with intravenous bisphosphonates. Dentists will find this information in the medical chart or by consultation with the medical team, and the protocols for patients at risk for osteonecrosis of the jaws should be followed.

The stable post-transplantation period ends when a grafted organ begins to fail, heralding the chronic rejection period. Laboratory parameters indicating organ failure and biopsies are used to confirm this process. For dentists, these patients are often the most complicated to manage, since the organ is failing and the patient remains immunosuppressed. Only emergency dental treatment is indicated, and the transplantation physician's input is essential. The treating dentist must consider the ramifications of organ failure and make appropriate provisions.

In addition to the above general post-transplant considerations for dental management, there are specific considerations for face transplant and HSCT. Face transplantation may affect the dentition, occlusion, and sensation.[68] Mucosal constriction due to trauma and surgical scarring may limit mouth opening and impair oral hygiene, function, and access for dental treatment. Mouth opening may also be restricted due to TMJ trauma or dysfunction. There may be malocclusion in patients with a grafted maxilla. There may be palatal fistulas at suture points of the donor and the recipient.[97] Acute episodes of graft rejection are common within the first year of transplantation.[106] Although mucosal graft rejection is not as common as seen in the skin, it has been described in the literature and the dentist should be able to identify it.[41]

The engraftment phase post HSCT may take place within 2–3 weeks; however, the immune reconstitution may take months. Therefore, decisions about the timing of routine dental care are individualized, and will range from a few months post transplant to a year. In the interim the patient should be encouraged to maintain good self-care practices.

There is controversy in the literature regarding changes in the oral microbiome following HSCT, with most studies showing a shift toward enterococci and increases in *Klebsiella pneumoniae*, *Pseudomonas* spp., *Candida albicans*, staphylococci, and enteric bacilli.[11,107,108] Variation between studies may be partially explained by different types of transplant, the intensity of the conditioning regimen, the chemotherapy courses, and the timing of bacterial testing. Patients have shown some benefit from chlorhexidine mouth rinses during this period.

Oral complications of HSCT and cGVHD may affect dental treatment. If dry mouth develops, preventive measures should be applied, including moistening the mouth, fluoridation, and frequent dental evaluations. Toothpastes need to address the gingival and mucosal sensitivity associated with cGVHD, and therefore neutral pH, mint-free toothpastes are advised.

Gingivitis and gingival recession post HSCT are common.[23] cGVHD may affect the gingivae and periodontium, and atrophy may result in thin gingival tissues. There is anecdotal evidence linking gingival recession to cGVHD.[109]

cGVHD may manifest as a progressive limitation of mouth opening, and dental treatment may be challenging. If there is limited access to the posterior teeth, extractions may be the only treatment option, and may need to be performed by an oral surgeon.

Considering that the conditioning regimen for HSCT includes cytotoxic agents and occasionally TBI, maxillofacial and dental developmental abnormalities affect about 55%–63% of pediatric HSCT patients.[64] These abnormalities include agenesis, root hypoplasia with arrested root development and shortened or tapered V-shaped roots, and smaller than normal or crowded teeth. These affect the occlusion and increase the tendency for dental decay. Orthodontic treatment may be considered to realign the occlusion.

SUMMARY

There are a wide range of oral considerations in the transplantation population. Dentists need a strong knowledge base in medicine and oncology to minimize adverse outcomes from provision of oral healthcare. As this challenging population grows, so does the need for qualified dental practitioners to treat them. Advances in the treatment of transplant patients pose new challenges in dental diagnosis and management, in particular with the nature and timing of dental procedures and preventive protocols.

Raj Nair, MS, MRACDS, PhD

Bacterial, viral, and fungal infections are some of the most common chief complaints in oral medicine. When encountering an oral infection, we believe that practitioners should always ask the following questions. First, does the patient have an infection? Microbiology specimens collected from a nonsterile site in the oropharynx will likely be positive; these results may simply represent normal colonization. Clinicians should carefully consider the organism involved and the clinical scenario that prompted the specimen to be collected. Second, does this infection represent a localized or disseminated process? Some patients with unusual oral fungal infections (e.g., *Cryptococcus* and histoplasmosis) may warrant further investigation for disseminated disease. Third, does this infection provide any clues to associated conditions or underlying medical comorbidities that require further evaluation? Oral manifestations of sexually transmitted infections (STIs), such as gonorrhea, chlamydia, and syphilis, should prompt clinicians to evaluate for other STIs. Episodes of thrush with any clear underlying cause and/or evidence of Kaposi sarcoma (KS) should prompt clinicians to consider whether the patient may have HIV. Although such questions seem rudimentary, we strongly encourage oral medicine clinicians to consider developing and following a consistent approach, such as the one outlined above, with each patient. Such approaches minimize the chance of inappropriately treating colonization and missing a potentially disseminated infection or an important associated condition.

One of the newest frontiers in oral medicine is understanding how bacteria and viruses interact with hosts. These interactions are complex, and research in this field has several titles; some examples include the microbiome, virome, and resistome. For simplicity, we will provide a little more detail about the microbiome, which is currently the best-studied field. The human oral microbiome contains over 1000 bacterial and fungal species.[1,2] Furthermore, the oral microbiome varies by location in the mouth. For example, different combinations of organisms exist in the gingival sulcus, tongue, cheek, and palate.[2–4]

Burket's Oral Medicine, Thirteenth Edition. Edited by Michael Glick, Martin S. Greenberg, Peter B. Lockhart, and Stephen J. Challacombe.

The oral microbiome plays a very important role in oral and systemic health by inhibiting pathogen colonization (colonization resistance), antagonizing pathogens by producing antimicrobial substances such as bacteriocin, and developing local and systemic immunity. Furthermore, oral bacteria can reduce nitrate to nitrite, which after gastric absorption becomes nitric oxide, which is essential for the vascular health.[5,6] The human oral microbiome also harbors a diverse range of antimicrobial resistance genes (ARGs), including resistance to tetracycline, amoxicillin, and gentamicin, which may act as a significant reservoir for ARGs to be transferred to pathogenic microbes.[7]

BACTERIAL INFECTIONS

Bacterial infections are common causes of concern in oral medicine. Several different infections are addressed in other chapters, such as angular cheilitis in Chapter 4 on "Red and White Lesions of the Oral Mucosa"; necrotizing gingivitis (NG) in Chapter 3 on "Ulcerative, Vesicular, and Bullous Lesions"; and bacterial sialadenitis in Chapter 9 on "Salivary Gland Diseases." The remainder of this chapter will focus on atypical bacterial infections, such as STIs, actinomycosis, and tuberculosis (TB).

The term sexually transmitted infections is now preferred over the historical term sexually transmitted diseases. This newer terminology acknowledges that some patients may have asymptomatic infections, which are still important and require treatment. The four most common bacterial STIs are chlamydia, gonorrhea, syphilis, and trichomoniasis (technically protozoa). These four organisms cause 376 million new infections in the world per year. In response, the World Health Assembly has led ambitious efforts to end STIs by 2030.[8]

Chlamydia

Epidemiology

Chlamydia is caused by *Chlamydia trachomatis*, an obligate intracellular gram-negative bacterium. Chlamydia is the most reported STI worldwide. Based on prevalence data from 2009 to 2016, the estimated pooled global prevalence of chlamydia in 15–49-year-old women is 3.8% (95% uncertainty interval [UI]: 3.3–4.5) and in men 2.7% (95% UI: 1.9–3.7).[9] In 2016, 403,807 cases of chlamydia were reported in 26 European Union (EU)/European Economic Area (EEA) member states, with an overall notification rate of 185 cases per 100,000 population.

Clinical Presentation

Patients acquire chlamydia via vaginal, anal, or oral sex with an infected partner. Chlamydia commonly causes genital infections in the cervix, urethra, or epididymis. Cervicitis is often asymptomatic in women. Urethritis manifests as pain or difficulty urinating, with or without cervical or penile discharge. Men who engage in receptive anal intercourse can also develop prostate infections.[10,11] Extragenital infections commonly present as pharyngitis and conjunctivitis.

In women, chlamydia infections can ascend to the fallopian tubes, ovaries, or uterus, causing pelvic inflammatory disease (PID). Left untreated, PID can lead to scarring, infertility, and ectopic pregnancies. Infections can also rarely ascend into the abdomen and cause liver abnormalities as well. Complications among males include infections of the epididymis and testes. Both male and female patients can also rarely develop a reactive arthritis.

Some *Chlamydia trachomatis* strains have an atypical presentation. Specifically, serovars (serologic variants) L1, L2, and L3 cause lymphogranuloma venereum (LGV), which manifests as genital ulcers with lymphadenopathy and requires different antibiotic management. LGV is managed differently than standard *Chlamydia trachomatis* infections and is more common in Africa, India, Southeast Asia, and the Caribbean. However, outbreaks have been reported outside of these areas. Due to breakdown of the mucosal barriers, patients with chlamydia are at greater risk of acquiring other STIs, including HIV.[10,11]

Diagnosis

Chlamydia trachomatis is generally diagnosed via nucleic acid amplification testing (NAAT) on cervical, ureteral, oral, rectal, or urinary specimens.[10]

Treatment

Doxycycline and azithromycin are the preferred antibiotics to treat *Chlamydia trachomatis* infections. Antibiotic recommendations between these two agents are often dictated by national and regional susceptibility data. For example, the British Association for Sexual Health and HIV (BASHH) recommends doxycycline.[10] However, either agent is considered acceptable in the United States.[12]

Oral/Facial Considerations

Patients can also acquire chlamydia infections in the oropharynx via oral sex. Oral infections are often asymptomatic, but fever and lymphadenopathy may occur. Tonsillar infections typically manifest as erythema with small punctate lesions. Lesions may also occur uncommonly in other locations in the mouth and are described as being erythematous, pustular, erosive, or ulcerated.[13]

Gonorrhea

Epidemiology

Gonorrhea is caused by *Neisseria gonorrhoeae*, a gram-negative bacterium. The 2016 global incidence of gonorrhea

was 0.9% (95% UI: 0.7–1.1) in women and 0.7% (95% UI: 0.5–1.1) in men. Among men and women aged 15–49 years, there were 87 million new cases of gonorrhea in 2016 globally.[8] In Europe, gonorrhea is more common in men, and 48% of all reported cases were in men who have sex with men (MSM). Gonorrhea is more common in younger individuals.[14] In the United States, recent trends demonstrate an increase in the incidence of gonorrhea.[15]

Clinical Presentation

Gonorrhea infects the same anatomic sites as chlamydia, and symptoms between the two infections overlap. For example, patients can also develop cervicitis, urethritis, epididymitis, conjunctivitis, and pharyngitis. Similarly, women can develop PID, ectopic pregnancy, and infertility as a complication. Gonorrhea can also be asymptomatic, like chlamydia. However, gonorrhea can manifest a disseminated infection, which classically involves the joints.

Diagnosis and Treatment

Like chlamydia, gonorrhea is diagnosed via NAAT. This can be performed in the urine and on swabs from the urethra, cervix, vagina, or oropharynx. Patients with suspected gonorrhea should be referred to a genitourinary medicine clinic for specimen collection, culture, partner notification, and treatment.[16] First-line therapy to treat gonorrhea is ceftriaxone. However, recent increases in antimicrobial resistance to ceftriaxone have been observed.[17] Like chlamydia, gonorrhea damages mucous membranes, which increases the risk of HIV and other STIs.[18,19]

Oral/Facial Considerations

Oropharyngeal gonorrhea is often asymptomatic.[20] When symptomatic, it can present with nonspecific multiple ulcers, fiery red oral mucosa, pseudomembrane, painful pharyngitis, atypical gingivitis, and lymphadenopathy (see Figures 21-1 and 21-2).

Figure 21-1 Gonococcal gingivitis.

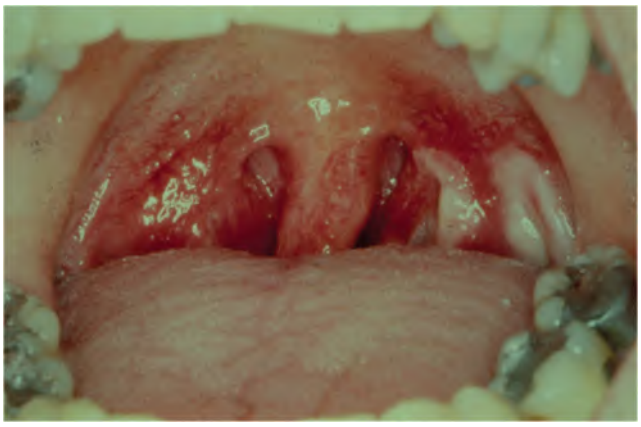

Figure 21-2 Gonorrhea: pseudomembranes in the fauces. *Source*: Courtesy of Dr. Stephen Challacombe.

Syphilis

Epidemiology

Syphilis is caused by *Treponema pallidum,* a spirochete bacterium. It is acquired primarily through sexual contact. The estimated pooled global prevalence of syphilis is 0.5% (95% UI: 0.4–0.6) for both men and women, with regional values ranging from 0.1% to 1.6 %.[8] Like chlamydia and gonorrhea, syphilis is more common in younger individuals and MSM. Recent trends suggest that the incidence of syphilis has been increasing.[21,22]

Clinical Presentation

Syphilis is often considered the "great imitator" because patients can present in a variety of ways. In general, active syphilis infections can be divided into primary, secondary, and tertiary stages. Primary infections occur generally within the first month of exposure. Patients will classically present with a painless genital ulcer (chancre) at the initial inoculation site (Figure 21-3A, B). However, some patients may not develop or recall developing an ulcer. In secondary syphilis, patients develop a disseminated infection, which manifests as a diffuse rash (classically on the palms and soles).[22–24] In tertiary syphilis, which is very rare, patients classically present with a cardiovascular infection or a syphilitic gumma. Cardiovascular manifestations classically are aneurysms. However, patients may also present with aortic regurgitation and coronary ostial occlusive disease.[25]

Syphilis may be passed from an infected mother to her child during pregnancy, causing congenital syphilis. Patients with congenital syphilis may have deformed bones, severe anemia, jaundice, hepatomegaly, splenomegaly, blindness, deafness, meningitis, or skin rash.[22–24]

Diagnosis

Syphilis is diagnosed using a combination of treponemal and nontreponemal tests (Figure 21-3C, D). Consultation with a physician is strongly considered when interpreting

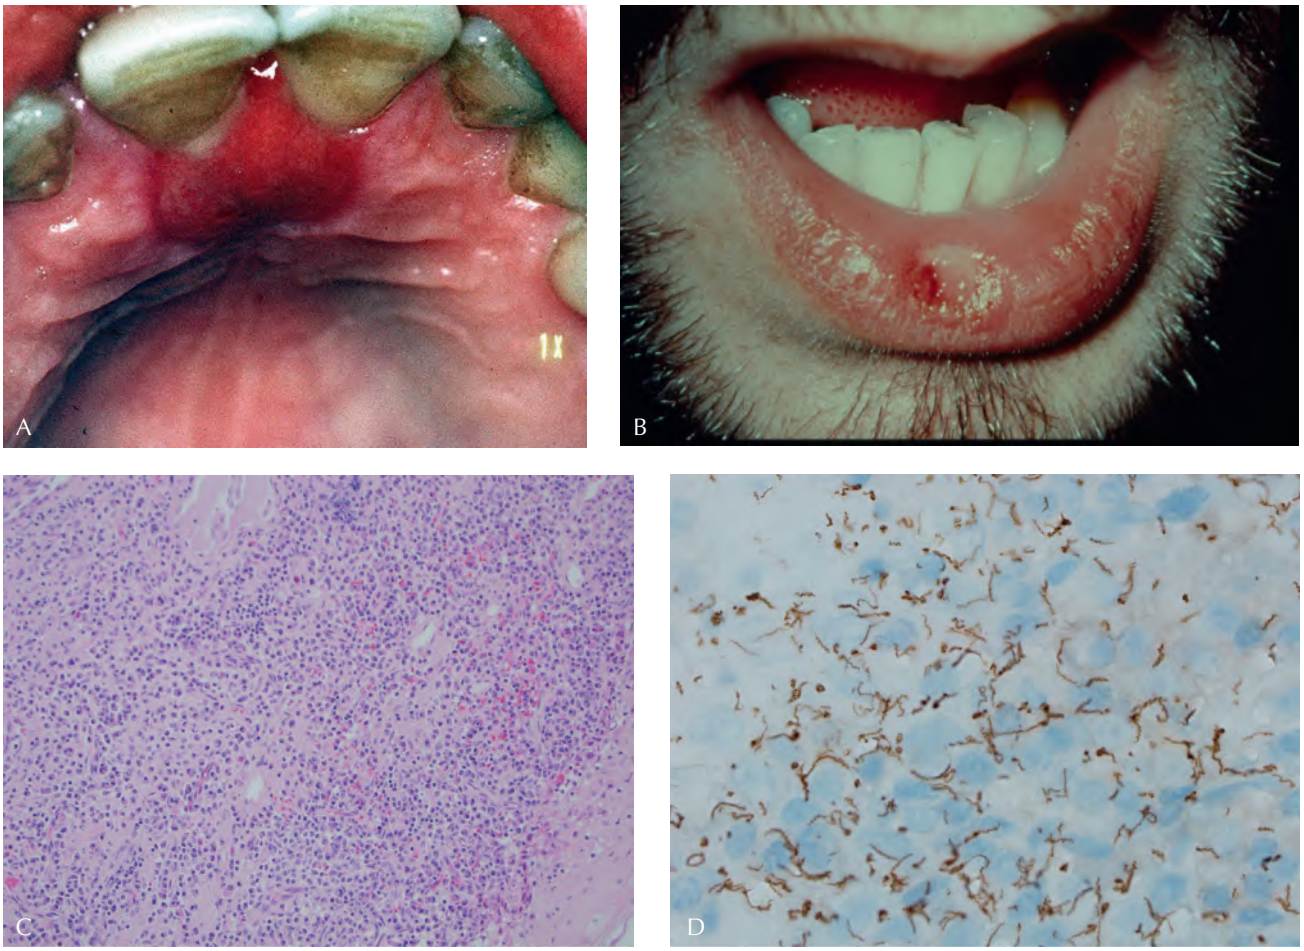

Figure 21-3 (A) Syphilitic patch on the hard palate of primary syphilis. Reproduced with permission from Alam F, Argiriadou AS, Hodgson TA, Kumar N, Porter SR. Primary syphilis remains a cause of oral ulceration. *Br Dent J*. 2000;189:352–354. (B) Primary syphilis: irregular ulceration of the lower lip. *Source*: Courtesy of Dr Stephen Challacombe. (C) H&E and an immunohistochemical stain for a syphilitic oral lesion. The H&E shows polyclonal plasmacytosis, which can be found in syphilis. (D) The immunohistochemical stain shows spirochetes.

syphilis diagnostic test results. Treponemal antibody tests will remain positive after patients receive treatment. Quantitative nontreponemal tests should decline after treatment, but the results may never return to negative.[24]

Treatment

Syphilis is treated based on the duration and severity of disease. Consultation with a physician is strongly recommended prior to initiating syphilis treatment. In general, early syphilis (<1 year) is usually treated with a single dose of intramuscular (IM) benzathine penicillin G. Late syphilis (>1 year) is treated with IM penicillin once weekly for three consecutive weeks. Patients who have evidence of neurologic involvement (neurosyphilis) require intravenous (IV) penicillin for 10–14 days.[26]

Oral/Facial Considerations

Approximately 15% of patients with primary syphilis will present with highly infectious intraoral chancres, as either solitary or multiple lesions. Chancres typically present as painless, sometimes necrotic, ulcers with a rolled border and associated lymphadenopathy. Common sites of occurrence are the lips, tongue, palate, and nostrils. Lymphadenopathy commonly accompanies these lesions. As mentioned previously, the lesions heal spontaneously without treatment.[13] If there is a clinical concern for syphilis, patients should still seek medical care, even if the lesion has healed.

Typical oral lesions in secondary syphilis are described as a mucous patch, which presents as thickened whitish plaque affecting the oral mucosa. Necrosis and sloughing may occur. Commonly affected sites include the tongue, lip, buccal mucosa, and palate. These patients may also present with mucosal ulcers and erythematous macular lesions.[27] Syphilis-related gummas classically occur on the hard palate, but may also occur on the soft palate and the alveolus. A gumma begins as a swelling, which eventually ulcerates and then goes through repeated phases of healing and breakdown. Bone destruction of the hard palate may occur with

Figure 21-4 Sublingual swelling and discharge from actinomycosis. *Source*: Courtesy of Dr Stephen Challacombe.

palatal perforation and, in some cases, oral nasal fistula. A gumma may erode into underlying blood vessels.[28]

Infants with congenital syphilis may also develop orofacial malformations, including Hutchinson's notched incisors, mulberry-shaped molar teeth, corneal keratitis, frontal bossing, saddle nose, and hard palate defects.[23]

Actinomycosis

Epidemiology

Actinomyces spp. naturally colonize the oropharynx (Figure 21-4), gastrointestinal tract, and pelvis in humans. Infections with *Actinomyces* spp. (called actinomycosis) rarely occur. The annual incidence is fewer than 1/300,000 per year. The incidence of actinomycosis has thought to have declined due to an overall improvement in oral hygiene over time. The male:female ratio is between 1.5:1 and 3:1.[29–32] Risk factors for acquiring actinomycosis include poor oral hygiene; local tissue damage by trauma, recent surgery, or irradiation; intrauterine devices (IUDs) for pelvic infections; and diabetes.[32,33]

Clinical Presentation

Actinomycosis commonly occurs in the orocervical (50%), thoracic (20%), and abdominal pelvic regions (20%). Over time, the infection will slowly erode through facial planes and develop chronic sinus tracts. Most infections are thought to occur due to muscular injury, allowing the bacteria to penetrate into body areas and grow in an anaerobic environment.[31,32]

Diagnosis

The differential diagnosis for actinomycosis includes cancer, TB, appendicitis, pneumonia, and PID. Most cases are diagnosed when a biopsy reveals classic gram-positive filamentous bacteria with or without "sulfur granules." However, the term sulfur granules is a misnomer. These granules are actually composed of a protein–polysaccharide complex and are mineralized by host calcium. Although difficult to achieve, actinomycosis can sometimes be cultured under anaerobic conditions. Other diagnostic approaches, such as immunohistologic, polymerase chain reaction (PCR), and serologic techniques, are generally not commercially available.[31,32]

Treatment

Actinomycosis is treated with a prolonged course of systemic antibiotics with or without surgery. Penicillin-based antibiotics (penicillin, amoxicillin, amoxicillin-clavulanate) are preferred.[31,32]

Consultation with an infectious diseases doctor is recommended to assist with antibiotic monitoring and treatment duration.

Oral/Facial Considerations

Orocervicofacial actinomycosis classically develops after dental manipulation, oral trauma, or in the setting of poor oral hygiene. Patients generally present soft tissue swelling, in or near the mandible. However, infections also occur in the check, chin, and maxilla. Like other forms of actinomycosis, patients will slowly develop sinus tracts with or without sulfur granules. Complications include myositis and osteomyelitis. The differential diagnosis includes malignancies and granulomatous diseases.[30,31,34]

Tuberculosis

Epidemiology and Clinical Presentation

TB is caused by *Mycobacterium tuberculosis*. Individuals acquire TB by inhaling airborne particles from other infected people. Once inhaled, TB proliferates inside of alveolar macrophages. When enough macrophages are recruited, local complexes of enlarged lymph nodes can be seen on a chest radiograph. These are called "ghon complexes," where TB can remain dormant for decades. Patients who initially develop TB (also called the primary disease stage) generally have fevers and other nonspecific symptoms. Once primary TB symptoms resolve, patients are considered to have latent TB. This means that they likely still have residual TB bacteria, which can reactivate at some point later in life.

Only about 10% of patients will develop reactivation TB later in life. When reactivated, TB generally presents with a chronic respiratory infection with cough, fevers, night sweats, and weight loss. Patients classically have an upper lobe cavitary lesion on chest radiographs. However, TB can reactivate anywhere in the body.[35,36]

TB is a major global health problem. Worldwide there were 10.0 million (range: 9.0–11.1 million) individuals

Table 21-1 Risk factors for tuberculosis (TB).

Risk Factor	Comment
HIV	Persons living with HIV are 15–22 times more likely to develop TB than persons without HIV In 2018, 251,000 death from HIV-associated TB were reported
Diabetes	A person with diabetes has a 2–3 times higher risk for acquiring TB Diabetes can worsen the course of TB and TB can worsen glycemia control for people with diabetes
Malnutrition	Malnutrition increases the risk of TB and TB can lead to malnutrition
Tobacco	Tobacco smoking increases the risk of TB by 2–3-fold and is associated with poor TB treatment results
Harmful use of alcohol	Harmful use of alcohol increases the risk of TB 3-fold and it is also a strong risk factor for poor TB treatment adherence

Source: World Health Organization, 2020.

diagnosed with TB in 2018.[37] Although the incidence of TB remains stable in most nations, multidrug- and extensively drug-resistant TB remains a growing public health concern.[38]

Medical risk factors for TB include HIV, diabetes, malnutrition, smoking, and alcohol use (Table 21-1).[39–41] Societal risk factors for TB include overcrowding, poorly ventilated housing, malnutrition, smoking, stress, social deprivation, and poor social capital.[42] In industrialized countries, most cases occur in minority groups, particularly recent immigrants from countries with high TB endemicity.

Latent TB can be diagnosed two different ways. The most common approach is tuberculin skin testing on the forearm with purified protein derivative (PPD), a mycobacterial antigen. Interferon gamma release assays (IGRA), are blood tests that detects sensitization to *Mycobacterium tuberculosis*.[35,38,43] In the United States, the Centers for Disease Control (CDC) recommend screening certain high-risk populations for latent TB (Table 21-2). Patients with a positive screening test should be evaluated for the presence of active TB disease. However, a negative latent TB screening test should not be used to rule out active TB.

Diagnosis

Active TB is generally diagnosed via culture of the bacterium. To improve the test sensitivity, serial sampling of respiratory tract specimens is common. Special acid-fact bacteria (AFB) stains can aid in diagnosis, but these are nonspecific. Newer PCR-based platforms are often used in conjunction with standard AFB stains and culture.[35,38,43]

Table 21-2 High-risk groups recommended for purified protein derivative testing.

1) People who have spent time with someone who has tuberculosis (TB) disease
2) People with HIV infection or another medical problem that weakens the immune system
3) People who have symptoms for TB disease (fever, night sweats, cough, and weight loss)
4) People from a country where TB disease is common (most countries in Latin America, the Caribbean, Africa, Asia, Eastern Europe, and Russia)
5) People who live or work somewhere in the United States where TB disease is more common (homeless shelters, prison or jails, some nursing homes)
6) People who use illegal drugs

Table 21-3 Treatment for tuberculosis (TB) infection.

Category	Medication Regimens*
Latent TB	Isoniazid monotherapy daily for 9 months Rifampicin-based treatment daily for 4 months Isoniazid and rifapentine weekly for 3 months Isoniazid and rifampicin-based treatment daily for 3 months
Active TB without central nervous system involvement	Isoniazid (with or without pyridoxine), rifampicin, pyrazinamide, and ethambutol for 2 months, then isoniazid (with or without pyridoxine) and rifampicin for a further 4 months
Active TB with central nervous system involvement	Isoniazid (with or without pyridoxine), rifampicin, pyrazinamide, and ethambutol for 2 months, then isoniazid (with or without pyridoxine) and rifampicin for a further 10 months

* Modify the treatment regimen according to drug susceptibility testing. Management of these cases should be done by a multidisciplinary team including TB team, Infectious Disease, Microbiology, and Oral Medicine. Some treatment regimens may vary based on local guidelines.
Source: National Institute for Health and Care Excellence. *Tuberculosis*. Updated September 2019. www.nice.org.uk/guidance/ng33.

Treatment

Patients with latent TB receive different treatment regimens than those with active disease. Those with latent TB require a prolonged course of one or two antibiotics. They are often screened for underlying medical problems prior to initiating therapy.[44] Patients with active TB generally receive a combination of four different antibiotics when they start treatment (Table 21-3). Adherence to antibiotics is frequently monitored via directly observed therapy. After a couple of weeks of therapy, treatment regimens are generally modified based on adherence, tolerability, and clinical response. The usual course of therapy is six to nine months and involves several drug regimens (Table 21-3).[44] However, antibiotic selection

and treatment regimens may vary if patients have known or suspected drug-resistant TB. Drug-resistant TB is more challenging to treat and may require IV antibiotics.[38,45] Patients with multidrug- or extensively drug-resistant TB require often require complex antibiotic treatment regimens for a prolonged period of time. Despite these intensive regimens, patients with extensively drug-resistant TB frequently have poor outcomes.[44,46]

Public health efforts to combat TB include educational interventions, vaccination, screening high-risk patients, contact tracing, and early diagnosis and treatment.[44] Bacillus Calmette-Guerin (BCG) is a live vaccine made from a weakened strain of *Mycobacterium bovis*. BCG continues to be administered in many developing countries, but it is not routinely used in the United States and is rarely administered in the United Kingdom. Contact tracing to identify and screen close contacts of recently diagnosed TB patients is considered an important part of combating TB. In hospital settings, patients are placed in airborne isolation, with precautions such as N95 respirators to reduce TB transmission to healthcare workers.[44,47,48]

Oral/Facial Considerations

Oral manifestations may occur in up to 3% of patients with long-term active TB. Lesions may occur in the oral tissues and the neck lymph nodes. The latter is termed scrofula. Oral lesions can be found in various soft tissues and very occasionally in supporting bone. Oral lesions may be primary or secondary to pulmonary tuberculosis. Stellate ulcers affecting the dorsal surface of the tongue are a classic presentation. A TB oral ulcer usually has undermined edges and a granulating floor, but the clinical picture can be variable. Lesions may also affect the gingiva, floor of the mouth, palate, lips, and buccal mucosa (Figure 21-5). Macroglossia, parotitis, intraosseous lesions, periauricular swelling, and trismus have been reported in some oral TB cases.[49]

Figure 21-5 Palatal tuberculosis ulcer in a patient with pulmonary tuberculosis.

Standard fluid-resistant masks likely provide some protection against TB for dental healthcare personnel. However, routine dental care should be deferred in patients who remain contagious with TB. In the United States, patients with TB are no longer considered contagious if they meet the following criteria: (1) three consecutive AFB sputum smears collected at 8–24-hour intervals; (2) compliant with an adequate treatment regimen for at least two weeks; and (3) improvement in symptoms. If oral care must be provided for a patient who is contagious with TB, patients should be placed in a negative-pressure room and healthcare workers should wear an N95-, FFP2-, or FFP3-level respirator. If an oral medicine provider plans on treating a patient with active TB, it is strongly recommended to consult with an infection prevention specialist or hospital epidemiologist, who may be able to share clinic- or hospital-specific protocols. TB protocols may recommend scheduling the patient as the last case of the day to minimize exposure to other patients and staff. TB patients should be instructed to wear a surgical mask while in patient care areas. High-efficiency particulate air (HEPA) filters may also be used to filter out TB. Consultation with the multidisciplinary TB team is strongly recommended in these cases.[44,47,50]

FUNGAL INFECTIONS

Candidiasis, which accounts for the vast majority of oral fungal infections, is described in detail as part of Chapter 4, "Red and White Lesions of the Oral Mucosa." Other fungal infections can be divided into those that generally infect immunocompromised or immunocompetent patients. *Aspergillus*, *Rhizopus* (mucromycosis), *Fusarium*, and *Cryptococcus* generally arise as opportunistic infections in immunocompromised patients. If a patient is diagnosed with one of these infections, oral medicine providers should consider referring or screening them for an underlying immunodeficiency. Other fungi such as *Coccidioides immitis*, *Histoplasma capulatum*, *Blastomyces dermatitis*, *Paracoccidioides brasiliensis*, and dermatophytes also infect immunocompetent subjects.[51,52] A thorough history and physical examination should be performed for patients with atypical fungal pathogens, as these pathogens can also cause disseminated infections. Furthermore, oral medicine clinicians should strongly consider consultation from an infectious diseases specialist to assist with diagnosis and management of unusual oral fungal infections.

In this section we discuss less common fungal infections, which can have oral manifestations including the following:

- Common endemic mycoses in the Americas include blastomycosis, histoplasmosis, and paracoccidioidomycosis in

Central and South America. Primary infection occurs through the respiratory tract, with dissemination to the skin and viscera via hematogenous and lymphatic spread.[52]

- Nonendemic fungal infections include aspergillosis, cryptococcosis, and mucormycosis. This group of fungal infections often presents as solitary oral ulcers. However, reactive epithelial and pseudoepitheliomatous hyperplasia may lead to heaped-up, exophytic mucosal lesions potentially misinterpreted as squamous cell carcinoma (SCC). Early diagnosis and treatment of mucormycosis is crucial to prevent local invasion and disfigurement of the oral and maxillofacial tissues.[51]

Blastomycosis

Epidemiology

Blastomyces dermatitidis is a dimorphic fungus that can grow either as a yeast or in mycelial form. Most cases occur in the United States and Canada. It is a normal inhabitant of soil and agricultural and construction workers are at highest risk of infection, particularly those working in the Mississippi and Ohio River Valleys, around the Great Lakes, and near the St. Lawrence Seaway. This geographic distribution has led to the designation by some as "North American blastomycosis." However, cases of blastomycosis infections have also been described in Mexico and Central and South America.[53]

In the United States, the yearly incidence is about 1–2 cases per 100,000 population; Wisconsin has the highest rates in the US with between 10 and 40 cases per 100,000 population. Some 1,216 blastomycosis-related deaths occurred during 1990–2010 in the United States, with an overall age-adjusted mortality rate of 0.21 per 1 million person-years.[54]

Clinical Presentation

Both immunocompetent and immunocompromised individuals can develop blastomycosis. Risk factors for blastomycosis include outdoor activities such as forestry work, hunting, and camping. Immunosuppressed patients, such as HIV patients, solid organ transplant patients, and those receiving tumor necrosis factor (TNF) antagonists, are also at higher risk for developing blastomycosis.[54,55]

Patients with blastomycosis generally present with pneumonia due to inhaling fungal spores. Immunocompetent patients frequently present with indolent symptoms such as malaise, low-grade fever, and mild cough. If the infection goes untreated, the signs and symptoms may progress to include dyspnea, weight loss, and production of blood-tinged sputum.[56] Some patients develop acute respiratory distress syndrome, with a mortality rate of up to 50–89%.[55] Disseminated blastomycosis occurs more frequently in immunosuppressed individuals such as those with HIV or organ transplant recipients.[56]

Most blastomycosis infections are localized to the lung, but 25–40% will develop extrapulmonary infection leading to cutaneous, osteoarticular, genitourinary, or central nervous system (CNS) disease. This is usually due to the spread of organisms from the pulmonary lesions through the lymphatic system. The skin lesions (typically on exposed surfaces) start as subcutaneous nodules, slowly progressing to well-circumscribed indurated ulcers.[57]

Diagnosis

The differential diagnosis for blastomycosis is broad and includes other fungal pathogens and atypical bacteria, including tuberculosis. Blastomycosis can be diagnosed using real-time nucleic acid detection, antibody identification through enzyme immunoassay, antigen detection, biopsy, and culture on Sabouraud agar.[58–60] Blastomycosis characteristically has broad-based unipolar budding yeast forms on histology.[58] Clinically, it is diagnosed via a positive blastomycosis antibody in the setting of a compatible clinical presentation, including appropriate epidemiologic risk factors.

Treatment

All cases of blastomycosis should be treated to prevent extrapulmonary dissemination.[56] Mild to moderate pulmonary disease can be treated with azole-based antifungals. Itraconzole for up to 12 months is a common regimen. Moderately severe pulmonary disease should be initially treated with lipid formulation of amphotericin B (AmB) for one to two weeks or until improvement is noted. This is followed by oral itraconazole therapy. Serum levels of itraconazole should be determined after two weeks from the treatment to ensure adequate drug exposure.[56,61] Table 21-4 details the treatment recommendation for disseminated and CNS blastomycosis according to the current guidelines.[56]

Oral/Facial Considerations

Oral lesions are rarely the primary site of infection. Indeed, most cases of oral involvement demonstrate concomitant pulmonary lesions on chest radiographs. The most common appearance of the oral lesions of blastomycosis is a nonspecific, painless ulcer with indurated borders and verrucous mucosal hyperplasia, often mistaken for SCC.[62–64]

Histoplasmosis

Epidemiology

Histoplasmosis is caused by the fungus *Histoplasma capsulatum*, a dimorphic fungus with both yeast and mycelial forms. Infection results from inhaling dust contaminated with droppings, particularly from infected birds or bats.

Table 21-4 Blastomycosis treatments.

Pulmonary	**Moderate to severe** Lipid formulation amphotericin B (AmB) 3–5 mg/kg per day *or* AmB deoxycholate 0.7–1 mg/kg per day for 1–2 weeks or until improvement *then* Itraconazole 200 mg 3 times per day for 3 days, *then* 200 mg twice per day for a total of 6–12 months **Mild** Itraconazole 200 mg 3 times per day for 3 days, *then* 200 mg once or twice per day for a total of 6–12 months Itraconazole serum level should be done 2 weeks after treatment
Disseminated	**Moderate to severe** Lipid formulation AmB 3–5 mg/kg per day *or* AmB deoxycholate 0.7–1 mg/kg per day for 1–2 weeks or until improvement *then* Itraconazole 200 mg 3 times per day for 3 days, *then* 200 mg twice per day for at least 12 months **Mild** Itraconazole 200 mg 3 times per day for 3 days, *then* 200 mg once or twice per day for a total of 6–12 months **Osteoarticular blastomycosis** At least 12 months of antifungal therapy Itraconazole serum level should be done 2 weeks after treatment
Central nervous system	Lipid formulation AmB 5 mg/kg per day for 4–6 weeks *then* Fluconazole 800 mg per day, *or* itraconazole 200 mg 2–3 times per day, *or* voriconazole 200–400 mg twice per day for at least 12 months or until resolution of cerebrospinal fluid abnormalities Itraconazole serum level should be done 2 weeks after treatment
Immunosuppressed patients	Lipid formulation AmB 3–5 mg/kg per day *or* AmB deoxycholate 0.7–1 mg/kg per day for 1–2 weeks or until improvement *then* Itraconazole 200 mg 3 times per day for 3 days, *then* 200 mg twice per day for at least 12 months Itraconazole serum level should be done 2 weeks after treatment Lifelong suppressive therapy with oral itraconazole 200 mg per day if immunosuppression cannot be reversed

Additional medication notes: Amphotericin is nicknamed "amphoterrible" because it is associated with substantial side effects, including chills, nausea, vomiting, and electrolyte disturbances. Caution should be employed when using amphotericin with ganciclovir or valganciclovir. Itraconazole is generally well tolerated. Itraconazole can cause QT prolongation and is also a CYP3A4 inhibitor.
Consider reviewing potential drug interactions prior to prescribing any new medications.
Management of these cases should be done by a multidisciplinary team, including Infectious Disease, Microbiology, and Oral Medicine.
Source: Chapman SW, Dismukes WE, Proia LA, et al. Clinical practice guidelines for the management of blastomycosis: 2008 update by the Infectious Diseases Society of America. *Clin Infect Dis.* 2008;46(12):1801–1812.

An African form of this infection is caused by a larger yeast, *H. huboisii*, which is considered a variant of *H. capsulatum*.[65]

Histoplasmosis is the most common systemic fungal infection in the United States and presents primarily as pulmonary disease; in endemic areas such as the Mississippi and

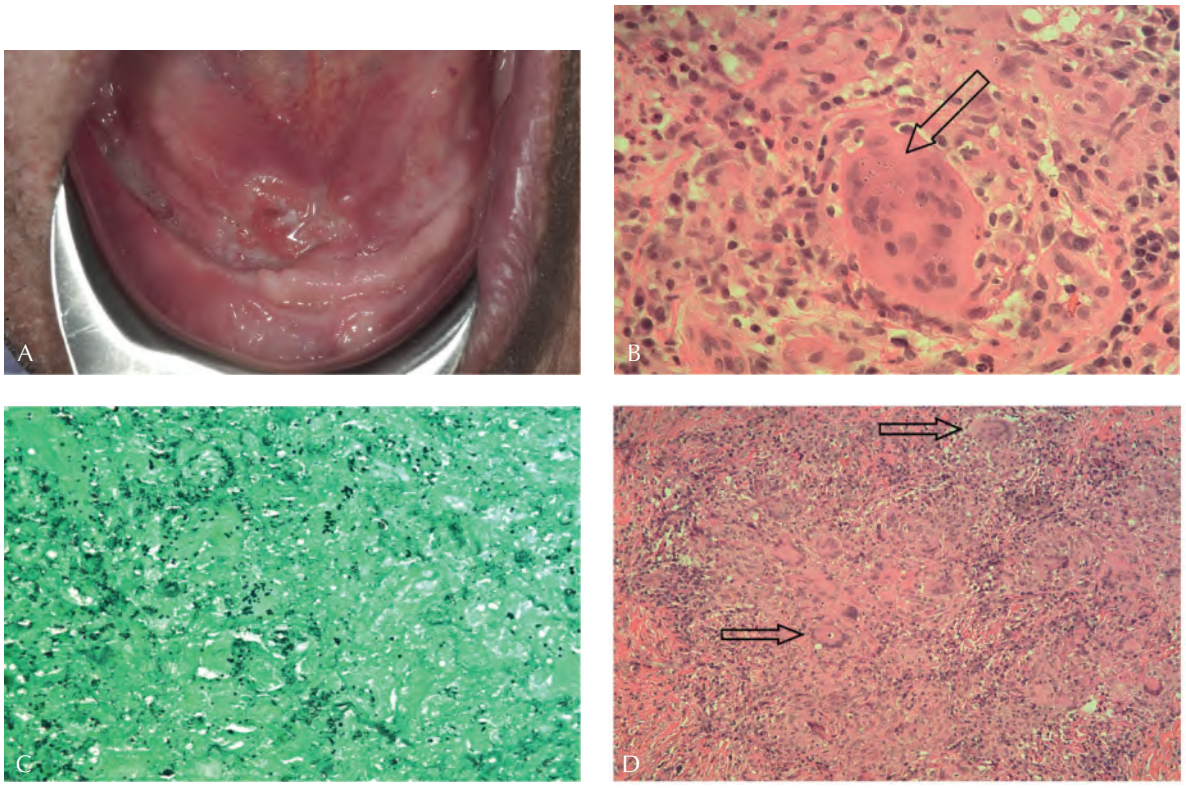

Figure 21-6 (A) Histoplasmosis. (B) H&E staining (20×) shows a giant cell with numerous small round fungal organisms. (C) Gomori methenamine silver staining shows the fungal organisms stained black. (D) H&E staining (10×) shows granulomas with multinucleated giant cells. Courtesy of Dr. Ross Kerr.

Ohio River valleys, serologic evidence of previous infection may be found in 60–90% of the population. The incidence of histoplasmosis in adults aged 65 years and older was calculated as 3.4 cases per 100,000 population in the United States in general and 6.1 cases per 100,000 population in the Midwest. Outbreaks of occupationally acquired histoplasmosis have been reported among agricultural workers and laborers in endemic areas. Particularly at risk are individuals working with aerosolized topsoil or dust with bat or bird droppings.[65,66] Symptomatic histoplasmosis is more prevalent among people with immunosuppression. In Latin America, histoplasmosis is one of the most common opportunistic infections among HIV-infected individuals, leading to a 30% mortality rate.[65]

Clinical Presentation

In many cases primary infection is mild, manifesting as a self-limiting pulmonary disease that heals to leave mediastinal fibrosis and calcification, which can be identified on chest radiographs. In a small percentage of cases, progressive disease results in cavitation of the lung and widespread dissemination of the organism. Common locations for disseminated disease include the liver, spleen, adrenal glands, intestinal tract, and meninges. Patients with the disseminated form of the disease may develop anemia and leukopenia secondary to bone marrow involvement. Immunosuppressed or myelosuppressed patients are more likely to develop a severe disseminated form of the disease, and disseminated histoplasmosis is one of the infections that characterize AIDS.[65]

Diagnosis

Antigen detection via enzyme immunoassay can be performed in blood, urine, cerebrospinal fluid (CSF), and bronchoalveolar lavage (BAL) samples for rapid diagnosis of disseminated and acute pulmonary histoplasmosis. Clinically, urine histoplasma antigen is commonly used to diagnose invasive infections. Of note is that chronic pulmonary disease can have a low antigen burden, making the test insensitive.[67] Other possible diagnostic methods are antibody detection via immunodiffusion, and identification of histoplasma DNA via various PCR techniques. It is important to note that there is some cross-reactivity with *Blastomyces* infections.[68,69] In disseminated disease, peripheral blood smear may show the organisms engulfed by white blood cells. Sputum fungal culture and bronchoalveolar lavage can also be performed. Histopathology of the involved tissue can demonstrate the characteristic 2–4 μm diameter budding yeast cells (Figure 21-6).[70]

Treatment

Immunocompromised patients with disseminated histoplasmosis are generally treated with liposomal AmB and/or itraconazole. Patients with moderate to severe disease should initially receive amphotericin-based therapy. Alternatives to amphotericin and itraconazole include voriconazole and posaconazole.[71] Fluconazole should not be used, as it is not thought to be active against *H. capsulatum*. Antifungal selection and duration are based on a combination of factors including duration of symptoms and severity of presentation.[70] Corticosteroids, such as methylprednisolone during the first one to two weeks of the antifungal therapy, should be considered for patients who develop respiratory complications including hypoxema and significant respiratory distress.[70,72] Antifungal therapies and steroids have limited benefit for patents with fibrosing mediastinitis, a rare complication from histoplasmosis.

Oral/Facial Considerations

Oral manifestations of histoplasmosis are most common in patients with disseminated disease (66%). Oral manifestations of histoplasmosis are also common in subacute (31%) and acute (19%) infections.[52] However, primary oral involvement has also been reported. In one study, 3% of HIV-positive patients in an endemic area had oral lesions of histoplasmosis, and oral histoplasmosis had been reported as the first sign of AIDS.[73] Patients diagnosed with histoplasmosis should be tested for HIV infection and evaluated for disseminated disease.

Oral mucosal lesions begin as an area of erythema that becomes a papule and eventually forms a painful, granulomatous-appearing ulcer, often with an indurated border, on the gingiva, palate, or tongue. Some lesions can appear fungating. Cervical lymphadenopathy may also be present. The differential diagnosis of oral histoplasmosis includes SCC, other chronic fungal infections, and lymphoma. Ulcers present for weeks or months may represent other lesions of infectious etiology (other deep fungal, mycobacterial, treponemal, or parasitic), traumatic ulcerative granuloma, SCC, lymphoma, or other malignancy.[74]

Paracoccidioidomycosis

Epidemiology

Paracoccidioidomycosis is caused by *Paracoccidioidomycosis brasiliensis*. About 15,000 cases of paracoccidioidomycosis have been reported since 1930. It occurs in South and Central America; however, the majority of cases have been reported in Brazil.[75,76] *Paracoccidioidomycosis brasiliensis* infections are thought to be due to inhalation of spores from colonized soil and/or wood. Like other dimorphic fungi, paracoccidioidomycosis has both a mold and a yeast form.

Clinical Presentation

Similar to tuberculosis, most patients are asymptomatic after an initial infection. The organism can be dormant within lymph nodes for many years and then reactivate later in life. The disease affects primarily men (15:1 ratio men,women) over 30 years of age. When reactivated, the infection involves primarily the oral mucosa, the lungs, and the skin. Other potential sites of involvement are the gastrointestinal tract, the liver, the bones, the CNS, and the male genitourinary tract. In severe cases, signs and symptoms may mimic those of TB and include fever, weight loss, and productive cough with bloody sputum. Paracoccidioidomycosis can occur in immunocompetent and immunocompromised individuals; however, symptoms usually get worse more quickly in immunocompromised patients such as HIV-infected subjects.[77]

Diagnosis

Paracoccidioidomycosis can be identified by direct examination of sputum or biopsy from ulcers or pus draining from lymph nodes. A 10% potassium hydroxide (KOH) preparation should be used to observe paracoccidioidomycosis yeasts. The microorganism is then isolated in culture.[78–80]

Treatment

The preferred agents to treat paracoccidioidomycosis are azole antifungals, with itraconazole being preferred due to lower relapse rates. AmB is generally avoided in patients with mild or moderate illness due to higher toxicity.[81] Trimethoprim/sulfamethoxazole (cotrimoxazole) is also used for the treatment of paracoccidioidomycosis.[82] However, patients treated with cotrimoxazole generally require a longer treatment duration.

Oral/Facial Considerations

Oral mucosal lesions are a prominent feature of paracoccidioidomycosis and present as ulcers; oral complaints are often the presenting symptoms of these patients. Lesions of the gingival mucosa are most common, followed by the palate and lips. The lesions are frequently painful. Ulcerative lesions with crusting also occur on the facial skin and may infiltrate subcutaneously.[83]

Aspergillosis

Epidemiology

Organisms of the fungal genus *Aspergillus* cause multiple infections, including invasive aspergillosis, chronic necrotizing aspergillosis, allergic bronchopulmonary aspergillosis, and aspergilloma. Commonly found in soil, on plants, in decaying organic matter, and in dust from houses and building materials, *Aspergillus* spp. represent a variety of

organisms that are ubiquitous in the environment. Colonization of the respiratory tract in humans occurs. Thus, oral medicine clinicians should carefully consider whether a positive *Aspergillus* culture is compatible with an infection or simply colonization. *A. fumigatus* complex is generally considered the most pathogenic species.

The epidemiology of *Aspergillus* infections varies based on disease presentation. Immunocompromised patients, particularly those receiving chemotherapy, classically present with a fungal pneumonia from *Aspergillus*. In addition to the lungs, invasive aspergillosis can involve the CNS, bones, eyes, heart, and kidneys.[84,85]

Clinical Presentation

There are many risk factors that are strongly associated with acquiring invasive aspergillosis, such as allogeneic stem-cell transplantation, prolonged severe neutropenia (>10 days), immunosuppressive therapy, chronic granulomatous disease, solid organ transplantation, acute leukemia, aplastic anemia, and preexisting cavity (aspergilloma). Moreover, other risk factors weakly associated with increased risk for acquiring invasive aspergillosis include advanced chronic lung disease, primary immunodeficiency, HIV infection, diabetes, cystic fibrosis, severe burns, malnutrition, multiple myeloma, immunocompromised patients, age >55 years, and smoking.[84]

Diagnosis

Invasive aspergillosis has a high mortality rate; therefore, early diagnosis is crucial to improve prognosis. The diagnosis of invasive aspergillosis is still challenging, as microscopy and culture of lower respiratory specimens have low sensitivity. It is also often difficult to obtain tissue for histopathology from critically ill patients. Invasive diagnostic procedures such as bronchoscopy with BAL and/or biopsy, percutaneous transthoracic computed tomography (CT)-guided needle aspiration, and video-assisted thoracoscopic biopsy can show the characteristic angular, dichotomously branching, septate hyphae. Culture confirmation to distinguish *Aspergillus* spp. from other fungi with similar morphologic features is important (Figure 21-7). False-negative results occur with specimens obtained from unaffected areas. Thus, lack of positive fungal smear or culture does not rule out the diagnosis. Tissue biopsy for histopathology is the historical gold standard method for diagnosing invasive aspergillosis. PCR based on amplification of *Aspergillus*-specific fungal gene is promising, but often not commercially available.[84] Serum biomarkers such as *Aspergillus* galactomannan antigen and serum beta-D-glucan are frequently used in clinical settings. However, false-positive galactomannan results are common in patients who receive certain types of IV antibiotics. Serial galactomannan values improve the sensitivity and specificity of the test; however, the sensitivity is low in those receiving antifungal drugs as prophylaxis. Serum immunoglobulin (Ig) G antibodies to *Aspergillus* can be used to diagnose aspergilloma.[84]

Figure 21-7 *Aspergillus niger* spores. Source: spoonielife.wordpress.com. Reproduced with permission.

Due to the limitations of available diagnostic tests, immunocompromised patients frequently receive empiric treatment for invasive aspergillosis if they have a compatible syndrome (e.g., a malignancy on immunosuppressive chemotherapy and evidence of fungal pneumonia on CT scan), regardless of test results.

Prophylaxis

Patients with hematologic malignancies commonly may receive antifungal prophylaxis. The choice of agent is based on a variety of factors, including anticipated duration of immunosuppression, antineoplastic regimen, and local epidemiology.

Treatment

Aspergillus spp. are usually sensitive to the following antifungal drugs: AmB; azoles such as voriconazole, posaconazole, and isavuconazole; or echinocandins such as caspofungin and micafungin. Voriconazole is the preferred agent to treat invasive *Aspergillus* infections. Combination therapy with multiple antifungal agents is occasionally administered. Reversal of the underlying immune deficiency or surgical resection of the infected focus may also be combined with antifungal therapy to treat invasive aspergillosis.[84,86,87]

Oral/Facial Considerations

Oral colonization with *Aspergillus* spp. is common, although oral infections are rare. Oral medicine clinicians may also see allergy-mediated disease, such as allergic pulmonary aspergillosis and allergic fungal rhinosinusitis. These conditions are best managed by referral to medical providers, such as pulmonary specialists and otolaryngology to aid in diagnosis and management. Therapy may include corticosteroids and surgical debridement; antifungal agents are sometimes adjunctive treatments.[85,86]

Cryptococcosis

Epidemiology

Cryptococcosis is a worldwide infection that develops after fungal spores are inhaled from soil contaminated from bird droppings, primarily with two species, *Cryptococcus neoformans* and *C. gattii*. The infection is common in immunocompromised patients with one of the following underlying conditions: AIDS, steroid exposure, transplantation, liver disease, malignancy, and sarcoidosis.

The incidence is particularly high in HIV patients, with an estimated 220,000 cases of cryptococcal meningitis occurring worldwide each year resulting in nearly 181,000 deaths. Most cryptococcal meningitis cases occur in sub-Saharan Africa.

Clinical Presentation

The clinical presentation of cryptococcal infections is variable. Patients may have an insidious presentation with months of fatigue, lethargy, and memory loss. However, other patients may have an acute illness with sudden onset of fevers and headaches. Meningoencephalitis and meningitis are two of the most dreaded complications. Symptoms include fever, headache, lethargy, and mental changes and can lead to permanent neurologic damage.[88,89]

Diagnosis

Cryptococcosis can be diagnosed via microscopic examination, culture of tissue or body fluids, PCR, or serologic testing. Cryptococcal antigen testing of the blood CSF is a rapid test that is highly sensitive and specific for invasive infections.[90,91]

Treatment

In resource-limited settings with a high prevalence of cryptococcal meningitis and no access to cryptococcal antigen screening, primary prophylaxis with itraconazole or fluconazole may be effective in HIV-positive patients with a CD4 count of <100 cells/μL. Treatment of an active cryptococcal infection depends on many factors, such as the site of involvement, the immune status of the host, and the disease severity. Consultation with an infectious diseases physician is strongly recommended for patients with severe cryptococcal infections, particularly those with CNS involvement. AmB with or without flucytosine is the mainstay of therapy. Furthermore, close monitoring and CSF pressure during treatment may be required. Flucytosine is sometimes added to AmB to improve clearance of CSF cryptococcosis. Less severe infections are treated with fluconazole or itraconazole. Fluconazole is generally preferred due to superior tolerability and absorption. Treatment requires long courses of medication of at least six months or longer. Lifelong maintenance therapy may be required in patients with cryptococcal meningoencephalitis.[89,90,92]

Oral/Facial Considerations

Oral lesions of cryptococcosis may occur in patients with disseminated disease and immunosuppression. They have been described as ulcers and tumor-like nodules occurring on the gingiva and tongue (Figures 21-8 and 21-9).[91,93]

Figure 21-8 Cryptococcus lesions on the face.

Mucormycosis

Epidemiology

The term mucormycosis describes infections caused by the class of fungi known as the mucorales. Mucorales include *Rhizopus*, *Mucor*, and *Lichtheimia* (formerly *Absidia*).[94] The term "zygomycosis" has also been used for these infections. These organisms are typically found in the soil and decaying organic matter. These fungi are highly pathogenic when identified in a sterile site. However, in nonsterile sites they can be cultured from the human nose, throat, and oral cavity of healthy asymptomatic individuals. Infection classically occurs in patients with decreased host resistance (Figure 21-10), such as those with diabetic ketoacidosis, hematologic malignancies, solid organ or bone marrow transplants, history of corticosteroid therapy, graft-versus-host disease, patients with severe trauma or burns, and patients on deferoxamine therapy. Premature neonates are also considered vulnerable for acquiring the disease.[95–97]

Clinical Presentation

Mucormycosis is characterized by arterial invasion and a fulminant course, frequently resulting in death. The hallmark of infection is the formation of emboli, with resulting necrosis of involved tissue. Mucormycosis may present as a pulmonary, sinus, rhinocerebral, skin, or disseminated infection. The three most common forms of mucormycosis are rhino-orbiti-cerebral in diabetics, pulmonary in patients with hematologic malignancies or transplants, and infections from direct tissue inoculation related to combat or natural disasters.[95,98,99]

Treatment

The judicious use of immunosuppressants like corticosteroids, and adequate control of diabetes, may help in reducing the risk of infection with mucormycosis. Additionally, the use of rooms equipped with HEPA filters and the use of masks for patients with severe immunosuppression are possible preventative measures. Posaconazole is used as a secondary preventative measure in patients expected to continuing to be immunosuppressed after completing the therapy for mucormycosis.[95]

Diagnosis

Early diagnosis is essential for improved survival and reduced morbidity from extension and dissemination of disease. Negative cultures do not rule out mucormycosis because the fungus is frequently difficult to culture; instead, a biopsy for culture and direct examination should be performed. The histopathology shows necrosis and nonseptate hyphae, which are best demonstrated by a periodic acid–Schiff stain or the methenamine silver stain. Necrosis and occlusion of vessels are also frequently present. Newer techniques of identification include the use of PCR; however, this is not generally commercially available.[100]

Treatment

First-line therapy consists of a combination of aggressive surgical debridement and antifungal therapy. Although there are no randomized controlled trials, liposomal AmB is considered the drug of choice. Second-line treatment includes azoles, specifically posaconazole and isavuconazole. Echinocandins, such as caspofungin, are also sometimes used in combination with other antifungals.[95,101–103] The mortality rate is 50–100% in spite of therapy.[94]

Oral/Facial Considerations

The rhinomaxillary form of the disease, a variant of the rhinocerebral form, begins with the inhalation of the fungus. The fungus invades blood vessels, causing direct tissue toxicity, thrombosis, and ischemia. The fungus may spread from the oral and nasal region to the brain, causing death in a high percentage of cases. The most common symptoms of the rhinomaxillary form include proptosis, loss of vision, nasal discharge, sinusitis, and palatal necrosis.[103]

The most common oral manifestation of mucormycosis is ulceration of the palate, which results from necrosis due to invasion of a palatal vessel. The lesion is characteristically large, deep, and may lead to exposure of underlying bone. Ulcers from mucormycosis have also been reported on the gingiva, lip, and alveolar ridge. The differential diagnosis for oral mucormycosis is broad. Solitary mucosal ulcers of several weeks' and months' duration may represent lesions of other infectious etiology, traumatic ulcerative granuloma, SCC, lymphoma, or other malignancy. The initial manifestation of the disease may be confused with pain from an odontogenic infection or conventional bacterial maxillary sinusitis. More advanced disease with ulcer and palatal

perforation may suggest an antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis (e.g., Wegener granulomatosis).[98,103]

VIRAL DISEASES

Viruses are unique since they need a host cell to survive, unlike bacteria and fungi. Viruses can cause acute, chronic, and latent infections. Viruses can also be associated with malignancies, either via chronic inflammation or DNA damage. The most relevant viruses to the orofacial region include the families *Herpesviridae* and *Papillomaviridae*. However, there several other systemic viral infections that can present with oral and orofacial manifestations (Table 21-5). The majority of viral infections affecting the orofacial region are self-limiting in otherwise healthy individuals, while atypical presentations with systemic complications are more likely to occur in immunocompromised hosts.[106]

Transmission of viruses in a clinical setting from patient to dental healthcare personnel (DHCP) can be reduced by following simple steps. First, all DHCPs should receive routine vaccines for viral illnesses, including hepatitis B. DHCPs should always follow standard infection control procedures when caring for patients. Third, DHCPs should report any occupational exposures and follow local postexposure prophylaxis guidelines to minimize the chance of acquiring a viral infection from a patient. Appropriate diagnosis of oral viral infections is critical, especially to distinguish it from other infections, as some of them may well be malignant or have the potential to turn sinister.

Herpes Group of Viruses

The herpes group of the *Herpesviridae* family includes eight DNA viruses in three subclasses as alpha, beta, and gamma herpes viruses. Alpha herpes viruses include the herpes simplex virus-1 (HSV-1), herpes simplex virus-2 (HSV-2), and varicella-zoster virus (VZV, HHV-3). Beta herpes viruses are cytomegalovirus (CMV, HHV-5), human herpesvirus-6 (HHV-6), and human herpesvirus-7 (HHV-7). Gamma herpes viruses consist of Epstein–Barr virus (EBV, HHV-4) and human herpesvirus-8 (Kaposi sarcoma herpes virus or KSHV, HHV-8).[107–110]

Alpha Herpes Viruses

Herpes Simplex Virus

HSV-1 generally affects the areas above the waistline and HSV-2 mainly causes genital lesions or lesions below the waistline. However, HSV-1 and -2 can affect either area, including the oral cavity (Figures 21-11 and 21-12). Primary infection of HSV-1 occurs either during childhood as gingivostomatitis or, if not exposed then, as pharyngotonsillitis in an adult. Latent reactivation of HSV-1 most commonly manifests as herpes labialis or a common cold sore. However, atypical forms and severe disseminated forms can occur in immunocompromised individuals. The main mode of transmission of HSV-1 is through contaminated saliva and transmission may occur via kissing a child.

Both primary and secondary or recrudescent infections are self-limiting. Immunosuppression, ultraviolet sun exposure, stress, changes in weather, especially the colder months, could all attribute to the initiation of herpes labialis. Primary infection is common among children and young adults, either asymptomatic or in the form of gingivostomatitis, following a usual course of fever, headache, irritability, loss of appetite, lethargy, hypersalivation, and cervical lymphadenopathy. The majority who suffer from recurrent herpes labialis may experience a prodromal phase of tingling, burning sensation, itching, mild pain, and/or fever. Clinically, single or multiple small erythematous papules that develop and form vesicles appear on either upper or lower lip, which may or may not coalesce. They will either rupture or may heal by crusting, leaving no noticeable scar in most circumstances. An atypical clinical presentation may occur in immunocompromised patients and the elderly. The healing may be prolonged with pain in the immunocompromised patient. There may be widespread vesicles with ulcerations involving large areas of the lip mucosa and adjacent cutaneous surfaces of the perioral region. The diagnosis is clinical. However, HSV DNA using molecular diagnostic techniques can be considered in atypical cases and immunocompromised patients. Antiviral treatment is often recommended for immunocompromised patients and in moderate to severe infection in otherwise healthy individuals. Oral or systemic acyclovir, 200 mg tablets, 5 times daily for 7 days or topical application of 5% acyclovir cream every 4 hours for 5 days is the recommended dose. Valacyclovir 1–2 mg twice daily may be used for prophylaxis.

Patients rarely present with ocular manifestations of HSV. Those with a history of HSV who are complaining of ocular pain or blurry vision should be referred to a physician for further evaluation. Patients may also present with neurologic complications from HSV infections. These include encephalitis, meningitis, and Bell's palsy. These symptoms can present with or without oropharyngeal disease.

Varicella-Zoster Virus

Children who acquire VZV develop chickenpox, a diffuse rash. Nonimmune adults who acquire VZV generally have a more severe presentation. Chickenpox can lead to orofacial lesions such as vesicles, especially over the facial skin and the oral mucosa, in addition to the cutaneous lesions of the

Table 21-5 Signs and symptoms of common orofacial manifestations of viral infections.

Orofacial Signs and Symptoms	Usual Site[†]	Disease Associated	Possible Virus Associated	Underlying Factors to Be Considered
Erythema, ulceration	Lips, oral mucosa	Erythema multiforme	HSV	Drug reactions?
Vesicle and/or bullae	Oral mucosa Gingivostomatitis in a child (primary) Pharyngotonsillitis in an adult (primary)	Herpes simplex infection	HSV-1	
	Lips	HSV—herpes labialis	HSV-1	Secondary infection Latent
	Localized depending on the affected nerve	Herpes zoster	VZV	Past history of chickenpox
	Oral mucosa, lips, hand, and foot	Hand, foot, and mouth disease	Enterovirus	
	Oral mucosa	Pemphigus vulgaris?	HSV? CMV?	
Ulceration	Lips	Erythema multiforme	HSV?	
	Oral mucosa	HIV disease	CMV	
	Oral mucosa	Behçet's syndrome	HSV? CMV?[104,105]	Immunodeficiency
	Soft palate/oropharynx	Herpangina	Coxsackie	
White patches	Lateral border of the tongue, (bilateral)	Hairy leukoplakia	EBV	HIV
White growths	Oral mucosa, perioral region	Papilloma	HPV	Other sexually transmitted diseases
Prodromal tingling sensation	Lips	Herpes simplex secondary infection	HSV	
	Face, oral mucosa, and lips (unilaterally)	Herpes zoster	VZV	Immunosuppression, HIV
Pain	Localized lip lesion	Herpes simplex	HSV	Immunosuppression
	Localized depending on nerve involved	Herpes zoster	VZV	Past history of chickenpox
Pigmentation (with or without swelling)	Palate, gingiva	Kaposi sarcoma	HHV-8	Immunosuppression, HIV
Swelling	Palate, oral mucosa	Lymphoma	EBV	Immunosuppression, HIV
	Salivary (parotid) glands	Mumps	Paramyxovirus	

[†] Oral mucosa = nonspecific site, include mucosa covering the entire oral cavity and tongue.
CMV, cytomegalovirus; EBV, Epstein–Barr virus; HHV, human herpesvirus; HPV, human papillomavirus; HSV, herpes simplex virus; VZV, varicella-zoster virus.
Source: Adapted from Nair RG, Salajegheh A, Itthagarun A, Pakneshan S, Brennan MT, Samaranayake LP. Orofacial viral infections—an update for clinicians. *Dent Update*. 2014;41(6):518–520, 522–524. doi:10.12968/denu.2014.41.6.518.

trunk. Vesicles normally do not survive in the oral cavity, leaving an erythematous papular lesion. If not secondarily infected with bacteria, the lesions on the facial skin will usually heal without scarring.

Once a person has had chickenpox, VZV remains latent in sensory ganglia until reactivation and replication, resulting in herpes zoster (shingles). Herpes zoster generally affects those above the age of 50 years or the immunocompromised. It is characterized by a unilateral, distinctive painful vesicular rash over a dermatome, corresponding to the sensory ganglion where the VZV is latent (Figures 21-13 and 21-14). Orofacial manifestations are within the ophthalmic, maxillary, and mandibular nerve distribution of the trigeminal nerve. Maxillary and mandibular distribution may lead to intraoral vesicles and painful ulcerations. Preventative therapy includes vaccination against VZV.

Figure 21-11 Primary herpes involving lips and gingiva.

Antiviral therapy is not indicated for chickenpox in otherwise healthy individuals, but may be considered in children 12 years or older, patients with chronic cutaneous or pulmonary disease, patients on short to intermittent courses of aerosol corticosteroids, and those on long-term salicylates. Treatment is based on symptomatic relief and antiviral drugs. In general, antiviral therapy reduces the acute symptoms of pain and malaise, limits the spread and duration of the skin lesions, and may prevent the development of postherpetic neuralgia and reduce ophthalmic complications. Strict hand washing, wearing of gloves, and vaccination of staff against VZV is important in prevention of transmission of herpes virus in the clinical setting.

Like HSV, VZV complications may be ocular, such as herpes zoster ophthalmicus and acute retinal necrosis. Other

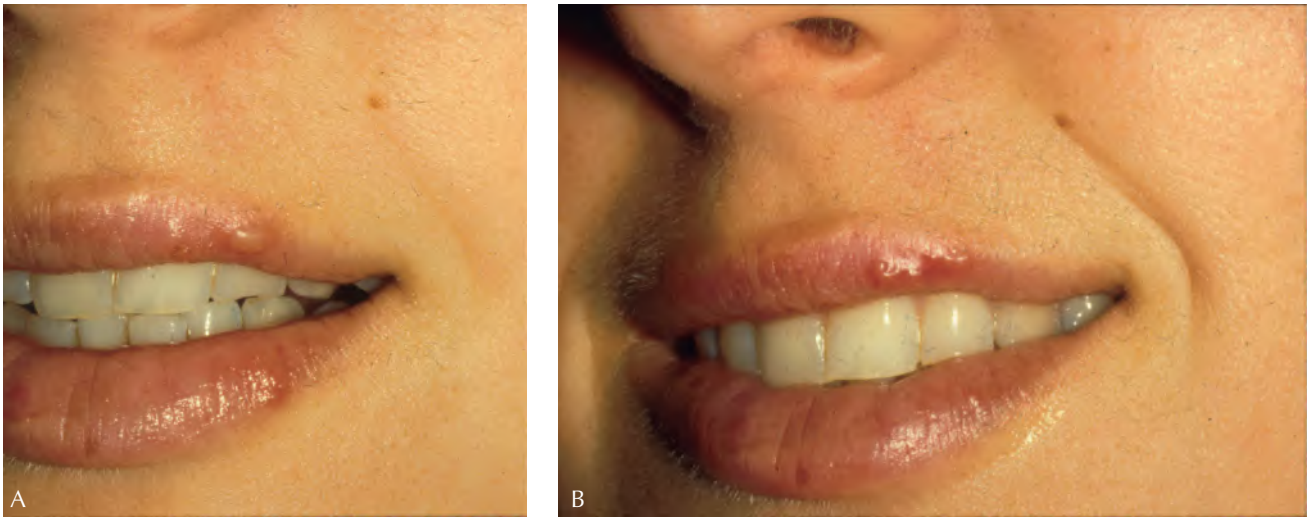

Figure 21-12 (A) Secondary herpes simplex lesions of the upper lip, one hour following prodrome stage. (B) The same herpetic lesions five hours following prodrome stage.

Figure 21-13 Herpes zoster.

Figure 21-14 Herpes zoster.

neurologic complications include aseptic meningitis and encephalitis. Oral medicine providers should also be aware that altered taste and oral lesions can be a manifestation of Ramsay Hunt syndrome, a triage of ipsilateral facial paralysis, ear pain, and vesicles in the auricle. VZV infections can be treated with acyclovir and valacyclovir.

Beta Herpes Viruses

Cytomegalovirus

CMV is known to cause mononucleosis-like disease characterized by pharyngitis, lymphadenopathy, and fever in a healthy immunocompetent individual, requiring no specific therapy. In the orofacial region, the mononucleosis-like disease can present with palatal petechiae and submandibular lymphadenopathy. This virus also has been implicated in nonspecific oral ulcers (Figures 21-15 and 21-16) and salivary gland disease, especially in HIV-infected patients. CMV can be diagnosed via antibody testing, PCR, and histopathology.

CMV can reactivate in immunocompromised patients and in any body tissues. Common syndromes include retinitis, colitis, and pneumonitis. Patients may also present with a nonspecific CMV syndrome with evidence of fevers, myelosuppression, and CMV viremia.

CMV infections are generally treated with ganciclovir and valganciclovir.

Figure 21-16 Cytomegalovirus lesion of the buccal mucosa.

Human Herpesvirus-6

HHV-6 is one of the first "ancient" human herpes viruses identified by molecular characterization. The main mode of viral transmission is through contaminated saliva. HHV-6 is present in the saliva of a large proportion of the healthy adult population. The primary infection is usually asymptomatic and commonly occurs during childhood by age 2 years. The clinical form is called exanthema subitum or roseala infantum (also called sixth disease). This biphasic disorder usually runs a benign course, causing fever, then a maculopapular rash on subsidence of fever at the end of the fourth febrile day. Uvulo–palatoglossal junction ulcers are useful early signs. The condition requires no antiviral treatment. Recent reports have emphasized the critical role of HHV-6 in the etiology of human oral SCC.[111] However, it is unclear whether the virus acts in combination with other carcinogens as a so-called co-carcinogen.

HHV-6 has been associated with several other conditions in immunocompromised patients, including encephalitis. It can be detected using PCR or paired serologic testing. HHV-6 can be treated with ganciclovir and foscarnet.

Human Herpesvirus-7

HHV-7 was first identified in 1990 and is closely related to HHV-6. It establishes latency in macrophages and T lymphocytes and reactivates frequently, with asymptomatic virus shedding through saliva. Most children acquire infection by the age of 3–4 years, and seronegative individuals are at risk of infection at any age. The spectrum of diseases caused by primary HHV-7 infection is similar to HHV-6, with milder clinical presentation. Diagnostic testing for HHV-7 is rarely performed. However, PCR and serologic testing platforms exist. Severe complications due to HHV-6 and -7 are treated with ganciclovir and its derivatives, foscarnet, or cidofovir.

Gamma Herpes Viruses

Epstein–Barr Virus

EBV can cause local or systemic infections and benign or malignant diseases of the orofacial region. They include

infectious mononucleosis or glandular fever, oral hairy leukoplakia (OHL), a white patch on the side of the tongue with a hairy appearance, and malignancies such as lymphomas (non-Hodgkin and Burkitt) and nasopharyngeal carcinoma.[112]

Clinical features of infectious mononucleosis are pharyngitis, cervical lymphadenopathy, generalized arthromyalgia, and associated fever and malaise. Classically, patients with EBV infections will develop a morbilliform rash following administration of amoxicillin. Symptomatic treatment is indicated such as antipyretics, analgesics, and anti-inflammatories, with no specific antiviral drug treatment. One important complication of mononucleosis includes splenic rupture. Patients with EBV who complain of significant abdominal pain should be referred for medical evaluation. OHL is a classic feature of immunosuppression, HIV disease, and iatrogenic immunosuppression such as cancer therapy. Clinically, lesions appear as white corrugated patches, commonly on the lateral border of the tongue and gingiva (Figure 21-17).

EBV-related lymphomas may present as a swelling and/or an ulcer in the oral cavity and orofacial region (Figure 21-18). Lymphomas and nasopharyngeal carcinomas need more aggressive cancer therapies, depending on the type and stage of the disease. Lymphomas generally manifest as painless anterior cervical lymphadenopathy.

Human Herpesvirus-8

HHV-8 is associated with KS, which is most commonly found in patients with HIV disease or AIDS. KS infection in non-HIV patients is rare and is classically associated with older males of Mediterranean decent. HHV-8 has been found in all the different types of KS affecting humans, hence it is known as Kaposi sarcoma herpes virus. KS seen in HIV disease or AIDS-associated KS is usually asymptomatic, with either purple or bluish macules or swellings affecting the orofacial skin and oral mucosae. However, KS lesions can occur anywhere in the body, including the lungs and other organs. In the oral cavity, the hard palate is the most common site, though other areas of the oral cavity could be involved. Management may include intralesional injections of cytotoxic drugs or sclerosing agents, and surgery is warranted only to restore esthetics such as the labial gingivae, for example.[113] Antiretroviral therapy (ART) has significantly improved the management of orofacial KS associated with AIDS. Systemic chemotherapy is used in patients with severe disease.

Figure 21-17 Lymphoma of the anterior cervical lymph nodes.

Figure 21-18 Human papilloma virus–related warts on the oral mucosa.

Human Papilloma Virus

The *Papillomaviridae* family is a group of double-stranded circular DNA viruses commonly found in the oral and oropharyngeal mucosa, tracheobronchial mucosa, and anogenital region. They are grouped into more than 100 types and HPV types 16 and 18 have been implicated in oral, oropharyngeal, and tonsillar carcinomas (Figures 21-19 and 21-20). More recently, there has been an increasing understanding of the risk factors of HPV in oropharyngeal cancers, especially the risk of orogenital sexual activity.

Orofacial manifestations of HPV are verruca vulgaris or the common wart on the perioral skin; oral papilloma of the oral mucosa; focal epithelial hyperplasia; and condyloma accuminatum, a sexually transmitted disease. Heck's disease or focal epithelial hyperplasia is a rare benign lesion attributed to subtypes 13 or 32 (Figure 21-21). Clinically, it presents as multiple white or mucosal-color papules or nodular lesions affecting the oral mucosae.

Management of HPV infection depends on the clinical presentation such as papilloma (Figure 21-22), typically using complete surgical excision and/or topical drug therapy. Laser and cryotherapy are not recommended due to lack of a tissue for histopathologic evaluation and a possible seeding of the

lesion to the surrounding tissue in the process. HPV vaccines are currently available and have a clear role in preventing many anogenital cancers and conditions related to HPV infection. The effectiveness of HPV vaccines in preventing oral HPV infection and cancer is unknown. Studies are underway to evaluate the long-term efficacy of the vaccine against both anogenital and non-anogenital endpoints.[114,115]

Coxsackie Virus

Coxsackie virus causes hand, foot, and mouth disease (strain A16) and herpangina. These viruses can pass through the oral mucosa and small intestine and the regional lymph nodes. Clinical features of hand, foot, and mouth disease include a mild prodrome followed by sparse distribution of vesicles with an erythematous halo affecting the oral mucosa, hands, and feet. Painful ulcerative lesions occur anywhere in the oral cavity, but are commonly found on the hard palate, tongue, and buccal mucosa. The enanthem (mucosal lesions) begins as 2–8 mm erythematous papules, a short vesicular stage, and yellow-gray ulcers with an erythematous halo. Lesions may coalesce and the tongue may become red, edematous, and painful, interfering with oral intake. Oral lesions heal without treatment within 5–7 days. Outbreaks of hand, foot, and mouth disease are common in daycare facilities. No specific treatment is necessary except for isolation of the patient, especially children, to avoid spread of the disease in a community.

Herpangina is also a disease of early life, with an incubation period of four days followed by an abrupt onset of fever with malaise, headache, and neck or back pain. The oral mucosal lesions consist of 1–2 mm gray-white papulovesicular lesions that progress to ulcers surrounded by an erythematous halo or rim, and the oropharynx may appear diffusely hyperemic. Lesions are distributed on the anterior tonsillar pillars, soft palate, uvula, and tonsils, and usually last for a week. Common complaints of affected patients are anorexia, dysphagia, and sore throat.

Hand, foot, and mouth disease and herpangina are typically diagnosed clinically. Only symptomatic treatment is necessary such as antipyretics, analgesics, and anti-inflammatories, if necessary.

Other Viruses with Orofacial Manifestations

Measles is caused by an RNA virus of the paramyxovirus group of the respiratory tract and skin through droplet infection, mainly affecting infants and young children. With an increase in measles vaccine coverage or a decrease in population density, the age distribution shifts toward older children. The first dose of the measles–mumps–rubella (MMR) vaccine should be given between 12 and 13 months of age and the second before school entry, but it can be given routinely at any time from three months after the first dose. In temperate climates, annual measles outbreaks typically occur in the late winter and early spring, while in tropical climates, a combination of high birth rates and variable associations of measles outbreaks with the rainy season creates highly irregular large outbreaks.

Measles is a highly contagious disease after an incubation period of about 10–12 days. Constitutional symptoms such as fever, malaise, conjunctivitis, coryza, and cough start and last for a week, followed by hyperpyrexia. Pathognomonic Koplik's spots are punctate blue-gray lesions surrounded by an erythematous ring (so-called grains of sand on a red background) on the buccal mucosa. They appear 1–2 days prior to the onset of the rash and remain for 2–3 days. Pinpoint raised red lesions on the soft palate may coalesce and the entire oropharynx turns red, lasting for 6–7 days. Other features include Herman spots on the tonsils as bluish-gray areas. Treatment is mainly based on supportive measures such as fluids and antipyretics.

Molluscum contagiosum is a disease due to a large DNA virus. Molluscum is primarily a disease of childhood. The clinical presentation includes asymptomatic, multiple flesh-colored, dome-shaped papules of the skin with a central depression. Lesions generally resolve in a few months. However, patients who are immunocompromised or deficient, such as those who are HIV infected, are more prone to develop severe disease. The diagnosis is typically clinical. When needed, treatments include physical destruction of the lesions with cryotherapy or curettage. Topical treatments have also been used, but none is particularly effective.

Congenital and Neonatal Viral Infections

Many organisms including viruses can infect the fetus and impair its development. The responsible organisms have been widely known as TORCH: **t**oxoplasma gondii, **o**ther microorganisms, **r**ubella virus, **c**ytomegalovirus, and **h**erpes viruses.[116] Awareness of occupational health hazards such as risk for pregnant female oral healthcare workers and pregnant patients is important in preventing such cross-infection, though it is very rare.[117]

Rubella

Rubella affects the fetus through a primary infection of the mother, but rare cases have been reported after a secondary infection or reinfection of the mother. The risk of fetus infection is highest in the first trimester (just before conception and during the first 8–10 weeks of gestation); the majority of infants infected at this age suffer from congenital defects and the treatment of the infants with congenital rubella is mainly supportive. Features of congenital rubella include congenital cataracts, congenital heart defects, sensorineural deafness, mental retardation, growth retardation, hepatosplenomegaly, jaundice, purpuric rash, or signs of meningoencephalitis. The majority of survivors progress poorly, with growth impairment and hearing, visual, and cardiac defects. Oral complications include hypoplastic enamel of both primary and permanent dentition.[118]

Cytomegalovirus

The neonatal disease rate is probably highest for children of women who have had a primary infection in the first half of pregnancy. Most infants with congenital CMV exhibit no signs of infection; however, infants with asymptomatic CMV infection may later develop neurologic deficits like microcephaly, intellectual disability, and motor defects, behavioral problems, and sensorineural hearing loss. Congenital CMV is perhaps the most common cause of congenital nongenetic sensorineural hearing loss.[119]

Herpes Simplex Virus Types 1 and 2

Transmission of HSV infection of the newborn usually occurs during pregnancy, intrapartum, and postnatally. Intrauterine viral transmission is highest during the first 20 weeks of gestation and may lead to abortion, stillbirth, and congenital anomalies. Manifestations of congenital HSV include skin lesions and scars, eye lesions (chorioretinitis, microphthalmia, and cataract), neurologic damage (intracranial calcifications, microcephaly, seizures, and encephalomalacia), growth, and psychomotor development retardation. Neonates infected intrapartum or postnatally by HSV can present with the disease localized to the skin, eye, and/or mouth, or can deteriorate rapidly as a result of respiratory distress, shock, multiorgan failure, disseminated intravascular coagulopathy, or encephalitis, with high rates of neurologic morbidity among survivors.

Varicella-Zoster Virus

Infection with the virus causing chickenpox, VZV, during early gestation can lead to either fetal loss or congenital varicella syndrome, which is a rare complication of infection with maternal varicella before 20 weeks of pregnancy. It can be associated with severe anomalies like dermatomal scarring, limb hypoplasia, ocular abnormalities, low birth weight, neurologic defects, and early death. Primary disease

in the mother around the time of delivery leads to neonatal infection. When maternal clinical infection occurs under 5 days prior to delivery to 2–5 days post delivery, a severe form of neonatal chickenpox is possible.[120]

Hepatitis Virus

Hepatitis viruses cause inflammation of the liver known as hepatitis. There are five main clinical types: hepatitis A (HAV), hepatitis B (HBV), hepatitis C (HCV), hepatitis D (HDV), and hepatitis E (HEV), with different modes of transmission, severity, and geographic distribution. Out of the five, types B and C lead to chronic disease, causing liver cirrhosis, cancer (hepatocellular carcinoma), and deaths. According to the World Health Organization (WHO), it is estimated that 325 million people globally live with the dangerous variants, HBV and/or HCV. Out of the 325 million, about 257 million were living with chronic HBV infection in 2016 and 71 million with chronic HCV infection as of 2015.

HAV infection can lead into mild to severe illness and is transmitted through contaminated food and water or from an infected individual (fecal–oral route). The majority of infected individuals recover completely after a short illness, with immunity lasting lifelong and mortality reported within a small group. HAV is prevalent in countries where there is a lack of clean water, sanitation, among MSM, and in persons who inject drugs (PWIDs). The treatment of HAV infections is supportive care. Prevention is through the HAV vaccine.

HBV infection presents as either an acute or a chronic disease, transmitted through contact with blood or other body fluids and vertical transmission from an infected mother to a child. Those who are chronically infected are prone to complications such as liver cirrhosis and hepatocellular carcinoma. HBV is highly contagious. Several antiviral medications are effective in treating HBV. Tenofovir (with or without emtricitabine) is preferred. Alternative agents include lamivudine, emtricitabine, adefovir, and entecavir. Once a person develops HBV, there is no cure. It is generally diagnosed via serologic testing (Table 21-6). The best mode of prevention is through an effective vaccination against HBV.

HCV generally presents as a chronic disease with varying degrees of disease severity, including cirrhosis and liver cancer. HCV is highly infectious and can be transmitted through a very small quantity of infected blood, such as in case of the bore of a needle. The main mode of HCV transmission is through injecting drug use, accidental exposure, and unsafe conditions in healthcare practices, and transfusion of infected blood. Sexual activities are thought to play a minor role in HCV transmission.[121] Diagnosis is by testing for anti-HCV antibodies. However, many patients spontaneously clear HCV infections, so HCV ribonucleic acid (RNA) is required to confirm an active chronic infection. In chronic HCV infection, the two main concerns are liver damage, leading to cirrhosis, and hepatocellular carcinoma. A liver ultrasound is generally the screening test of choice for both. Patients with active HCV should be managed by antiviral medications, which are curative. Modern HCV direct-acting antiviral (DAA) treatment regimens feature fixed-dose combination pills. At the time of publication, the two most common are glecaprevir/pibrentasvir and sofosbuvir/velpatasvir; however, several other regimens also exist. Treatment is selected based on virus genotype, prior treatment history, and antiviral resistance. Treatment courses vary from 8 to 24 weeks. Unfortunately, there are no effective HCV vaccines available yet.[122,123]

HDV requires HBV for its replication, hence it occurs as a super-infection or simultaneously with HBV and can be

Table 21-6 Common serologic patterns of hepatitis B (HBV) and C virus (HCV) infection.

Serologic Result	Interpretation
HBV	
HbsAg *neg*, anti-HBc *pos*, anti-HBs *pos*	Immunity from natural infection
HBsAg *neg*, anti-HBc *neg*, anti-HBs *pos*	Immunity from vaccination
HBsAg *pos*, anti-HBc *pos*, IgM anti-HBc *pos*, anti-HBs *neg*	Acute infection
HBsAg *pos*, anti-HBc *pos*, IgM anti-HBc *neg*, anti-HBs *neg*	Chronic infection
HBsAg *neg*, anti-HBc *pos*, anti-HBs *neg*	Recovering from acute infection, *or* False-positive anti-HBc, thus susceptible *or* "Low-level" chronic infection Resolving acute infection
HCV	
Anti-HCV reactive	A repeatedly reactive result is consistent with current HCV infection, *or* past HCV infection that has resolved, *or* biologic false positivity for HCV antibody Test for HCV RNA to identify current infection
Anti-HCV reactive, HCV RNA detected	Appropriate counseling and referral for medical care and treatment
Anti-HCV reactive, HCV RNA not detected	No further action required in most cases

anti-HBc, hepatitis B core antibody; anti-HBs, hepatitis B surface antibody; HbsAg, hepatitis B surface antigen; IgM, immunoglobulin M.

chronic. The main mode of transmission is through infected blood, body fluids, and, though rare, vertical transmission from mother to child, among PWIDs, and through hemodialysis. HDV can be treated with interferon-based regimens. There is no vaccine for HDV, so the best prevention is vaccination for HBV.

HEV is also a highly infectious virus and can lead to serious illness and death. The main mode of transmission is through the fecal–oral route via contaminated water. It has been recorded globally and commonly in Southeast Asia. Pregnant women are at particularly high risk of complications from HEV. There is a vaccine available in China, but it is unavailable in the rest of the world.

Orofacial Manifestations and Considerations

Hepatitis viruses cause serious liver damage and its consequences, especially susceptibility to bleeding and contraindications of certain drugs that depends upon the severity. There are several physical signs of end-stage liver disease, such as icterus or yellowing of the mucous membrane, including the oral cavity, due to jaundice, petechial hemorrhages and ecchymosis, palmar erythema, Dupuytren's contracture of the palm, urticaria, gynecomastia, and spider nevi. However, these features are nonspecific and may be present from other conditions, including alcohol-related liver disease.

With regard to orofacial structures, sialosis affecting the parotid glands and a close relationship with oral lichen planus, Sjögren syndrome, and sialadenitis has been documented. Halitosis with fetid odor, cheilitis, atrophic tongue, xerostomia, bruxism, and crusted perioral rash have also been reported.

Considering modern oral health practices, there is no cause for concern in treating hepatitis patients as long as all infection control measures are in place. If a healthcare professional is infected, they must avoid patient care during the infectious stages with active signs and symptoms of the disease.

Potential exposure to hepatitis virus in an oral health practice may include needle stick or other sharps injury, contact with potentially infectious body fluids, and exposure to mucus membranes. DHCP should report any bloodborne exposures. Depending on the nature of the exposure, baseline serologic data may be obtained from both the patient and the dental healthcare worker. Exposed healthcare workers should be monitored closely after exposure and, depending on the nature of the exposure, postexposure prophylaxis (PEP) may be ordered.[124]

Human Immunodeficiency Virus

HIV is an RNA-based retrovirus that integrates into the DNA of and replicates in a subset of T cells called CD4 cells. These CD4 cells help coordinate immune system responses. If left untreated, the CD4 cell count will deplete over time, leaving individuals at risk for a variety of infections. If the CD4 cell counts drop to very low levels, patients can develop a syndrome called acquired immunodeficiency syndrome (AIDS). However, if initiated on ART in a timely fashion, people living with HIV have the same life expectancy as HIV-negative individuals.[125]

Early diagnosis, appropriate timely management, and long-term retention in care for HIV patients remain major public health challenges. It is estimated that about 69,000 HIV-positive people have died and 1.7 million new infections were reported in 2019 alone. However, new infections have reduced by 39% and HIV-related deaths by 51%, and more than 15 million lives were calculated to have been saved due to ART between 2000 and 2019.

AIDS is a stage where the body's immune system is severely compromised due to HIV. Due to advances in ART and substantial public health efforts to engage HIV-infected individuals in care, fewer people are developing AIDS over time.

The definition of AIDS is when the CD4 count falls below 200 cells/mm^3 of blood, or when the patient develops one or more opportunistic infections regardless of their CD4 count. HIV is generally diagnosed with a combined antibody/antigen immunoassay, followed by an HIV PCR. Early diagnosis and treatment of HIV are essential for two reasons. First, early treatment may prevent patients from developing AIDS. Second, patients who are on treatment and have an undetectable viral load are not able to transmit the virus to others.

Transmission of HIV occurs mainly through body fluids such as blood, semen, vaginal secretions, or vertical transmission from an infected mother to her child while pregnant or during delivery and by breast milk.

Risk factors for HIV transmission include unprotected anal or vaginal sex, presence of other sexually transmitted diseases, contaminated needle and other equipment sharing among PWIDs, blood transfusions, tissue transplantation, and needle stick injuries. Vertical transmission from an HIV-infected mother to child may also occur if the mother's infection is not controlled.

Antiretroviral regimen for a treatment-naïve patient generally consists of two nucleoside reverse transcriptase inhibitors (NRTIs) administered in combination with a third active drug from one of three drug classes: an integrase strand transfer inhibitor (INSTI), a non-nucleoside reverse transcriptase inhibitor (NNRTI), or a protease inhibitor. Pharmacokinetic (PK) enhancers (also known as a booster) may also be included in ART regimens to reduce pill burden. Most modern HIV regimens are fixed-dose combination pills that will include three active agents.

An ART regimen should not be stopped unless discussed with a medical provider.[12,126]

Orofacial Manifestations and Considerations

Orofacial manifestations of HIV are variable. Patients with acute HIV (recent infection) may present with a mononucleosis-type syndrome with fevers, pharyngitis, and lymphadenopathy. Later oral manifestations of HIV include pseudomembranous or erythematous candidiasis, angle cheilitis, OHP, NG, necrotizing periodontitis, linear gingival erythema, KS, non-Hodgkin lymphoma (group 1), and melanotic hyperpigmentation, HSV infection, and HPV infection (group 2). There has been a major reduction in candidiasis, OHL, KS, and HSV infection since the advent of ART. HIV-associated salivary complications include xerostomia, Sjögren syndrome–like illness, sialosis, salivary gland benign lymphoepithelial cysts within salivary glands, diffuse infiltrative lymphocytosis syndrome (DILS), mucous extravasation, and even ranula.[127]

In a small group of ART recipients, immune reconstitution may be dysregulated, leading to opportunistic infection and complications. This immune dysregulation is called immune reconstitution inflammatory syndrome (IRIS), with possible manifestations in the mouth as atypical viral and fungal infections and KS. IRIS is generally managed with supportive care.

Another unwanted effect of ART is lipodystrophy, where there is a redistribution of adipose tissue of the face, leading to esthetic concerns (Figure 21-23). In addition to the face, lipoatrophy may affect buttocks, arms, and legs. Lipohypertrophy or excessive fat accumulation can also be an undesirable side effect over the abdominal and mammary regions and the neck. Atrophy of fat from the bilateral face can affect a patient's self-esteem, social isolation, and depression. Lipodystrophy also has been associated with insulin resistance, hyperlipidemia, and endothelial dysfunction, leading to cardiovascular complications. Lipodystrophy is less common with newer ART regimens.

In a healthcare setting, if exposure to HIV is suspected, appropriate action must be taken. The HIV status of the source individual should be determined. Depending on the nature of the exposure, PEP medication regimens using three or more forms of ART may be administered. Follow-up should include counseling, baseline and follow-up HIV testing, and monitoring for drug toxicity and complications, if any.

Figure 21-23 Lipoatrophy of the face and sialosis due to HIV.

Coronaviruses

Coronaviruses are enveloped single-stranded RNA viruses that cause a variety of infections in both humans and animals. The virus is named because of its crown-like appearance on electron microscopy. Two genera of coronavirus, α and β, infect humans. Alpha coronaviruses are one of the causes of the common cold. Beta coronaviruses include several important human pathogens, including the Middle East respiratory syndrome coronavirus (MERS-CoV) and severe acute respiratory syndrome coronavirus (SARS-CoV-1 and SARS-CoV-2).

MERS-CoV, a novel zoonotic infection that likely originated from camels, was first identified in 2012 in Saudi Arabia. Patients with MERS-CoV typically present with a respiratory tract infection that can progress to pneumonia and death in up to one-third of patients.[128] Human-to-human transmission is thought to be limited. The WHO tracks MERS-CoV cases here: https://www.who.int/emergencies/mers-cov/en/.

SARS-CoV-1, a zoonotic infection that may have originated from palm civets, was first identified in Guandong Province in China in 2003. Patients with SARS-CoV-1 also typically present with an influenza-like illness that can progress to pneumonia and death in approximately 15% of patients. Like MERS-CoV, human-to-human transmission is thought to be limited with adequate infection control precautions. There are no current cases of SARS-CoV-1 infections. However, it has reemerged four times since 2003. The WHO tracks SARS-CoV-1 cases here: https://www.who.int/ith/diseases/sars/en/.

SARS-CoV-2 is a zoonotic virus that likely originated in bats in Wuhan, China at the end of 2019.[129] Coronavirus disease 2019 (COVID-19) is the name of the clinical syndrome for patients infected with SARS-CoV-2. Patients with COVID-19 often present with influenza-like illness symptoms, with fevers, cough, fatigue, and myalgia. However, other presentations include anosmia, dysgeusia, and diarrhea. Furthermore, a substantial proportion of patients may have no symptoms at all.[130]

The virus is primarily transmitted via large respiratory droplets. Aerosols and surfaces are other potential additional sources of transmission. Live virus can be detected in aerosols in carefully curated laboratory settings.[131] However, the clinical significance of these findings remains controversial. A 2020 systematic review of real-world data demonstrates no substantial transmission of SARS-CoV-2 from patients to healthcare workers wearing standard surgical masks while

caring for COVID-19-infected patients.[132] Respirators (e.g., N95) continue to be recommended by the CDC during aerosol-generating procedures and during procedures in the nose, throat, oropharynx, and respiratory tract.[133]

The incubation period is up to 14 days.[134] The virus spike protein binds to the receptor-binding domain of the cellular receptor angiotensin-converting enzyme 2 (ACE2), which is distributed throughout the respiratory tract, the ducts of salivary glands, and the conjunctiva.[135,136]

At the time of this writing, the current gold standard for diagnosing COVID-19 is NAAT, which is thought to have good sensitivity and excellent specificity. However, false negatives can occur, and a single negative test should not rule out the disease in symptomatic patients. Similarly, NAAT simply detects SARS-CoV-2 virus material and cannot differentiate between live and dead virus. Therefore, a positive test does not necessarily mean that someone is contagious. SARS-CoV-2 antibody testing is also commercially available. The sensitivity and specificity of these tests vary depending on the manufacturer. There are also significant limitations to interpreting antibody tests. For example, a positive test should not be interpreted as immunity to SARS-CoV-2 as some antibody tests do not evaluate for the presence of neutralizing antibodies. Similarly, patients who have a positive antibody test may still be contagious to others. Patients may also have a negative antibody test and still have COVID-19 if they present within the first few days of symptoms.[137]

Dentistry is classified as one of the highest-risk professions for transmitting COVID-19.[138,139] Until further research on COVID-19 transmission dynamics in dental settings is performed, dentists should wear the following personal protective equipment:

- FFP3 (Europe) or N95 (USA) respirator.
- Disposable gown.
- Gloves.
- Eye protection (goggles or face shield).

In case of the unavailability of FFP3 respirators (99.95% filtration of 0.3 micron particles), N95 (95% filtration of 0.3 micron particles; cannot be used in Europe as not CE marked) or FFP2 (94% filtration of 0.3 micron particles) masks were considered to provide enough protection provided that they are face-fit tested for the specific user.[140,141] This has been reviewed in multiple sources.

Current (2021) evidence-based treatments for COVID-19 include remdesivir and dexamethasone.[142,143] However, dozens of other agents are under active investigation throughout the world. At the time of this writing, SARS-CoV-2 vaccines are also an active area of research, with several commercially available worldwide.[144,145]

Vaccines against SARS-CoV-2

Since the beginning of the worldwide pandemic in early 2020, over 100 new vaccines have been developed worldwide with the objective of producing long-lived protective immunity. These fall into four main groups:

- Inactivated viral product vaccines.
- Protein-based vaccines.
- Viral vector vaccines.
- Genetic vaccines.

In addition, short-lived passive immunization protection has been developed using monoclonal antibodies.

Inactivated vaccines are produced relatively easily and are usually administered intramuscularly. They are, however, limited by the productivity of the virus in cell culture, as well as the safety measures needed to grow large amounts of SARS-CoV-2.

Recombinant protein vaccines can be divided into recombinant spike protein–based vaccines, recombinant RBD (part of the spike protein)-based vaccines, and virus-like particle (VLP)-based vaccines.

In *viral vector vaccines* viruses, like adenoviruses, are modified to carry SARS-CoV-2 genes, including replication of the whole spike protein. They enter host cells to create coronavirus viral proteins or replicate and expose the coronavirus proteins on their surface.

Genetic vaccines are based on mRNA, which can be incorporated into muscle cells and protein expressed, or plasmid DNA, which can be produced at a large scale in bacteria and contain expression promoters and the gene that encodes the spike protein. The advantage of these technologies is the possibility of large-scale production.

Monoclonal antibodies against COVID-19 are not preventive measures like vaccines, but treatments. They are laboratory-made monoclonal antibodies that mimic those produced naturally or by vaccines. The monoclonal antibodies are usually directed against the spike proteins.

Oral Manifestations

A systematic review from September 2020 covered the spectrum of oral signs and symptoms of patients with COVID-19.[146] Gustatory impairment was the most common oral manifestation, with a prevalence of 45%. Taste disorders were 38% for dysgeusia and 35% for hypogeusia, while ageusia had a prevalence of 24%. Oral mucosal lesions varied and included white and erythematous plaques, irregular ulcers, small blisters, petechiae, and desquamative gingivitis. The tongue, palate, lips, gingiva, or buccal mucosa may have been affected. The authors concluded that taste disorders may be common symptoms in patients with COVID-19 and should be considered in the scope of the disease's onset and progression. They also reported that oral mucosal lesions are more likely to present as coinfections and secondary manifestations with multiple clinical aspects.

ENDOCRINE DISEASES

The term "endocrine" was coined by Starling to contrast the actions of hormones secreted internally (hence *endo*crine) from those substances that are secreted onto external surfaces (exocrine, e.g., sweat or saliva).[1] The term "hormone" is derived from the Greek *hormân*, "to set in motion, stimulate," a derivative of *hormé* meaning "impetus" or "impulse." This describes well the dynamic actions of hormones and their ability to induce cellular responses and their regulation of the major physiologic processes of growth, reproduction, metabolism, and the maintenance of homeostasis (e.g., glucose and calcium). The release and actions of hormones are controlled by means of predominantly negative "feedback loops," as exemplified by the hypothalamus-pituitary-adrenal (HPA) axis (see Figure 22-1).

The most common endocrine disorders are (Figure 22-2):[2]

- Diabetes mellitus.
- Obesity.
- Thyroid disorders: hypothyroidism, hyperthyroidism, goiter.
- Menstrual disorders and/or hirsutism, usually due to polycystic ovarian syndrome (PCOS).
- Hypogonadism (in association with erectile dysfunction).
- Osteoporosis and metabolic bone disease.
- Subfertility (delay or difficulty in conceiving).
- Disorders of growth or puberty.

Endocrine disorders (the "endocrinopathies") are common, and are increasing in frequency. They encompass some of most prevalent of the chronic diseases, including diabetes mellitus[3] and increasingly obesity.[4,5] Endocrine diseases affect the entire system of endocrine glands, the hormones, synthesized and secreted by these glands, and the target organs that are susceptible to the effects of these hormones. Endocrine disorders are complex and their diagnosis is complicated by four interacting components:[6,7]

- The *hypothalamus* (Figure 22-3) contains most of the "sensing" organs and tissues, and is the part of the brain that monitors crucial determinants of homeostasis; that is, water, electrolyte and osmotic balance, metabolism, the fed and fasted state, and the stress response. Additionally, over the course of a lifetime, conception, pregnancy, growth, development, sexual maturation, and senescence are also regulated by the hypothalamus. Various "biologic clocks" exist that are linked into and exert control over the 24-hour circadian rhythm, the 28-day menstrual cycle, and the longer temporal cycles associated with growth, development, and sexual maturation, including as an example the timing of the onset of puberty. The hypothalamus most significantly is the link between the endocrine and nervous systems. The hypothalamus produces releasing and inhibiting factors that control the hormones of the pituitary, as well as other hormones throughout the body, via the pituitary—the second major component of the endocrine system.
- The *pituitary* is a small pea-sized endocrine gland that regulates all of the major endocrine glands located throughout the body. It does this by the release of trophic hormones that stimulate the growth of the other endocrine glands, or by the release of hormones that stimulate the endocrine glands to release the hormones synthesized

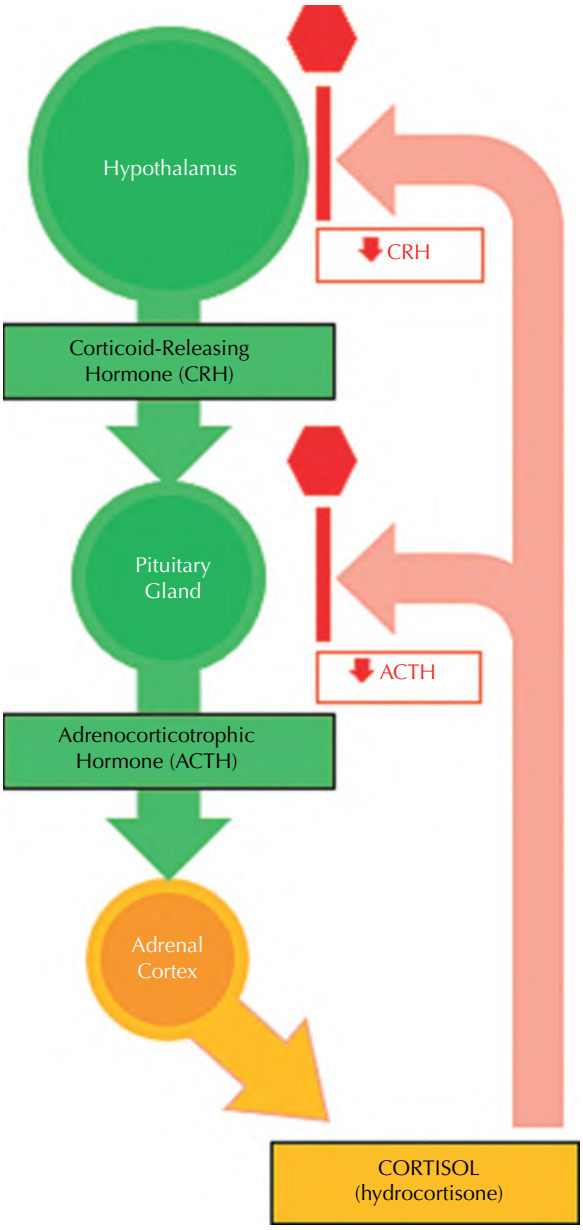

Figure 22-1 The hypothalamus-pituitary-adrenal (HPA) axis is an example of negative feedback inhibition. As the cortisol levels rise, the cortisol induces the hypothalamus to make less corticoid-releasing hormone, so causing the pituitary to make less adrenocorticotrophic hormone, which in turn causes the adrenal gland to produce less cortisol (the reverse applies: a lower cortisol level induces a rise in cortisol production). Courtesy of Mark Schifter.

within that gland itself. Except for oxytocin, all the hormones released by the major endocrine glands are under negative feedback control (meaning that the presence of circulating hormone downregulates further production of that hormone).

- *Major endocrine glands* includes the bilobed thyroid, the four parathyroid glands, the paired adrenal glands (sited atop the kidneys), the endocrine pancreas, and the gonads, testes, and ovaries). These glands synthesize and release the hormones that have the major effects on metabolism, water and electrolyte balance, glucose and calcium homeostasis, the stress response, as well as conception, growth, and development.
- *Hormones* are a class of signaling molecules, produced by endocrine glands that are generally transported by the circulatory system to target organs to regulate physiology and behavior (Box 22-1). Hormone production and function is complex, and includes biosynthesis and storage of a particular hormone in a particular gland, secretion (on receipt of the correct signal—often another hormone—by the gland), transport to the target cells/tissues, and recognition of the hormone by the target cell, via hormonal binding to a cell surface or intracellular receptor, resulting in transmission and amplification of the hormonal signal. The last stage is breakdown of the hormone.

In essence, it is either deficiencies or excess of these hormones of the major endocrine glands that result in significant disease states.[8] Malignancies of the endocrine glands are rare. There are a number of key aspects of endocrine disease about which dentists need to know:

- *Pathophysiology and management of the various endocrine diseases*. This ensures the safe delivery of dental care, the ability to possibly prevent disease progression or worsening morbidity, and to avoid serious potentially life-threatening complications of the patient's disease.
- *Complications that can arise from undiagnosed or poorly managed endocrine disease*. This includes knowledge of potentially life-threatening medical emergencies and the subsequent need to alter treatment planning (including awareness of potential drug interactions) or implement additional measures and resources so as to prevent the likelihood of such emergencies from occurring.
- *Manifestations of the disease in/on the stomatognathic system*. Recognition of the stomatognathic manifestations of endocrine disease is needed for the diagnosis of such conditions and also to identify those patients with poorly controlled or undiagnosed disease.

Hormones

There are five major classes of hormones (classified by their molecular weight and size and their precursor substrates; see Table 22-1),[9] and their function can be broadly classified into three areas of physiologic activity: growth and differentiation; maintenance of homeostasis; and reproduction.

Hormone release is the end-product of a long cascade of intracellular events. Polypeptide hormones, for example, require neural or endocrine stimulation of the cell to initiate

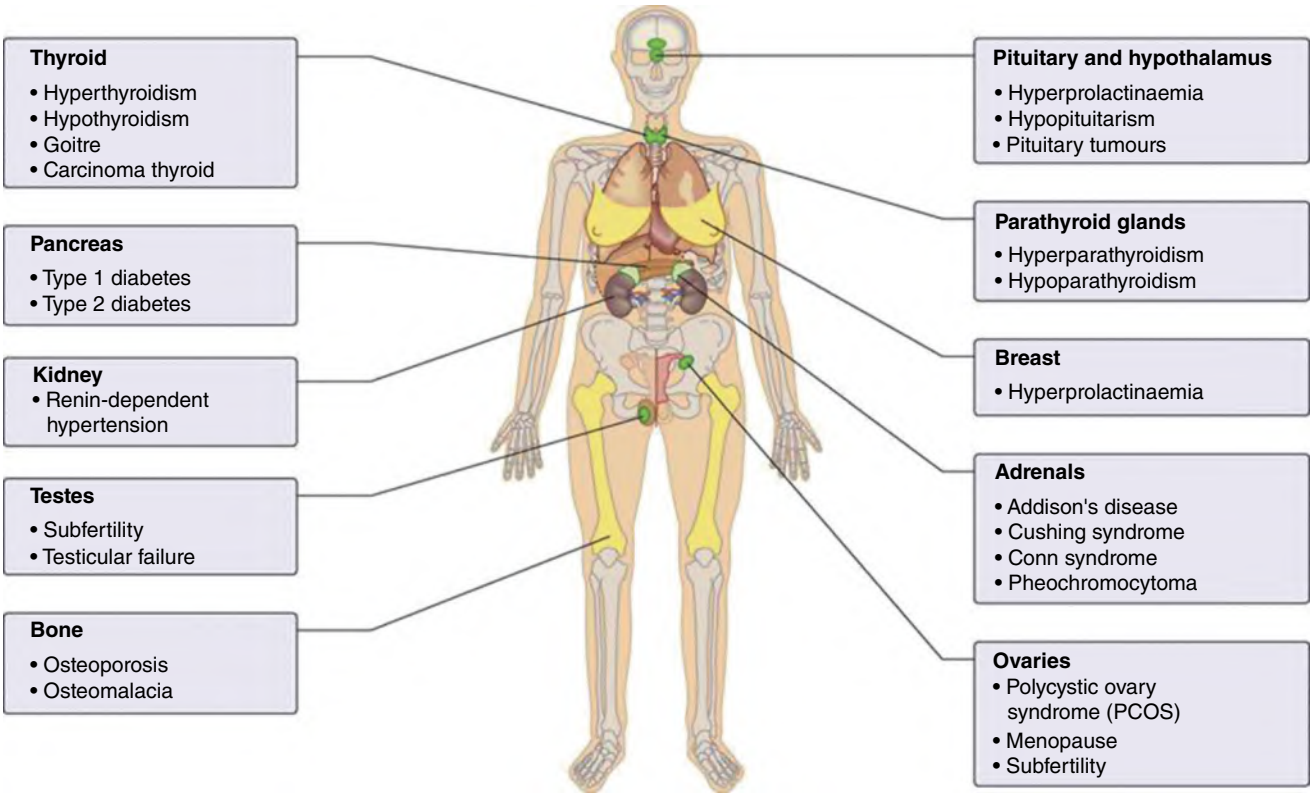

Figure 22-2 The major endocrine organs and common endocrine problems. *Source:* Kumar PJ, Clark ML (Eds.). *Kumar and Clark's Clinical Medicine*, 9th edn. Edinburgh: Saunders; 2017. Reproduced with permission.

transcription from DNA to a specific messenger RNA (mRNA) and subsequent translation into a polypeptide product. This product is often a precursor molecule or "pro-hormone" that is biologically inactive, and is then further processed and packaged into granules, in the Golgi apparatus. These granules are transported to the plasma membrane before release, which is itself regulated by a complex combination of intracellular regulators.

Hormone secretion can be (1) *continuous*, as seen with the thyroid hormones, with a half-life of 7–10 days for T4 and 6–10 hours for T3, and with little variation in levels over the day, month, and year; or (2) *pulsatile*, which is the normal pattern for the gonadotrophins—that is, luteinizing hormone (LH) and follicle-stimulating hormone (FSH)—with a large amount of hormone released in a pulse every 1–2 hours, depending on the phase of the menstrual cycle. Growth hormone (GH) is also secreted in a pulsatile fashion, but with undetectable levels between pulses.

There are major factors that control the release of various hormones over days, for example the circadian rhythm,

weeks, and months, and in the case of the growth and sex hormones over years.[10] The menstrual cycle is an example of a longer and more complex (28-day) biologic rhythm.[11] Other regulatory factors include physiologic "stress" and acute illness, which produce rapid increases in adrenocorticotropic hormone (ACTH) and cortisol, GH, prolactin, epinephrine, and norepinephrine. Over the course of the sleep–wake cycle the secretion of GH and prolactin is increased, especially during the rapid eye movement (REM) phase of sleep. Food intake results in many hormones being released to regulate the body's control of energy intake and expenditure, and these are therefore profoundly influenced by feeding and fasting. Secretion of insulin is increased, while testosterone and GH are decreased after ingestion of food, and secretion of a number of hormones is altered during prolonged food deprivation.

Most hormones are secreted directly into the circulation from the endocrine glands. In contrast to this, the hormones released from the hypothalamus are excreted at much higher concentrations and are confined to the pituitary portal system. Many hormones are bound to proteins within the circulation—it is important to note that only the free (unbound) hormone is available to the tissues and is biologically active. This binding to the plasma proteins serves to buffer against very rapid changes in plasma levels of the hormone and additionally plays a role in regulation of hormonal activity. Many of the tests of endocrine function measure the total rather than the free hormone, giving rise to difficulties in interpretation when the binding proteins are altered in disease states or by drugs. Binding proteins comprise both specific, high-affinity proteins of limited capacity, such as thyroxine-binding globulin (TBG), cortisol-binding globulin (CBG), sex-hormone-binding globulin (SHBG) and insulin-like growth factor (IGF)-binding proteins (e.g., IGF-BP3); and other, less specific,, low-affinity protein carriers, such as prealbumin and albumin.

Box 22-1 Signaling by the Endocrine System

The endocrine system is an information signal system like the nervous system, yet its effects and mechanisms are clearly different. The endocrine system's effects are slow to initiate, and prolonged in their response, lasting from a few hours up to weeks.

- Endocrine signaling relies on hormones that usually travel far via the circulatory system to reach their target organ.
- Paracrine signaling is a form of cell–cell communication in which a cell produces a signal to induce changes in nearby cells, altering the behavior or differentiation of those cells. Paracrine factors diffuse over only a relatively short distance (locally active), in contrast to hormones.
- Autocrine cell signaling entails the cell secreting a hormone or chemical messenger that binds to autocrine receptors *on that same cell*, leading to changes in the cell.

Table 22-1 Major classes of hormones.

Class		Examples	Receptor Types
1	Small neuropeptides	• Gonadotropin-releasing hormone • Thyrotropin-releasing hormone • Somatostatin • Vasopressin	
2	Amino acid derivatives	Catecholamines: • Epinephrine (adrenaline) • Norepinephrine (noradrenaline) • Dopamine • Thyroid hormone	• Interact with cell surface membrane receptors[#]
3	Large proteins[*]	• Insulin • Luteinizing hormone • Parathyroid hormone	
4	Steroid hormones[†]	• Cortisol • Estrogen	• Interact with intranuclear receptors
5	Vitamin derivatives	• Retinoids (vitamin A derivatives) • Vitamin D	• Lipid soluble

[*] Released by the "classic" endocrine glands: pituitary, thyroid, parathyroid, pancreatic islet cells, adrenals, and gonads.
[†] Synthesized from cholesterol-based precursors.
[#] An exception is thyroid hormones, which act via cytoplasmic receptors.

Hormone Receptors

These are broadly divided as follows:

- *Cell surface or membrane receptors*: typically, transmembrane receptors that contain hydrophobic sections spanning the lipid-rich plasma membrane and trigger internal cellular messengers.
- *Nuclear receptors*: these typically bind hormones and translocate them to the nucleus, where they bind hormone-response elements of nuclear DNA via characteristic amino acid sequences (so-called zinc fingers). Abnormalities of hormone receptors can be a rare cause of endocrine disease. The activation of intracellular kinases, phosphorylation, release of intracellular calcium and other "second messenger" pathways, and the direct stimulation of DNA transcription result in some or all of the following:
  - Stimulation or release of preformed hormone from storage granules.
  - Stimulation or synthesis of hormone and other cellular components.
  - Opening or closing of ion (e.g., calcium channels) or water channels (e.g., aquaporin water channels).
  - Activation or deactivation of other DNA-binding proteins, leading to stimulation or inhibition of DNA transcription.

The sensitivity and/or number of receptors for a hormone can be decreased after prolonged exposure to a high hormone concentration (downregulation). Equally, the reverse is true when stimulation is absent or minimal: the receptors are increased in number and/or sensitivity (upregulation).

Primary and Secondary Endocrine Gland Failure

Primary endocrine gland failure occurs when there is dysfunction or removal of the specific end-organ endocrine gland—the thyroid, parathyroid, endocrine pancreas, adrenal glands, or gonads (ovaries and testes). Causes of primary endocrine gland dysfunction or destruction include autoimmune disease, atrophic change, inflammatory or neoplastic infiltration, or complications related to treatment, such as radiotherapy or surgical removal of the gland.

Secondary disorders of the same endocrine axes are caused by diseases of the pituitary gland. The key to diagnosing the site of the disease, either primary or secondary, requires understanding of the negative feedback control system so as to correctly interpret blood tests used in the investigation of endocrine diseases. Primary hormone deficiency due to a disease process of the endocrine end-organ (e.g., thyroid, adrenal, or gonad) will lead to a loss of negative feedback and subsequent elevation in the corresponding anterior pituitary trophic (stimulating) hormone. In secondary gland failure, there will be low or "inappropriately normal" levels of the pituitary trophic hormone in the presence of low end-organ hormone levels; for example, if a patient has low circulating free T3 (fT3) and T4 levels in the context of low thyroid-stimulating hormone (TSH) levels, then the site of the disease is likely to be in or of the pituitary gland.

Investigations of Endocrine Function[12]

See Table 22-2.

Basal Blood Level

Basal hormone levels are especially useful for systems with long half-lives (e.g., T4 and T3, insulin-like growth factor-1 [IGF-1], androstenedione, SHBG) that vary little over the short term and so samples taken at any specific time are satisfactory.

For those hormones that fluctuate in accordance with the circadian rhythm (e.g., testosterone and cortisol), measurements must be taken at an appropriate time of day, which is 11:00 am for testosterone, while the patient is fasted, and between 8:00 and 11:00 am for cortisol, also with the patient fasted. LH/FSH, estrogen, and progesterone vary with time of menstrual cycle, and renin/aldosterone may vary with sodium intake, posture, and age.

Measurement of stress-related hormones (e.g., catecholamines, prolactin, GH, and cortisol) can be problematic, as the patient may be stressed by their attendance at the hospital or by the venipuncture itself, leading to falsely high levels. Sampling via an indwelling cannula at some time after the initial venipuncture overcomes this problem.

Urine Collection

This is done over the course of 24 hours and has the advantage of providing an "integrated mean" of a day's secretion of select hormones, namely the catecholamines and cortisol. However, in practice these results are often complicated by poor patient compliance and incomplete/wrongly timed collection. Age, sex, and weight of the patient are also confounding factors.

Saliva

Salivary analysis has the advantage of avoidance of venipuncture, and is being increasingly used, especially in children (for steroid estimations) or for samples collected at home.[13,14]

Stimulation and Suppression Tests

In general, stimulation tests are used to confirm suspected deficiency, and suppression tests to confirm suspected excessive levels of hormone secretion. These tests are valuable in instances when the secretory capacity of a gland is damaged,

Table 22-2 Diagnosis of endocrine disorders.

Gland/Disease	Hormonal Problem	Diagnostic Assays/Investigations
Acromegaly	Growth hormone (GH) excess	• Plasma GH • Plasma insulin-like growth factor-1
Hyperprolactinemia	Prolactin excess	• Plasma prolactin
Adrenal		
Cushing's syndrome	Excess cortisol	• 24 h urinary free cortisol • 1 mg dexamethasone suppression test • Midnight serum or salivary cortisol
Addison's disease	Low cortisol (and aldosterone)	• Adrenocorticotropic hormone stimulation test
Aldosteronism	Excess aldosterone	• Plasma renin activity • Plasma aldosterone after saline infusion
Pheochromocytoma	Excess epinephrine and/or norepinephrine	• Plasma catecholamines • 24 h urinary catecholamines
Thyroid		
Hyperthyroidism	Excess T4 and/or T3	• Suppressed thyroid-stimulating hormone (TSH; most sensitive test)
Hypothyroidism	Low T4 and/or T3	• Elevated TSH (most sensitive test)
Gonadal Failure/Diseases		
Male—hypogonadism	Low serum testosterone	• Low serum free testosterone levels
Female—ovarian failure	Loss of ovarian estradiol	• Elevated serum gonadotropins (follicle-stimulating hormone and luteinizing hormone)

such that despite maximal stimulation by the trophic hormone, there is diminished output of primary hormone. For example, with the short ACTH stimulation test for adrenal reserve, the healthy subject shows a normal response, while the subject with primary hypoadrenalism (Addison's disease) demonstrates an impaired cortisol response to the injection of cosyntropin (Synacthen®, Mallinckrodt, Dublin, Ireland), a potent ACTH analogue.[15]

Causes of Endocrine Disease

Endocrine diseases can be divided into two major disease states: hormone excess and hormone deficiency (Table 22-3).[16] Hormone resistance can be considered as a separate and distinct third condition,[17] but in practice the effect is one of hormone deficiency.

Hormone Excess

Hormone excess can be caused by autoimmune disorders, the excess therapeutic administration of hormones, or autonomous release with tumors, as can be seen with benign adenomas of the parathyroid, pituitary, and adrenal glands.

Hormone Deficiency

The commonest cause of hormone deficiency is from glandular destruction by autoimmune diseases (Table 22-4) and iatrogenic causes, namely surgery and radiotherapy. Rare cases include infection, inflammation, infarction, hemorrhage, or tumor infiltration. Autoimmune-mediated damage is highly prevalent, as seen with Hashimoto's thyroiditis and that of the pancreatic islet β cells in type 1 diabetes mellitus (T1DM).

Hormone Resistance

Hormone resistance results in a disease state that is similar to that seen with hormone deficiency, but diagnosis is more difficult and complicated as there are usually normal levels of the hormone on testing. The more severe hormone resistance disorders are due to inherited defects in membrane receptors, nuclear receptors, or the pathways that transduce receptor signals. These disorders are characterized by defective hormone action despite the presence of increased hormone levels. The most prevalent acquired forms of functional hormone resistance include insulin resistance in type 2 diabetes mellitus (T2DM) and leptin resistance in obesity.[8,18]

Table 22-3 Endocrine disorders.

Hormone Excess	Examples
Neoplastic	
Benign	• Pituitary adenomas • Hyperparathyroidism • Thyroid nodules (autonomous) • Adrenal nodules (autonomous) • Pheochromocytoma
Malignant	• Adrenal cancer • Medullary thyroid cancer • Carcinoid tumors*
Multiple endocrine neoplasia (MEN)	• MEN1 • MEN2
Autoimmune	• Graves' disease
Iatrogenic	• Cushing's syndrome (excess corticosteroid administration)
Infections/inflammatory	• Subacute thyroiditis
Receptor mutations (for activation)	• Luteinizing hormone (LH) • Thyroid-stimulating hormone • Parathyroid hormone (PTH) receptors
Hypofunction (Hormone Deficiency)	
Autoimmune	• Hashimoto's thyroiditis • Type 1 diabetes mellitus • Addison's disease
Iatrogenic	• Radiation induced • Hypopituitarism • Hypothyroidism
Infectious/inflammatory	• Sarcoidosis of the hypothalamus
Hormone mutations	• Growth hormone (GH) • LH • Follicle-stimulating hormone (FSH) • Vasopressin
Enzyme defects	• 21-Hydroxylase deficiency (congenital adrenal hyperplasia)
Developmental defects	• Turner's syndrome (females)
Nutritional (vitamin) deficiency	• Vitamin D • Iodine
Hemorrhage/Infarction	• Adrenal insufficiency
Hormone Resistance	
Receptor mutations	
Membrane	• GH • Vasopressin • LH • FSH • Adrenocorticotropic hormone • Gonadotropin-releasing hormone • Growth hormone-releasing hormone • PTH • Leptin • Ca^{2+}

Table 22-3 (Continued)

Hormone Excess	Examples
Nuclear	• Androgen receptor • Estrogen receptor • Glucocorticoid receptor • Peroxisome proliferator activated receptor • Vitamin D receptor
Signaling pathway mutations	• Albright's hereditary osteodystrophy
Postreceptor	• Type 2 diabetes mellitus • Leptin resistance

* Of neuroendocrine origin, derived from primitive stem cells of the gut wall, but can occur throughout the body.

Table 22-4 Endocrine glands and autoimmune disease(s).

Clinical Syndrome	Organ	Prevalence (if known*)	Antibody	Antigen
Stimulating				
Graves' disease† Neonatal thyrotoxicosis	Thyroid	1 in 100	Thyroid-stimulating immune-globulin (TSI, TSAb)	Thyroid-stimulating hormone receptor
Destructive				
Autoimmune hypophysitis Selective hypopituitarism (e.g., growth hormone deficiency, diabetes insipidus)	Pituitary specific cells			
Myxedema† (primary hypothyroidism)	Thyroid	1 in 100	Thyroid microsomal Thyroglobulin	Thyroid peroxidase enzyme (TPO) Thyroglobulin
Primary hypoparathyroidism	Parathyroid		Parathyroid chief cell	
Addison's disease‡ (primary hypothyroidism)	Adrenal (adrenal cortex but sparing medulla)			
Type 1 diabetes mellitus	Pancreas beta-islet cells	1 in 500	Autoantibodies to GAD_{67} and GAD_{65}	Glutamic acid decarboxylase (GAD)
Pernicious anemia§ (stomach)	Gastric parietal cell intrinsic factor			
Primary ovarian failure	Ovary	1 in 500		
Primary testicular failure	Testis			
Vitiligo (skin)†	Skin melanocytes		Anti-melanocyte	

* Prevalence for Northern European/Caucasian populations.
Stomatognathic system manifestations:
† Associated with lichen planus, including oral lichen planus.
‡ Hyperpigmentation ("bronzing") and increased number of melanotic macules of the oral mucosa.
§Atrophic glossitis.
Associated diseases include myasthenia gravis and autoimmune liver diseases.

HYPOTHALAMUS AND PITUITARY

Hypothalamus

The hypothalamus (Figure 22-3) contains vital sensors to monitor and control key functions such as appetite, thirst, thermal regulation, the sleeping/waking cycle (circadian rhythm), the menstrual cycle, and the response to stress, exercise, and mood. It serves to integrate the many neural and endocrine inputs to control the release of pituitary hormone-releasing factors. The hypothalamic neurons secrete both pituitary hormone-releasing and pituitary-inhibitory factors (and hormones) via the portal (vein) system, which passes down the stalk into the pituitary.[19]

Pituitary Gland

The pituitary gland is a pea-sized structure situated at the base of the brain within the sella turcica, and is in intimate association with the hypothalamus. It plays a key role in the control of the endocrine system via feedback mechanisms, and hence has been termed the "conductor of the endocrine orchestra."[20]

The pituitary gland is divided into two anatomically, functionally, and developmentally distinct structures: the anterior and posterior lobes.

Anterior Pituitary (Adenohypophysis)

The anterior pituitary hormones (Figures 22-3 and 22-4) are under predominantly positive control by the hypothalamic-releasing hormones, apart from the release of prolactin, which is under tonic inhibition by dopamine. Therefore, pathologic conditions that interrupt the flow of hormones between the hypothalamus and the pituitary gland result in deficiencies of most hormones, but the oversecretion of prolactin. The anterior pituitary is a mixture of cells that produce GH, ACTH, TSH, LH, FSH, and prolactin. ACTH, TSH, FSH, and LH are all intermediaries in their respective endocrine axes; each responds to a specific hypothalamic hormone (Figure 22-5) and, in turn, acts upon an end-organ gland to bring about the endocrine response.

There are five major anterior pituitary axes:

- Gonadotrophin axis.
- Growth axis.
- Prolactin (lactation) axis.
- Thyroid axis.
- Adrenal axis.[21]

The role of the anterior pituitary hormone prolactin is for the initiation and maintenance of lactation. Prolactin levels are increased during pregnancy, breast-feeding, nipple stimulation, stress, and chest wall injury, and by medications with antidopaminergic properties (e.g., antipsychotics).

Posterior Pituitary (Neurohypophysis)

The posterior pituitary (Figures 22-3 and 22-4) is a group of neural cells that are an extension of the hypothalamus and have secretory capacity. The posterior pituitary only secretes two hormones, arginine vasopressin (AVP), also known as antidiuretic hormone (ADH), and oxytocin, both of which are nonapeptides (oligopeptides formed from nine amino acids; Figure 22-5). The primary physiologic functions of oxytocin include contraction of the myoepithelial cells of the alveoli of the mammary gland, which is important during lactation as part of the "let-down response," and contraction of the uterus during childbirth and immediately postpartum.

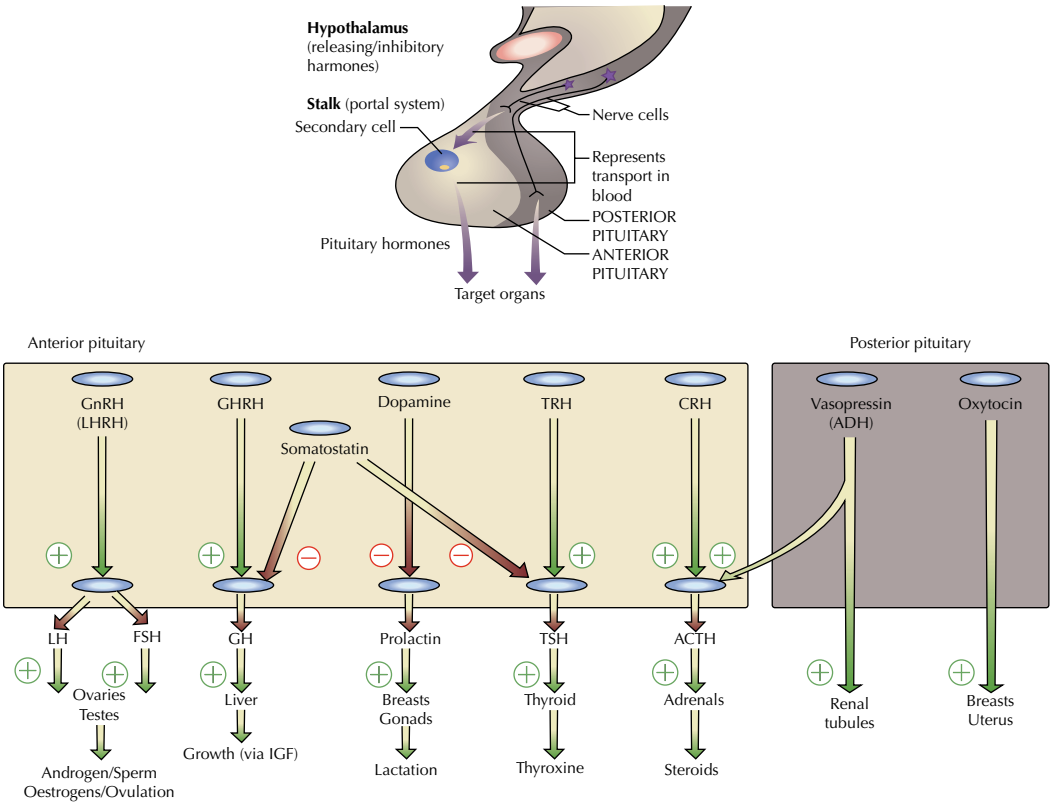

Figure 22-5 The hypothalamic-releasing hormones and their corresponding pituitary trophic hormones. ACTH, adrenocorticotrophic hormone; CRH, corticotrophin-releasing hormone; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone; GnHR, gonadotrophin-releasing hormone; LH, luteinizing hormone; LHRH, luteinizing hormone-releasing hormone; TRH, thyrotrophin-releasing hormone; TSH, thyroid-stimulating hormone. *Source:* Kumar PJ, Clark ML (Eds.). *Kumar and Clark's Clinical Medicine*, 9th edn. Edinburgh: Saunders; 2017. Reproduced with permission.

Hormone Excess

Hormone excess is seen with pituitary adenomas that are usually benign and slow growing. The symptoms related to the physical enlargement of the adenoma include visual impairment or headache. Occasionally these are detected incidentally as a finding on a magnetic resonance imaging (MRI) or computer tomography (CT) scan. They can result in increased secretion of the hormone(s) produced by the cells represented in these lesions and/or decreased secretion of other hormones due to compression by the tumor. In contrast, pituitary apoplexy (pituitary infarction) has a dramatic presentation with a sudden and severe headache, often with diplopia. Evaluation of masses within the sella turcica is best done with MRI (see Figure 22-6) and evaluation of the hormonal profile.

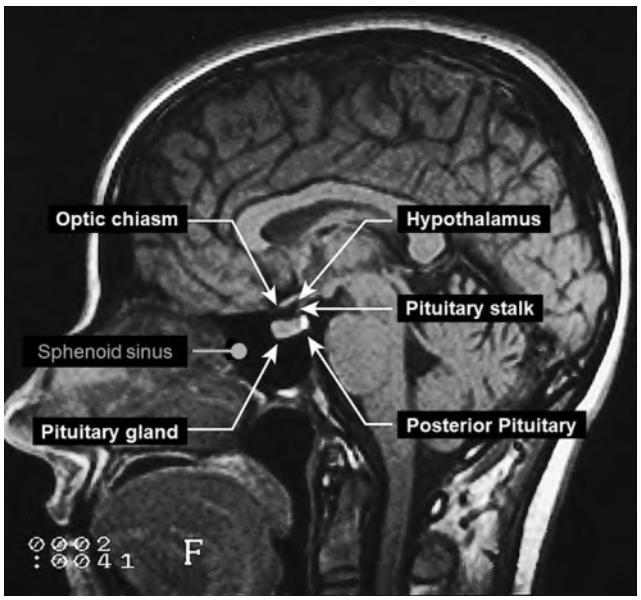

Figure 22-6 Magnetic resonance imaging (MRI) of a sagittal section of the brain, showing the pituitary fossa and adjacent structures. *Source:* Modified from Kumar PJ, Clark ML (Eds.). *Kumar and Clark's Clinical Medicine*, 9th edn. Edinburgh: Saunders; 2017. Reproduced with permission.

Hypopituitarism

Defects of the hypothalamic-releasing hormones or of the pituitary trophic hormones can be selective or multiple. Selective deficiencies of GH, LH/FSH, ACTH, TSH, and

vasopressin (ADH) are all seen from a variety of causes. Multiple deficiencies usually result from a tumor. There is generally a progressive loss of anterior pituitary function, with GH and the gonadotrophins usually being the first trophic hormones affected. Hyperprolactinemia, rather than prolactin deficiency, occurs relatively early, because of loss of tonic inhibitory control by dopamine. TSH and ACTH secretion is usually the last to be affected. Panhypopituitarism refers to deficiency of all anterior pituitary hormones and it is most commonly caused by pituitary tumors, or as a consequence of the surgery or radiotherapy used in the treatment of such tumors. ADH and oxytocin secretion will only be significantly affected if the hypothalamus is involved, either by a hypothalamic tumor or by suprasellar extension of a pituitary lesion. ADH and oxytocin deficiency is rarely seen with an uncomplicated pituitary adenoma. In general, the symptoms of deficiency of a pituitary-stimulating hormone are the same as primary deficiency of the peripheral endocrine end-organ; for example, TSH deficiency results in primary hypothyroidism and so causes similar symptoms due to lack of thyroid hormone secretion.[22]

Clinical Features

The symptoms and signs will reflect the extent of the hypothalamic and/or pituitary deficiencies, with mild deficiencies being generally clinically silent.

- *Secondary hypothyroidism* and *adrenal failure* both lead to tiredness and general malaise.
- *Hypothyroidism* results in weight gain, slowed mentation, slowness of action, dry skin, and cold intolerance.
- *Hypoadrenalism* causes mild hypotension, hyponatremia, and, ultimately, cardiovascular collapse during severe intercurrent stressful illness.
- *Gonadotrophin/gonadal deficiency* leads to loss of libido, loss of secondary sexual hair, amenorrhea, and erectile dysfunction.
- *Hyperprolactinemia* can cause galactorrhea and hypogonadism, including amenorrhea.
- *GH deficiency* causes growth failure in children and impaired wellbeing in some adults.
- *Weight increase* can be due to hypothyroidism.
- *Weight loss* can occur with severe combined deficiency (pituitary cachexia).
- *Panhypopituitarism* when long-standing gives the classic picture of pallor with hairlessness ("alabaster skin").

Treatment entails hormone replacement by synthetic equivalents. Steroid and thyroid hormones are essential for life. Both are given as oral replacement drugs, as in primary thyroid and adrenal deficiency, aiming to restore biochemical normality (see Table 22-5).

Table 22-5 Hypopituitarism: hormone replacement regimens.

Axis	Replacement Regimen
Adrenal	• Hydrocortisone 15–40 mg daily (starting dose 10 mg on rising/5 mg lunchtime/5 mg evening) Normally no need for mineralocorticoid replacement
Thyroid	• Levothyroxine 100–150 µg daily
Gonadal	
Male	• Testosterone—intramuscular, oral, transdermal, or implant
Female	• Estrogen/progesterone (cyclical)—orally or as patch
Fertility	• Human chorionic gonadotrophin *plus* Follicle-stimulating hormone (purified or recombinant) or gonadotropin-releasing hormone—for testicular development, spermatogenesis, or ovulation
Growth	• Children—recombinant growth hormone (GH); used to achieve normal growth in children • Adults—advocated for replacement therapy; GH has effects on muscle mass and wellbeing
Thirst	• Desmopressin 10–20 µg, 1–3 times daily by nasal spray or orally 100–200 µg 3 times daily • Carbamazepine, thiazides, and chlorpropamide—very occasionally used in mild diabetes insipidus
Lactation (breast)	• Dopamine agonist (e.g., cabergoline 500 µg weekly)

ABNORMALITIES OF GROWTH AND STATURE

Growth Hormone

GH is the pituitary factor responsible for growth in humans. GH secretion is stimulated by growth hormone-releasing hormone (GHRH), released into the portal system from the hypothalamus (Figure 22-7). There is a separate GH-stimulating system that interacts with ghrelin, a hormone that is synthesized by the stomach. It is unknown how the two systems interact. GH binds to receptors mainly found on liver cells, which results in turn in the release of IGF-1, for which there are multiple binding proteins (IGF-BP) in the plasma. Of these, IGF-BP3 can be measured to assess GH status. The metabolic actions of this system are increased collagen and protein synthesis; retention of

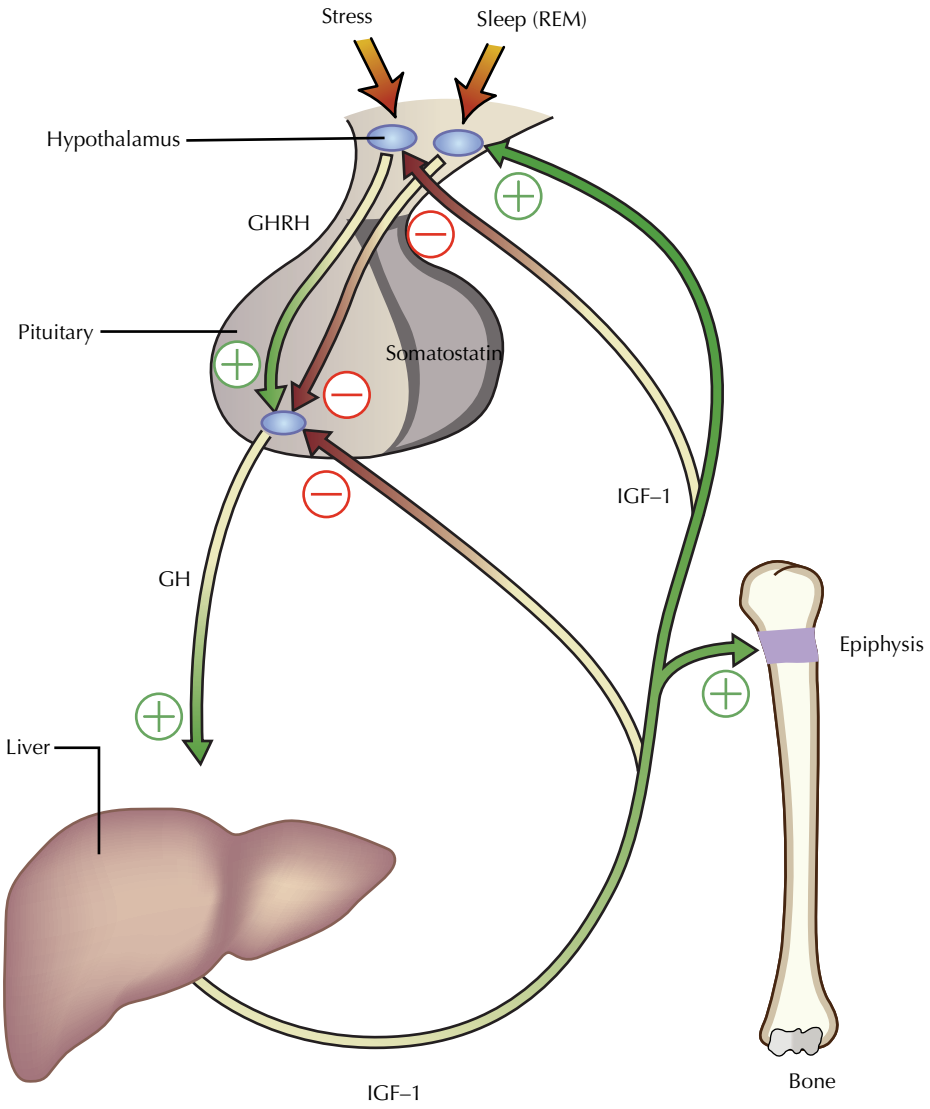

Figure 22-7 Growth hormone (GH): release and action. Pituitary GH is secreted under dual control of growth hormone-releasing hormone (GHRH) and somatostatin, and stimulates release of insulin-like growth factor 1 (IGF-1) in the liver and elsewhere. IGF-1 has peripheral actions, including bone growth by acting on the epiphyseal plate (epiphysis). *Source:* Kumar PJ, Clark ML (Eds.). *Kumar and Clark's Clinical Medicine*, 9th edn. Edinburgh: Saunders; 2017. Reproduced with permission.

calcium, phosphorus, and nitrogen (necessary for anabolism; i.e., the building of molecules); and opposing the actions of insulin. GH release is intermittent, mainly nocturnal during REM sleep, and is significantly increased during adolescence, but afterward declines.

Apart from GH, the following factors play a role in the normal linear growth of humans:

- *Genetics*: children of short parents will probably be short and vice versa.
- *Nutrition*: inadequate nutrients result in impaired growth, either from inadequate dietary intake or small bowel disease, for example coeliac disease.
- *General health*: serious systemic disease, such as chronic infection, will impair growth.
- *Intrauterine growth retardation*: this will result in poor long-term growth, whereas premature infants tend to catch up.
- *Emotional deprivation and psychologic factors*: these play a role in growth and development, although the mechanisms are complex and not fully understood.

Growth Assessment and Treatment

Growth charts and associated computer programs are now available for national and specific ethnic groups to monitor

and predict a child's final height. The Centers for Disease Control and Prevention (CDC) have readily available (downloadable) growth charts consisting of a series of percentile curves that illustrate the distribution of selected body measurements in US children (Figures 22-8 and 22-9).[23,24] These growth charts are also essential for predicting the treatment and prognosis of orthodontic and/or orthognathic treatment.[25]

Growth Failure (Short Stature)

This is usually noted by the child's parents. Height velocity is more helpful than current height. This requires at least two measurements some months apart and, ideally, multiple serial measurements. Height velocity is the rate of current growth (centimeters per year), while the current attained height is largely dependent upon previous growth. Computer programs are available to calculate the key indices, which include standard deviation scores based on the degree of deviation from age/sex norms.[26]

Further investigations include dynamic assessment of GH levels, IGF and IGF-BP3 blood levels, thyroid function tests, and assessment of bone age, by radiographs of the nondominant wrist and karyotyping in females for Turner's syndrome.[27]

Risk Factors for Short Stature

Risk factors for short stature include:[28]

- Intrauterine growth retardation, and weight and gestation at birth.
- Systemic disorders, especially small bowel disease.
- Congenital abnormalities (i.e., skeletal, chromosomal, or other).
- Endocrine status, particularly thyroid.
- Dietary intake.
- Drugs, especially steroids for asthma.
- Emotional, psychological, family, and school problems.

A child with normal growth velocity is unlikely to have significant endocrine disease and the most common cause of short stature in this situation is pubertal or "constitutional" delay. However, low growth velocity without an apparent systemic cause requires investigation (Table 22-6), as does sudden cessation of growth, since this suggests major physical disease, and in the absence of findings of systemic disease then a cerebral tumor or hypothyroidism is most likely.

Tall Stature

Tall stature (as opposed to gigantism/acromegaly) is most commonly hereditary, because of having tall parents. However, if the child's stature is usually tall and not consistent with the stature of the parents, chromosomal abnormalities such as Klinefelter syndrome or Marfan syndrome, or metabolic abnormalities, need to be considered. GH excess is a very rare cause and is usually clinically evident.

Acromegaly and Gigantism (Growth Hormone Excess)

GH is released from the somatotropic cells within the lateral wings of the anterior pituitary gland and is the primary trophic hormone responsible for postnatal growth and development. GH excess causes what is more formally termed *pituitary gigantism* in children if this occurs before fusion of the epiphyseal plate (growth). Gigantism is a nonspecific term that denotes excessive growth in a pediatric patient.[29] GH excess results in *acromegaly* if it occurs after the bony growth plates have fused. In almost all cases this is due to GH-secreting pituitary adenoma.

GH's major trophic effect is the release of IGFs from the liver. IGFs, as their name suggest, are proteins with significant homology to insulin, with a wide range of functions, but principally act to increase bone growth (specifically bone length). Although many cells have GH receptors and may respond to GH, the vast majority of the growth-stimulating effects of GH are mediated by IGF-1. GH release is under positive regulation by the hypothalamic peptide GH-releasing hormone. The amount and pattern of GH production and IGF release change markedly across the life cycle, with maximal release during the intense growth periods of late childhood and adolescence and low levels with advanced age. GH is released from the pituitary in a pulsatile fashion, with peak secretion at night. Thus, serum GH values vary considerable over the course of a 24-hour period, so a random sample may not reliably indicate true GH levels. In contrast, IGF-1 serum levels are relatively constant over the course of the day, so an IGF-1 sample can be taken at any time of the day and is indicative of GH levels.

Gigantism is very rare, with 0.6% reported in a large pediatric cohort.[30] Acromegaly is rare, with an overall prevalence of estimated prevalence in Europe of 30–70 individuals per million, affecting men and women equally.[31] The rapid growth seen with gigantism can be distinguished from that of precocious puberty. In gigantism, growth occurs in the absence of early secondary sexual characteristics, as the pituitary tumors (somatotroph adenomas) that lead to GH excess result in the loss of production of other pituitary hormones, particularly the gonadal trophic hormones, FSH, and LH, which are responsible for sexual development. Mild to moderate obesity is also commonly seen in these patients.

The mean age at diagnosis of acromegaly is usually 40–45 years, but as the progression of disease is so slow, the interval from the onset of symptoms until diagnosis can be as much as 12 years. Manifestations include the classic facial appearance of coarse facies, macrognathia, macroglossia,

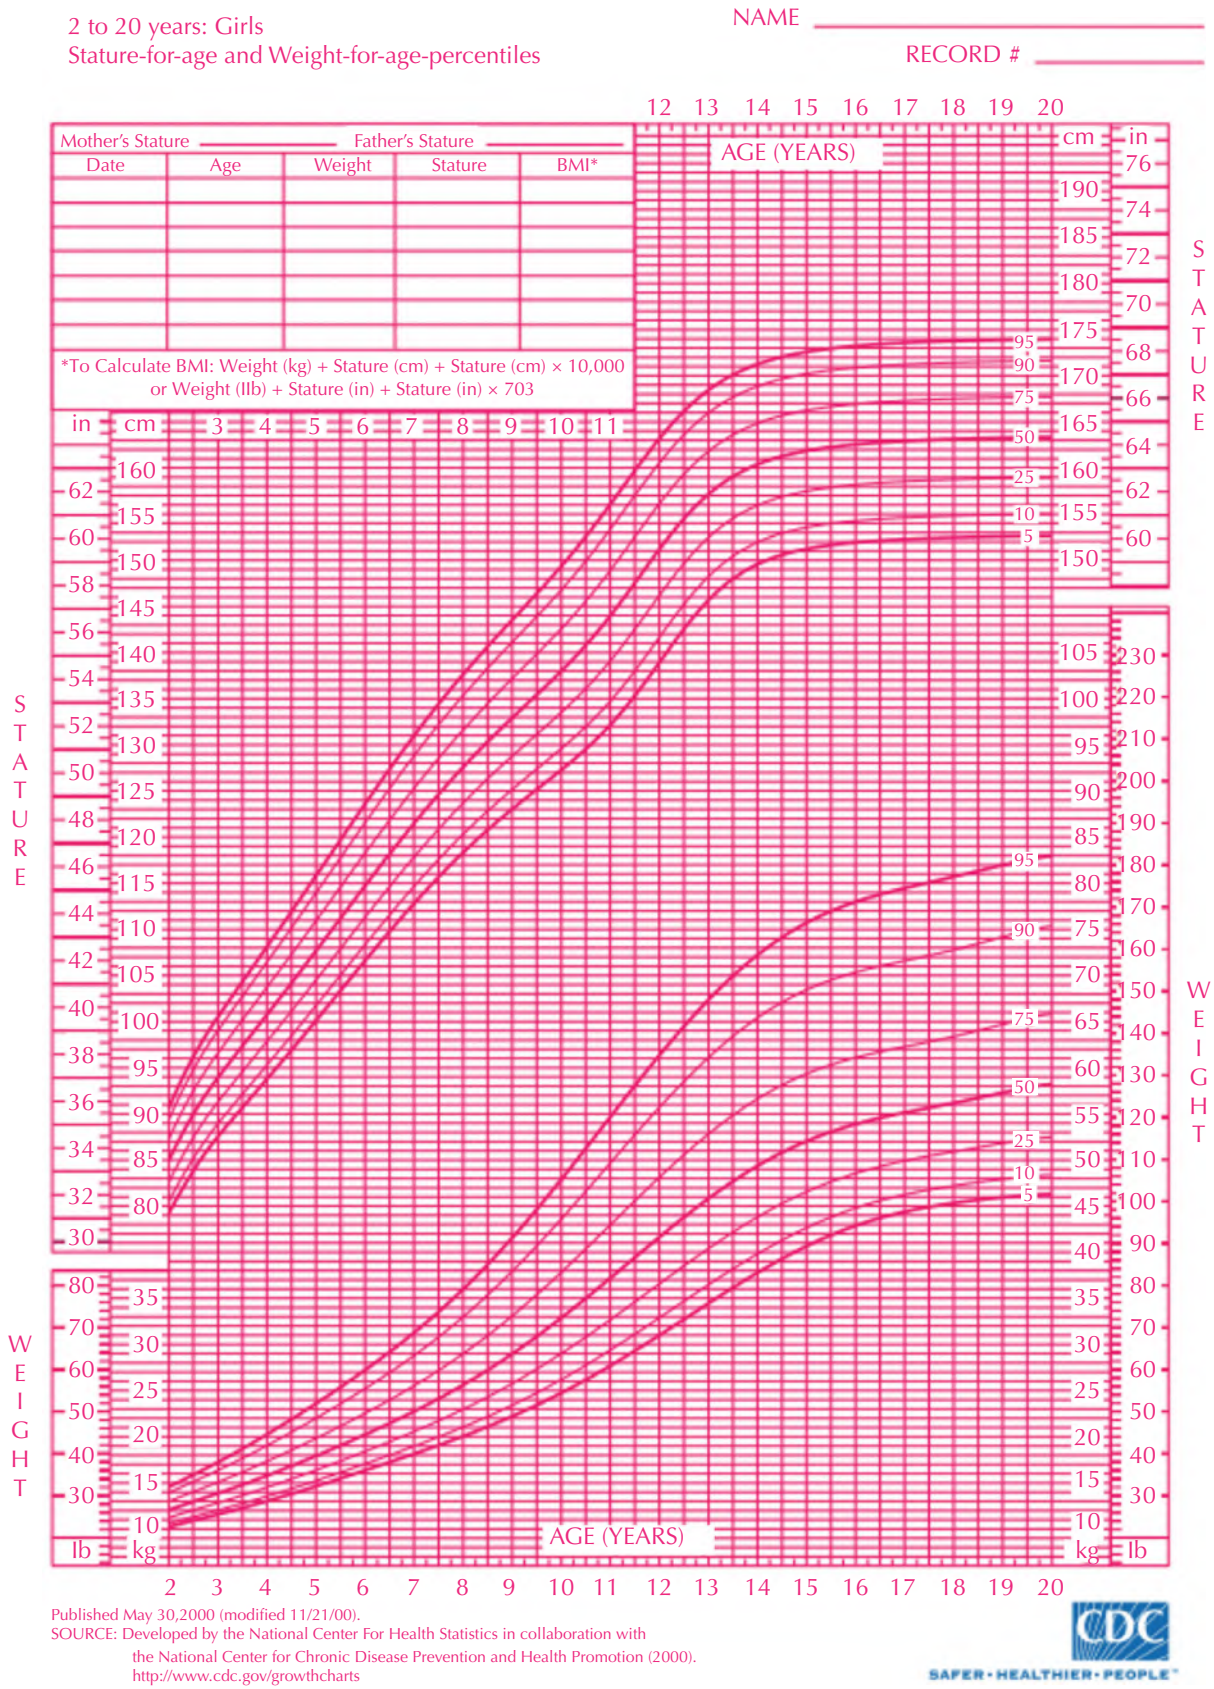

Figure 22-8 Height chart for girls.

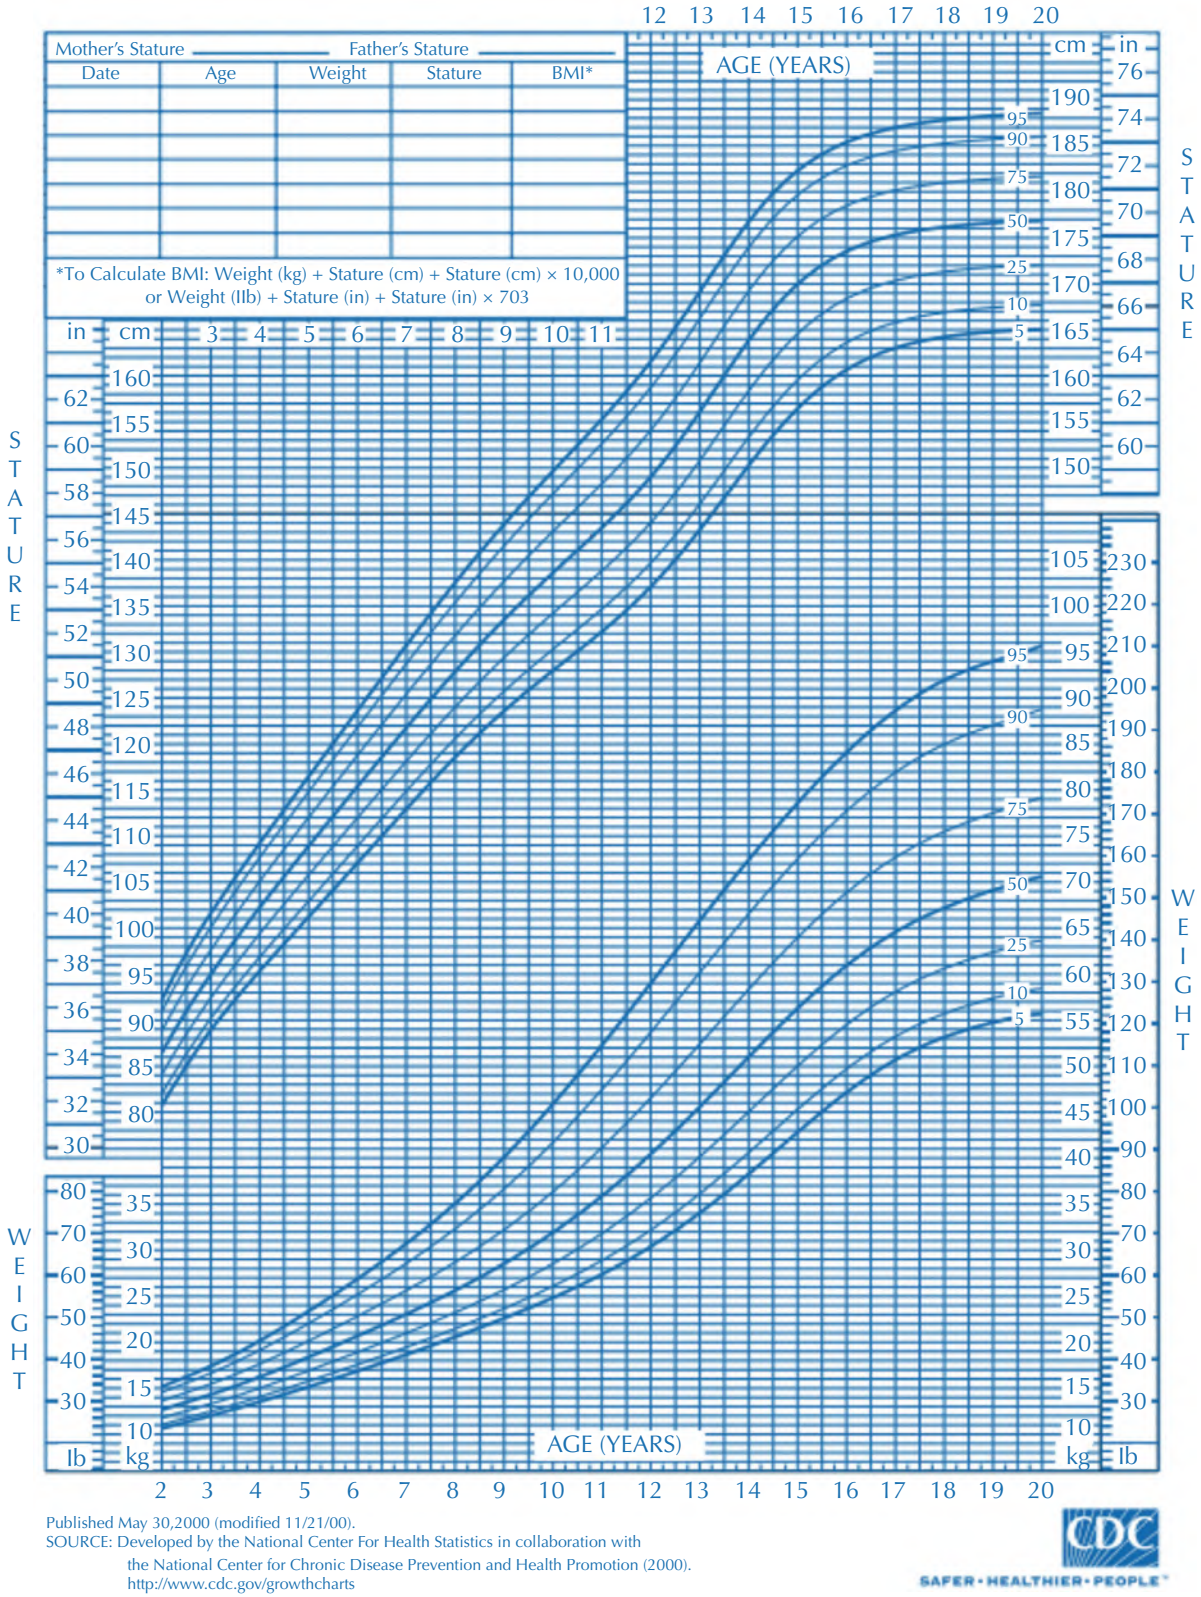

Figure 22-9 Height chart for boys.

Table 22-6 Clinical features of common causes of short stature.

Cause	Family History	Growth Pattern	Bone Age	Comments
Constitutional delay	Positive	• From birth: slow • Growth: delayed • Puberty: late but spontaneous	Moderate delay	• Difficult to differentiate from GH deficiency • Growth velocity assessment essential
Familial short stature	Positive	• From birth: slow • Growth: normal • Puberty: normal onset and growth	Normal	• Check height of parents/family members • Growth velocity: normal
Growth hormone (GH) deficiency	Rare	• From birth: slow • Overweight • Puberty: delayed	Moderate delay Worsens over time	• Need high level of clinical suspicion • Investigate early
Primary hypothyroidism	Rare	• From birth: slow • Puberty: delayed	Marked delay	• Check thyroid-stimulating hormone and T4
Small bowel disease • Celiac disease • Crohn's disease • Ulcerative colitis	Possibly	• From birth: slow • Growth: slow • Thin for height • Puberty: delayed	Delayed	• Check for irregular bowel habit, colic • Oral manifestations of celiac disease/ inflammatory bowel disease (IBD) • Check for anemia • Serology: celiac and IBD

large diastemas, and enlargement of the nose and frontal bones (frontal bossing) (Figure 22-10). Soft tissue edema, due to a direct effect of GH on sodium retention, leads to a "doughy" feel to the hands and feet, as well as an increase in shoe, hat, glove, and ring sizes. Patients can also have increased sweating, deepening of the voice due to enlargement of the thyroid cartilage and vocal cords, enlargement of the synovium and cartilages with hypertrophic arthropathy (knees, ankles, hips, spine, and other joints), skin tags, nerve compression (causing paresthesia of the hands, as in carpal tunnel syndrome), enlargement of the soft tissues of the pharynx and larynx (which can lead to obstructive sleep apnea), increased risk of uterine leiomyomata, colonic polyps, and organomegaly (including the thyroid, heart, liver, kidneys, and prostate). Some 50% of patients with GH excess develop hypertension, 10% develop cardiomegaly with heart failure, which accounts for much of the increased mortality associated with acromegaly and 30% develop insulin resistance or T2DM. Surprisingly, patients seldom independently seek care as the changes are so insidious, and treatment is often initiated when a relative or friend, who has not seen the patient for some time, notes the typical changes as described here.[17]

Diagnosis

Diagnosis is often made on the clinical presentation, with a third diagnosed by the changes in appearance, a quarter because of the visual field defects and/or headache, and the reminder by an astute clinician, including the patient's family physician (investigating potential causes for hypertension), dermatologist, and in particular the dentist.[32] Key investigations are serum GH levels, IGF-1 levels, MRI, which will reveal a pituitary adenoma, visual field examination, and glucose challenge test.

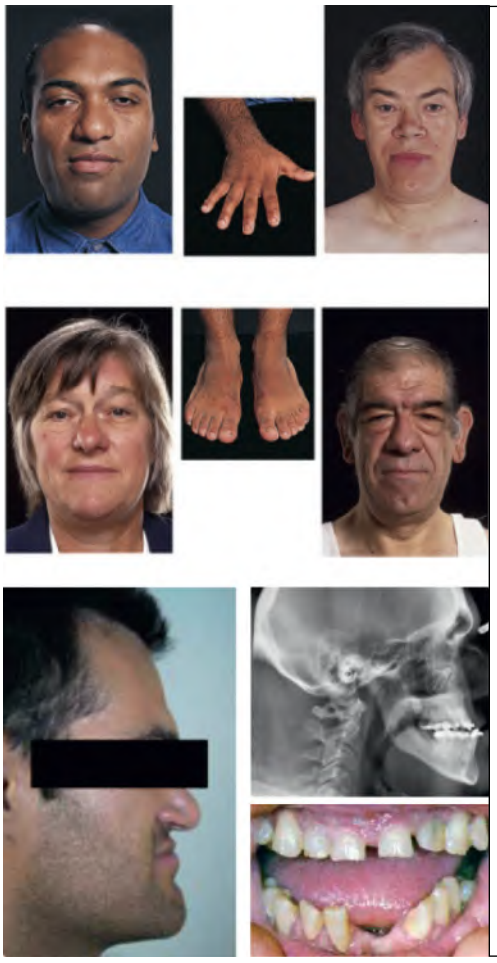
Treatment

Untreated acromegaly results in significant morbidity and increased rate of premature death. The aims of treatment are to establish a "safe" GH level and a normal IGF-1 level. If present, hypopituitarism also needs to be addressed. Concurrent hypertension and/or diabetes should be treated with conventional agents, but usually resolve with treatment of the acromegaly.

Treatment is usually surgical, most commonly by a transsphenoidal approach, or transfrontal for large adenomas, with radiotherapy reserved for situations in which GH levels fail to normalize. There are three potential targets for medical therapy: (1) somatostatin receptor agonists, either octreotide or lanreotide, which are given as monthly depot injections—these are generally effective, but do increase the risk for the development of gallstones; (2) dopamine agonists, either bromocriptine or cabergoline, which are best for patients with mild residual disease; and (3) growth hormone receptor antagonist, that is pegvisomant, a genetically modified analogue of GH that is reserved for patients who otherwise fail all other interventions.[33]

Symptoms

- Hypertension
- Dyslipidemia
- Obstructive sleep apnea (OSA)
- Headaches
- Deepening voice
- Visual changes (bitemporal hemianopsia)
- Gastroesophageal reflux disease (GERD)
- Colon polyps
- Insulin resistance
- Renal failure
- Osteopenia
- Arthritis
- Carpal tunnel syndrome
- Hypogonadism
- Amenorrhoea
- Erectile dysfunction



Signs

- Cardiomegaly
- Heart Failure
- Valvopathy
- Visual deterioration
- Deepening voice
- Diabetes mellitus
- Hyperhidrosis (excessive perspiration
- Changed appearance
- Enlarged hand and feet

Stomatognathic

- Prognathism
- Macroglossia
- Frontal bossing
- Class III malocclusion
- Anterior open bite
- Increasing interdental spacing and diastemas
- Thickened lips

Figure 22-10 Symptoms and signs of acromegaly. *Sources:* Kumar PJ, Clark ML (Eds.). *Kumar and Clark's Clinical Medicine*, 9th edn. Edinburgh: Saunders; 2017. Prognathic jaw clinical photo and radiograph from Ivry G, Felsenfeld AL. Acromegaly: a dental disease? *J Calif Dent Assoc*. 2016;44(9):577–580. Reproduced with permission.

Stomatognathic Manifestations and Complications of Acromegaly

The predominant clinical findings in acromegaly—prognathism with evolving or established class III malocclusion; the development of significant diastemas, especially of the mandibular dentition; and radiographic findings of enlarged sella and frontal bossing (on lateral cephalogram)—mean that hygienists, dentists, and dental-related specialists are key in making the initial diagnosis of acromegaly. Following diagnosis and appropriate treatment, oral health professionals can facilitate oral rehabilitation. However, even patients with treated acromegaly can still have ongoing disease-related morbidities, which need to be identified on taking a comprehensive medical history. The key concerns in particular are treatment-refractory hypertension, valvopathy, and obstructive sleep apnea (OSA). The sleep apnea seen in association with acromegaly is predominantly obstructive and is related to thickening of walls of the upper airway, including the soft palate. However, the patient with acromegaly and sleep apnea presents special problems, as retropositioning the mandible to treat the prognathism is inconsistent with the principles involved in the management of OSA, necessitating alteration in conventional treatment planning.[34,35]

HYPERPROLACTINEMIA

Hyperprolactinemia can be caused by hyperplasia of the so-called lactotroph cells (prolactinomas) or decreased tonic dopaminergic inhibition of prolactin secretion (e.g., compression by a central nervous system tumor).[36] Prolactinomas can cause hypogonadism by suppressing gonadotropin secretion. In women, hypogonadism results in low serum estrogen levels that can present as oligomenorrhea, amenorrhea, infertility, and osteoporosis. In men, hypogonadism causes low serum testosterone concentrations that result in decreased libido and energy, decreased facial hair growth, loss of muscle mass, and osteoporosis. Hyperprolactinemia in men may also

be associated with impotence even when the serum testosterone concentration is normal. It can cause galactorrhea (leakage of milk from the breast other than during lactation) in women, but this only occurs very rarely in men.

Prolactinomas are relatively common, accounting for 30–40% of all clinically recognized pituitary adenomas. The diagnosis is made more frequently in women than in men, especially between the ages of 20 and 40 years, presumably because the hyperprolactinemia disrupts their menstrual cycle.[37] Such tumors can be identified by the enlargement of sella turcica incidentally observed on lateral cephalograms.[38]

Prolactinomas can be treated with dopamine agonists, such as cabergoline or bromocriptine. These drugs have the dual effect of decreasing hormone secretion and tumor size. If the adenoma does not respond to increasing doses of these medications or there is imminent visual loss, transsphenoidal surgery is required for removal of the tumor.[39]

DISORDERS OF ANTIDIURETIC HORMONE

Thirst Axis

Thirst and the symptoms of thirst, xerostomia and the signs of dehydration, namely hyposalivation and dry mucous membranes of the mouth, are of course of great relevance to the clinical practice of oral healthcare providers. Thirst and water regulation are largely controlled by vasopressin, also known as antidiuretic hormone (ADH). ADH is synthesized in the hypothalamus and then migrates in neurosecretory granules via axonal pathways to the posterior pituitary. Pituitary diseases that spare the hypothalamus do not lead to ADH deficiency, as the hormone still can "leak," even from the end of a damaged axon.

The kidney is the predominant site of action of ADH at normal concentrations. ADH stimulation of the vasopressin-2 (V2) receptors allows the collecting ducts to become permeable to water, via the migration of aquaporin-2 water channels, resulting in the reabsorption of hypotonic luminal fluid. ADH acts to reduce diuresis (i.e., less urine) and results in retention of water. At high concentrations, ADH can also cause vasoconstriction, via the V1 receptors present in the vascular tissues, thus limiting blood supply to the kidneys, resulting in further water retention and less urine output.

ADH is regulated by osmoreceptors in the anterior hypothalamus that can sense plasma osmolality. ADH secretion is suppressed at levels below 280 mOsm/kg, thus allowing maximal urine formation (diuresis). Above this level, plasma vasopressin increases in direct proportion to plasma osmolality. At the upper limit of normal (295 mOsm/kg), maximum antidiuresis is achieved (little if any urine production), with thirst being experienced at about 298 mOsm/kg.

DIABETES INSIPIDUS

Disorders of ADH are in essence disorders of water balance. ADH deficiency is termed diabetes insipidus (DI) and is a syndrome characterized by the inability for the kidneys to retain water.[40] It can be caused by inadequate pituitary production of ADH (termed *central DI*), or resistance to the actions of ADH on the kidneys (termed *nephrogenic DI*). DI can also be gestational, or present as an iatrogenic artefact of alcohol or some types of drug abuse. The primary presenting symptom is polyuria (>3 L/d), and resultant hypernatremia, nocturia, and compensatory polydipsia (excessive thirst/water intake). Daily urine output may reach as much as 10–15 L, leading to dehydration that may be very severe if the thirst mechanism or consciousness is impaired or if the patient is denied fluid. Diagnosis of DI is made by a water deprivation test, requiring medical supervision.[41]

Treatment is with the synthetic vasopressin (ADH) analogue desmopressin (also known as DDAVP, 1-desamino-8-d-arginine vasopressin, desamino cys-1-d-arginine-8 vasopressin), which has the advantages of a longer duration of action than vasopressin and no vasoconstrictive effects. It is reliably given by an intranasal spray 10–40 μg once or twice daily, but can also be given orally (100–200 μg three times daily or intramuscularly 2–4 μg daily). For patients with DI, a reversible underlying cause (e.g., a hypothalamic tumor) should be investigated for and treated, if found. Other causes of polyuria and polydipsia include diabetes mellitus (DM), hypokalemia, and hypercalcemia, which should be excluded. In the case of DM, the cause is an osmotic diuresis secondary to glycosuria, which leads to dehydration and increased thirst, owing to the hypertonicity of the extracellular fluid.[42]

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE

Excessive ADH (syndrome of inappropriate antidiuretic hormone, SIADH) is a syndrome of too much total body water and consequent hyponatremia, of which the electrolyte disturbance is the main concern and the cause of the presenting clinical features.[43] Major causes of SIADH include central nervous system (CNS) disturbances such as stroke, infection, trauma, and hemorrhage. Other causes are medications, serious illness (especially in the elderly), and some types of cancer. The clinical presentation tends to be slow, with the patient exhibiting confusion, nausea, irritability, and, later, fits and coma, but with no edema. Mild symptoms usually occur with plasma sodium levels below 125 mmol/L and serious manifestations occurring below 115 mmol/L.[44] The elderly may show symptoms with milder abnormalities. SIADH needs to be differentiated from dilutional hyponatremia

Table 22-7 Physiologic effects of the thyroid hormones.

Target Organs/Tissues	
Cardiovascular system	↑ Heart rate ↑ Cardiac output
Respiratory center	Maintains normal • Hypoxic drive • Hypercapnic drive (response to CO_2 concentration in the blood)
Neuromuscular function	↑ Muscle contraction and relaxation ↑ Muscle protein turnover
Sympathetic nervous system	↑ Catecholamine sensitivity ↑ β-adrenergic receptor numbers on: heart, skeletal muscle, adipose cells, and lymphocytes ↓ Cardiac α-adrenergic receptors
Gastrointestinal system	↑ Gut motility
Metabolism Carbohydrate	↑ Hepatic gluconeogenesis/glycolysis ↑ Intestinal glucose absorption
Lipid	↑ Lipolysis ↑ Cholesterol synthesis and degradation
Bone	• Bone turnover and resorption
Hematologic system	• Oxygen release by red blood cells to tissues

due to excess infusion of glucose/water solutions or diuretic administration (thiazides or amiloride). ACTH deficiency can give a very similar biochemical picture to SIADH; therefore, it is necessary to ensure that the HPA axis is intact, particularly in neurosurgical patients, in whom consequently ACTH deficiency is relatively common.

Management entails identifying the underlying cause and correcting this, when possible. Symptomatic relief includes fluid restriction, with an intake of only 500–1000 mL water daily; if complied with, this will usually correct the biochemical abnormalities. Such fluid restriction can result in salivary hypofunction and so directly contribute to higher rates of dental decay, and candidiasis.[45,46] Newly available, ADH (V2) antagonists (e.g., tolvaptan, sold as Samsca® in the United States; Otsuka America Pharmaceutical, Rockville, MD, USA) are being used with good effect.[47]

THYROID DISEASE

Thyroid disease occurs frequently and is the most common endocrine disease. The thyroid gland synthesizes three hormones: (1) thyroxine (T4), which is a prohormone; (2) triiodothyronine (T3), the active hormone that is critical in regulating the body's metabolic rate; and (3) calcitonin, which regulates bone metabolism. Adequate levels of thyroid hormone are essential in infants for normal CNS development, in children for normal skeletal growth and maturation, and in adults for the normal function of multiple organ systems (Table 22-7). In general, there are five main types of thyroid disease, and disease can be intercurrent in the same patient:

- Hypothyroidism (termed "myxedema" when it occurs in adults and "cretinism" when it occurs in infants and children), caused by a deficiency of thyroid hormones.
- Hyperthyroidism (thyrotoxicosis), due to an excess of thyroid hormones with consequent significant clinical issues, especially of the cardiovascular system.
- Abnormal thyroid function tests (TFTs), in an otherwise euthyroid (the state of having normal thyroid gland function) patient.
- Structural abnormalities, mainly goiter, which may be seen as diffuse enlargement of the thyroid gland, or single or multiple nodules, due to focal enlargement of only a portion of the gland,
- Neoplasms.

Epidemiology

Thyroid disease has prevalence of 6% as of 2019 and it is estimated that over 12% of Americans will develop some form of thyroid disease over the course of their lifetime.[48] Of these, some 60% are unaware of their condition. Thyroid diseases

are far more common in women. The management for most thyroid disorders is life-long and well tolerated. In the United States, autoimmune inflammation is the most common cause of thyroid disease whilst worldwide hypothyroidism and goiter due to iodine deficiency is much more common.[49] Although thyroid nodules are common, thyroid cancer is rare. Thyroid cancer accounts for less than 1% of all cancer in the US,[50] although it is the most common endocrine tumor and makes up greater than 90% of all cancers of the endocrine glands.[51]

Thyroid Gland: Anatomy and Physiology

The thyroid gland consists of two lateral lobes connected by an isthmus, closely attached to the thyroid cartilage and to the upper end of the trachea, and thus moves on swallowing. Embryologically, it originates from the base of the tongue and descends to the middle of the neck. Remnants of thyroid tissue can sometimes be found at the base of the tongue (lingual thyroid) and along the line of its descent.

Internally, the thyroid gland consists of follicles lined by cuboidal epithelioid cells within which is colloid (iodinated glycoprotein thyroglobulin), synthesized by the follicular cells. Each follicle is surrounded by basement membrane, and between them are parafollicular cells containing the C cells that secrete calcitonin. The thyroid also synthesizes triiodothyronine (T3), which acts at the cellular level, and L-thyroxine (T4), which is the prohormone. Inorganic iodine is essential for the synthesis of the two thyroid hormones and the precursor molecule, thyroglobulin (Figure 22-11). Globally, dietary iodine deficiency is a major cause of thyroid disease. Dietary supplementation of salt and bread has reduced the number of areas where "endemic goiter" still occurs. Surprisingly, in Western countries iodine deficiency is now a concern, given the decline in adventitious iodine in dairy products with use of noniodoform disinfectants in milk production and "food fads," with the use of noniodized rock salt in place of iodized salt in cooking. In the United States iodine intakes have fallen, and it is uncertain whether the iodine status for most pregnant woman is satisfactory, leading to calls for systematic iodine supplementation.[52]

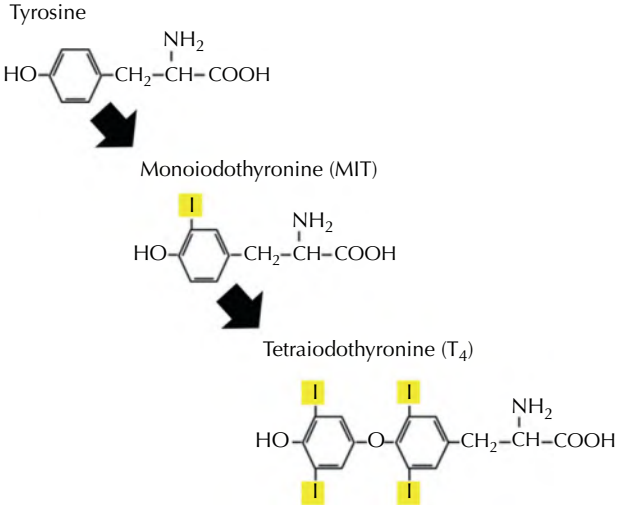


Figure 22-11 The conversion of the amino acid tyrosine, with the addition of iodine (yellow) atoms.

In plasma, more than 99% of all T4 and T3 is bound to hormone-binding proteins: TBG, thyroid-binding prealbumin, and albumin. Only unbound—that is, free—hormone is biologically active. Circulating T4 is peripherally deiodinated to T3, which has a far greater affinity for its receptors than T4. T3 binds to the two thyroid hormone nuclear receptors (TR-α and TR-β) of the target cells to cause gene transcription.

Control of the hypothalamic-pituitary-thyroid axis is, as is universal throughout the endocrine system, by negative feedback control. Thyrotropin-releasing hormone (TRH) is a peptide produced in the hypothalamus, which stimulates the pituitary to secrete TSH (Table 22-8). TSH, in turn, stimulates growth and activity of the thyroid follicular cells, which consequently secrete T3 and T4 into the circulation. T3 and T4 both exert negative feedback on the hypothalamus, leading to a decrease in the secretion of TRH and so a decrease in TSH and in turn a decrease in T3 and T4. The decrease in circulating T3 and T4 prompts increased release of TRH and, again, in turn an increase in TSH and then T3 and T4.

Hypothyroidism

Hypothyroidism, defined as the inadequate release of the two thyroid hormones T3 and T4, is usually primary; that is, due to disease of the thyroid gland, However, it may be secondary, due to disease of hypothalamic or pituitary, with consequent reduction in TSH, and so a decline in T3 and T4 release by an otherwise intact thyroid gland.

Hypothyroidism is one of the most common endocrine conditions, with a prevalence rate of 4.6% for the US population. Approximately 0.3% present with clinically overt disease and the remaining 4.3% with subclinical disease (decreased T3 and T4 levels but no clinical evidence of disease).[53] Of those with subclinical hypothyroidism, 2% per annum develop clinically evident hypothyroidism, hence the lifetime prevalence for an individual is higher—perhaps as high as 9% for women and 1% for men, with mean age at diagnosis around 60 years.[54]

Causes

Autoimmune

- *Atrophic (autoimmune) thyroiditis.* This is associated with the development of antithyroid autoantibodies with

Table 22-8 Thyroid function tests and role in clinical practice.

Normal Hypothalamic-Pituitary Function

Indication	Serum TSH*	Serum T4	Serum T3
Euthyroid	Normal	Normal	Normal
Primary hypothyroidism	High	Low	Normal or low
Subclinical hypothyroidism	High	Normal	Normal
Hyperthyroidism	Low	High or normal	High
Subclinical hyperthyroidism	Low	Normal	Normal

- If serum TSH is normal—no further testing indicated or required.
- If serum **TSH is HIGH**—the lab will add free T4 to determine degree of ***hypo***thyroidism.
- If serum TSH is LOW—both free T4 and T3 are added to the patient's sample to determine degree of ***hyper***thyroidism.

Clinical indications for additional testing:

- **Pituitary/hypothalamic disease suspected,** e.g., a young woman with amenorrhea and fatigue: test TSH.
- **Patient has symptoms of hyper- or hypothyroidism and normal TSH result:** test T4.

* With central hypothyroidism, serum TSH may be low, normal, or slightly high.
T3, triiodothyronine; T4, thyroxine; TSH, thyroid-stimulating hormone.

consequent lymphoid infiltration of the thyroid glands, and eventual atrophy and fibrosis. It is associated with other autoimmune conditions including pernicious anemia, vitiligo, and other endocrinopathies.[55,56]

- *Hashimoto's thyroiditis.* This is most common in middle-aged women. High levels of autoantibodies are developed and directed against thyroid peroxidase (the enzyme that coverts T4 to T3).Atrophic changes are followed by regeneration, with this cycle leading to clinically evident generalized goiter, which is firm and hard on palpation.
- *Postpartum thyroiditis.* A destructive form of thyroiditis associated with the immune changes of pregnancy, this can occur up to year post parturition. It confers, as seen with most pregnancy-associated endocrine disease, a lifetime risk for the development of permanent hypothyroidism, necessitating ongoing screening for affected women.[57]

Defective Hormone Synthesis

- *Iodine deficiency.* This can result in endemic goiter, which can be massive, due to borderline iodine deficiency with consequent TSH stimulation, and therefore hyperplasia and hypertrophy of the thyroid gland. At a global scale, approximately 2 billion people suffer from iodine deficiency, of which approximately 50 million people present clinical features of hypothyroidism. The effect of chronic iodine deficiency and related hypothyroidism leads to cretinism in children, which causes growth delay, short stature, and severe cognitive impairment.[58]

Clinical Features

Hypothyroidism produces many symptoms and signs, but these can be subtle and difficult to distinguish from other causes of tiredness and fatigue. The alternate term "myxedema" refers to the typical appearance of patients with long-standing significant hypothyroidism, due to the accumulation of mucopolysaccharides in the subcutaneous tissues, presenting with mucinous, nonpitting edema, particularly of the hands, feet, and eyelids. The clinical presentation includes dry hair, thick skin, deepening of the voice, weight gain, complaints of cold intolerance, and bradycardia. Diagnosis is difficult in children, young women, and the elderly and TSH and serum T3 and T4 should be undertaken to exclude hypothyroidism in these subjects, even if only suspected. If hypothyroidism is proven (low T3 and T4), investigations are required to differentiate primary disease from diseases affecting the hypothalamus-pituitary-thyroid axis.[59]

Treatment

The commonest treatment for hypothyroidism is synthetic T4 (thyroxine), levothyroxine (sold in the United States as Synthroid®, AbbVie, North Chicago, IL, USA; Levoxyl®, Pfizer Medical, New York, USA; Tirosint®, IBSA Pharma, Parsippany, NJ, USA; and Euthyrox®, Provell Pharmaceuticals, Honey Brook, PA, USA).[60] The goals of treatment are amelioration of the patient's symptoms, normalization of the serum TSH levels, reduction in the size of goiter (if present), and, of most concern, avoidance of overtreatment (iatrogenic thyrotoxicosis). Both the initial and maintenance doses of levothyroxine are titrated

to effect, based on the serum T4 and TSH and serial electrocardiograms, to exclude the development of atrial fibrillation, a known complication of hyperthyroidism.[61] The starting dose is 100 μg/daily for the young and fit with no cardiovascular disease; 50 μg/daily for the small, frail, and elderly; and even lower (i.e., 25 μg/daily) in patients with severe, long-standing hypothyroidism or with a history of ischemic heart disease. The usual maintenance dose is 100–150 μg daily.

Myxedema Coma and "Madness"

This can occur as the culmination of severe, long-standing hypothyroidism or can be precipitated by an acute event in a poorly controlled hypothyroid patient, such as infection, myocardial infarction, cold exposure, surgery, or the administration of sedative drugs, especially opioids. The presenting features frequently do not result in a coma, but rather with variable degrees of altered consciousness, such as confusion and lethargy. However, in rare instances, the initial presentation is with prominent psychotic features, termed "myxedema madness." If this is unrecognized, patients will progress to coma. The other major clinical findings will be of hypothermia, which needs to be assessed by manually examining the patient, in particular the hands (peripheries), as many automatic thermometers do not record subnormal temperatures.[62] The patient's vital signs will demonstrate marked hypotension and bradycardia (slow pulse) and blood tests will reveal marked hypoglycemia and hyponatremia (decreased serum sodium levels). Myxedema coma is a medical emergency, with a poor prognosis, requiring prompt hospitalization. The key aspects of treatment are replacement T4 and T3. In addition, prophylactic hydrocortisone 100 mg is administered intravenously (every eight hours) until adrenal insufficiency is excluded, as well as intensive supportive measures, including mechanical ventilation, fluids, and vasopressor drugs to correct hypotension, passive rewarming), and intravenous dextrose. Empirical antibiotic treatment is usually also given. Ongoing cardiorespiratory monitoring for arrhythmias is also mandated. The mortality rate, even with the best inpatient care, is 30–50%.[63]

Hyperthyroidism

Hyperthyroidism (also termed thyrotoxicosis) is defined as thyroid overactivity with consequent increased release and greater circulating levels of T3 and T4. Hyperthyroidism is common. The reported overall prevalence is about 3%, with men and women over 65 years having the highest prevalence, of which 50% are taking levothyroxine. In the National Health and Nutrition Examination Survey, there was a bimodal distribution based on age, with prevalence highest in those subjects aged 20–39 years and those aged older than 79 years.[53]

Causes

Exogenous Causes

- The use of *supraphysiologic doses of levothyroxine* that may be intentional, e.g., in patients' post treatment for thyroid malignancy in order to maintain suppression of serum TSH.
- *Amiodarone-induced thyrotoxicosis*.[64] Amiodarone is a class III antiarrhythmic agent (Vaughan Williams' classification) that blocks the potassium channels of the atrial, nodal cardiac muscle cells and the ventricular tissues (which coordinate the heartbeat). Its main effect is to prolong repolarization of the cardiac muscle and is indicated for the treatment and prevention of ventricular fibrillation and ventricular tachycardia.[65,66] It causes both hypothyroidism and hyperthyroidism due to its high iodine content and its direct toxic effect on the thyroid.[67]

Endogenous Causes

- *Graves' disease*, a "classic" autoimmune condition, is the most common cause in young patients. It features the development of autoantigenic serum immunoglobulin (Ig) G antibodies that bind to the TSH receptors in the thyroid, thus stimulating thyroid hormone overproduction and secretion. Other autoimmune antibodies develop concurrently, similar to those seen in autoimmune hypothyroidism, including antibodies to thyroid peroxidase (TPO) and thyroglobulin antibodies. These can occur in up to 80% of cases and result perversely in hypothyroidism.
- *Toxic nodular goiter* (solitary or multinodular) with autonomous production and release of T3 and T4. Common in the elderly population.[68]
- *Subacute thyroiditis* (also known as subacute granulomatous thyroiditis, or de Quervain's thyroiditis) of likely viral etiology. Its main feature is painful goiter.
- *Postpartum thyroiditis* (see earlier).

Clinical Features

- *Eye signs*. Lid lag and "stare," which can occur with hyperthyroidism of any cause. However, there are other features that are distinct with Graves' orbitopathy (described later).
- *Skin*. Graves' dermopathy is rare and can occur on any extensor surface. Pretibial myxedema is the most commonly described and is an infiltration of the skin on the shin. Thyroid acropachy is very rare and consists of clubbing and new periosteal bone formation of the fingers, causing marked swelling.
- *Excessive growth rate/velocity*. Common in children together with weight gain or behavioral problems, such as hyperactivity.
- *Cardiovascular*. In the elderly, a frequent presentation is with atrial fibrillation, other types of tachycardias, and/or heart failure. TFTs are mandatory in patients with atrial fibrillation.

- *Apathetic thyrotoxicosis* in elderly patients presents with a clinical picture more like that of hypothyroidism.

Investigations

- *Serum TSH*, which will be reduced in hyperthyroidism (<0.05 mU/L).
- *Raised free T4 or T3* confirms the diagnosis; T4 is almost always raised, but T3 is a more sensitive indicator of hyperthyroidism.
- *TSH receptor–stimulating antibodies* (TSHR-Ab), which are 99% specific for Graves' disease.
- *Thyroid peroxidase (TPO) and thyroglobulin antibodies* are present in 80% of cases of Graves' disease.
- *Scintiscan ^{99}Tm* is useful if there is doubt as to the nature of the goiter.

Treatment

The hyperthyroidism of Graves' disease is treated by reducing thyroid hormone synthesis with an antithyroid drug, or by reducing the amount of thyroid tissue with radioiodine (^{131}iodine) treatment or thyroidectomy. Radioiodine is more often the first line of treatment in North America. Treatment approaches vary around the world, indicative that no single approach is ideal.

- *Radioactive ^{131}I* is given orally and, since iodine preferentially concentrates in the thyroid, the gland is then slowly destroyed over the course of months by the local radiotherapy effect. It is contradicted in pregnant and breastfeeding women.[69]
- *Antithyroid drugs*. The main drugs are the thionamides: propylthiouracil, carbimazole (not available in the United States), and the active metabolite of the latter, methimazole, which inhibits the function of TPO, reducing oxidation and organification of iodide. Remission rates are in the range of 30–60%. The major toxicity with these agents is a selective agranulocytosis, but this only occurs in less than 1% of patients.
- *Surgery*. Generally, this will be a total thyroidectomy. That is typically an option for patients who relapse after antithyroid drugs and who prefer this treatment to radioiodine.
- *Beta blockers*, in particular propranolol (20–40 mg every 6 h), or longer-acting selective β1 receptor blockers, such as atenolol, may be helpful to control the adrenergic symptoms, especially in the early stages before the antithyroid treatment is fully effective.
- *Surveillance*. 40–70% of patients may relapse following antithyroid drug therapy. Hypothyroidism occurs in most patients treated by drugs or radioiodine, and is inevitable after total thyroidectomy, hence these patients will need to be maintained on appropriately titrated, life-long replacement levothyroxine.

There is a small risk of increased overall mortality seen in patients with hyperthyroidism. The major long-term consequence of treatment for hyperthyroidism is an increased risk of osteoporosis. Marked TSH suppression leads to the development of atrial fibrillation, requiring cardiac rate-limiting drugs such as digoxin, with an attendant risk for thromboembolic stroke. Hence anticoagulant prophylaxis is required, either with either warfarin or increasingly with direct oral anticoagulants (DOACs; previously known as new oral anticoagulant agents or NOACs), which include apixaban (Eliquis®, Pfizer Medical), dabigatran (Pradaxa®, Boehringer Ingelheim, Ridgefield, CT, USA), rivaroxaban (Xarelto®, Janssen Pharmaceuticals, Titusville, NJ, USA), and edoxaban (Savaysa®, Daiichi Sankyo, Basking Ridge, NJ, USA).[70]

Graves' Orbitopathy

Graves' orbitopathy, also known as thyroid eye disease (TED), is an autoimmune inflammatory disorder of the orbit and periorbital tissues. It has distinctive clinical features, including the "stare," due to retraction of the upper eyelid with lid lag, and swelling of the orbit, causing an exophthalmos of variable severity. It occurs most commonly in association with Graves' disease, but can also be seen, albeit more rarely, with Hashimoto's thyroiditis, and even in patients who are otherwise euthyroid. The condition mostly affects the middle-aged (30–50 years of age) and predominantly women. Cigarette smoking raises the incidence eightfold. Annual incidence is 16 per 100,000 in women and 3 per 100,000 in men.[71] About 3–5% have severe disease with intense pain, and sight-threatening corneal ulceration or compression of the optic nerve. Unilateral orbitopathy can occur, but this is rare.

Initial treatment entails regulation of thyroid hormone levels and limitation of further damage to the eye, with the use of topical lubricants to prevent corneal damage. High-dose corticosteroids are effective in the initial reduction of the orbital inflammation. Radiotherapy has been trialed, but there is controversy as to its efficacy, as is the case with selenium, which is limited to the treatment of mild disease. As of January 2020, the US Food and Drug Administration (FDA) approved the use of the medication Tepezza® (teprotumumab-trbw; Horizon Therapeutics, Lake Forest, IL, USA) for the treatment of adults with TED.[72] Teprotumumab-trbw is a monoclonal antibody that binds IGF-1R. In TED pathogenic orbital disease, autoantibodies stimulate the orbital fibroblasts, resulting in the production of hyaluronan (a high molecular mass polysaccharide), causing the marked infiltration and so swelling of the eyelids and orbital tissues and resulting in the clinical features of TED. Teprotumumab blocks the stimulatory effects of pathogenic autoantibodies on the orbital fibroblasts.[73] Orbital decompression surgery is

indicated in severe eye disease to prevent blindness from optic nerve compression. Surgery is also indicated, after the incipient thyroid disease has been stable for six months, to improve function and to increase lubrication of the corneal surface to prevent corneal keratitis and for cosmesis.[74]

Thyroid Crisis

A thyroid crisis (or "thyroid storm") is a rare, life-threatening exacerbation of hyperthyroidism, which presents with fever, delirium, seizures, coma, vomiting, diarrhea, and jaundice. The mortality rate due to cardiac failure, arrhythmia, or hyperthermia is as high as 30%, even with treatment. Thyrotoxic crisis is usually precipitated by acute illness (e.g., stroke, infection, trauma, diabetic ketoacidosis), surgery (especially involving the thyroid), or radioiodine treatment of a patient with partially treated or untreated hyperthyroidism. In-hospital management is required, which includes intensive monitoring, supportive care, identification and treatment of the precipitating cause, and measures that reduce thyroid hormone synthesis; that is, large doses of antithyroid drugs, such as propylthiouracil. Propranolol is also given to reduce tachycardia and other adrenergic manifestations.

Thyroid Hormone Resistance

This occurs when the effectiveness of thyroid hormone is reduced and includes flaws in thyroid hormone action, transport, or metabolism. These are rare, in general have a genetic basis, and to date there is limited effective treatment. There are three main causes:

- Thyroid hormone cell membrane transport defect.
- Thyroid hormone metabolism defect.
- Thyroid hormone action defects.

Goiter (Thyroid Enlargement)

Goiter is a swelling of the anterior base of the neck resulting from an enlarged thyroid gland, which may be visible or only evident on palpation (see Table 22-9). In the United States where iodine deficiency is rare, up to 15% of the population have palpable goiter and as many as 50% microscopic nodules. In areas of the world where iodine deficiency is common and widespread, up to 90% of the population have significant goiter, termed "endemic goiter."[75,76]

The initial screening for thyroid dysfunction starts by examining and then palpating the thyroid gland for diffuse changes or nodules, which may be single or multiple. It is performed as part of a head and neck examination, which could be argued to be within the remit of dentists and

Table 22-9 Goiter: types and causes.

represents a comprehensive examination of the patient, with a focus on dental disease, but in the context of potential disease of the related regional anatomy. The thyroid gland is examined with the patient's head extended to one side and with the examiner using the fingers of both hands to palpate the thyroid gland. Next, the patient is instructed to swallow, during which time the examiner can evaluate the anatomic extent of the lobules using the last three fingers of one hand. Note that the right lobule is usually larger than the left and that on relaxation, the thyroid outline cannot be observed in a healthy patient. Any anatomic abnormality of the thyroid gland is defined by its consistency, size, tenderness, and growth. If an abnormal finding is discovered, hormone and function and imaging studies, particularly ultrasound, needs to follow, with consideration for ultrasound-guided fine needle aspiration (FNA) biopsy.[77]

Thyroid Malignancies

Thyroid carcinoma is the most common malignancy of the endocrine system. Thyroid neoplasms can arise in each of the cell types that populate the gland, including thyroid follicular cells, calcitonin-producing C cells, lymphocytes, and stromal and vascular elements, as well as metastases from other sites (Table 22-10). Over the last 30 years, the incidence of thyroid cancer has increased from 4.9 to 14.3 cases per 100,000 individuals in the United States, with over 65,000 cases diagnosed in 2015.[78]

The risk factors for thyroid malignancy are (1) exogenous, namely exposure to radiotherapy of the head and/or head

Table 22-10 Thyroid malignancies.

Malignant Carcinoma (Arising from Thyroid Epithelium)	Prevalence
Follicular epithelial cell	
Papillary carcinomas	80–85%
Follicular carcinomas	2.5–7%
Poorly differentiated carcinomas	3–5%
Anaplastic (undifferentiated) carcinoma	1%
Neuroendocrine Tumor (Arising from the C [Calcitonin-Producing] Cells)	
Medullary thyroid cancer	<10%
Sporadic	
Familial	
Multiple endocrine neoplasia 2	
Lymphomas	1%
Metastases	
Breast, melanoma, lung, kidney

and neck region, which can include cranial radiotherapy, or from nuclear fallout following explosions of nuclear power plants, at Chernobyl (1986)[79] and more recently Fukushima (2011);[80] and (2) endogenous, specifically genetic abnormalities, patients who have a family history of papillary thyroid cancer in two or more first-degree relatives, multiple endocrine neoplasia type 2 (MEN 2), or other genetic syndromes associated with thyroid malignancy, such as Cowden's syndrome, familial polyposis, and Carney complex.[51]

Treatment

Papillary and Follicular Cancer

As most tumors are still TSH responsive, levothyroxine suppression of TSH is a mainstay of initial thyroid cancer treatment, followed by partial or near-total thyroidectomy (depending on the size of the tumor). This is followed by radioablation of the remnant thyroid gland (and tumor). Serum thyroglobulin is a sensitive marker of residual/recurrent thyroid cancer after initial treatment.

Anaplastic Thyroid Cancer

This is a poorly differentiated and aggressive cancer with a dismal prognosis, with most patients dying within six months of their diagnosis.

Medullary Thyroid Carcinoma

Medullary thyroid carcinoma (MTC) can be sporadic or familial, and accounts for about 5% of thyroid cancers. There are three familial forms of MTC: MEN 2A, MEN 2B, and familial MTC without other features of MEN.[81] The management of MTC is primarily surgical, as these tumors, unlike papillary and follicular thyroid cancer, do not take up radioiodine. Targeted small molecule tyrosine kinase inhibitors (TKIs) have shown benefit in large or recurrent disease. Examples include cabozantinib (sold in the United States as Cabometyx® and Cometriq®, Exelixis, Alameda, CA, USA), which inhibits the tyrosine kinases c-Met and vascular endothelial growth factor receptor 2 (VEGFR-2), and vandetanib (Caprelsa®, Sanofi Genzyme, Cambridge, MA, USA) acts as a kinase inhibitor of a number of cell receptors, mainly VEGFR, epidermal growth factor receptor (EGFR), and RET-tyrosine kinase.[82] The TKIs that target vascular growth receptors that have a role in angiogenesis have been shown to increase the risk of medication-related osteonecrosis of the jaws (MRONJ), particularly if given concurrently (fivefold increased MRONJ risk) with either a bisphosphonate or denosumab.[83] External radiation treatment has also been shown to provide benefit.

Thyroid Lymphoma

Treatment follows the guidelines used for other forms of lymphoma.

Stomatognathic Manifestations and Complications of Thyroid Disease

Both hypothyroidism and hyperthyroidism can occur in the same patient, because patients with clinically significant hypothyroidism are on replacement levothyroxine, and there is the risk of overtreatment and iatrogenic thyrotoxicosis. Similarly, patients on treatment for their hypothyroidism can develop marked hypothyroidism if they omit a number of doses, or if they are on an insufficient dose. Therefore, dentists need to be familiar with the symptoms and signs of both hypothyroidism and hyperthyroidism.

Patients with a history of thyroid cancer have probably undergone surgery or radioactive iodine therapy that can affect the adjacent regional tissues. Salivary gland dysfunction is one of the most common side effects of high-dose ^{131}I therapy for thyroid cancer.[84,85] ^{131}I targets the salivary glands, where it is concentrated and secreted into saliva. Dose-related damage to the salivary parenchyma results from ^{131}I irradiation and causes salivary gland swelling, pain, and hypofunction.[86–89]

Dental Management of the Patient with Thyroid Gland Disorders

Patients with autoimmune thyroid diseases (Hashimoto's thyroiditis) may also be susceptible to other autoimmune connective tissue disorders, including Sjögren syndrome. Antinuclear antibodies (ANAs) are found in one-third of

patients with autoimmune thyroid disorders, and Sjögren syndrome is found in nearly one-tenth of ANA-positive patients with autoimmune thyroid disorders.[90] The most common additional autoimmune disease identified in patients with primary Sjögren syndrome has been hypothyroidism;[91] also, there is a 7–17% prevalence of detectable thyroid antibodies in patients with Sjögren syndrome and rheumatoid arthritis.[92] Therefore, the thyroid patient who presents with signs and symptoms of hyposalivation and xerophthalmia should be evaluated for Sjögren syndrome.[84,93–95]

Hypothyroidism

In hypothyroidism, the orofacial findings include myxedema of the skin, an enlarged tongue (macroglossia), compromised periodontal health, delayed tooth eruption, delayed wound healing, and a hoarse voice. Salivary gland enlargement, changes in taste, and burning mouth symptoms have also been reported.[96,97]

Patients with hypothyroidism are susceptible to cardiovascular diseases; therefore, consultation with the patient's medical provider is indicated. Patients who have atrial fibrillation may be taking anticoagulants, depending on the severity of the arrhythmia. The use of epinephrine-containing local anesthetics is not contraindicated if the patient's hypothyroidism is well controlled, but in patients who have cardiovascular disease (congestive heart failure, atrial fibrillation) or who have uncertain control of their thyroid disease, local anesthetic and retraction cord soaked with epinephrine can be used, but cautiously. Hypothyroidism, especially if uncontrolled, can also lead to respiratory depression, so that patient positioning should be carefully considered when treating such patients. Consideration should be given to treating patients in a semi-upright position, with oxygen supplementation via nasal prongs or by the mask used in providing nitrous oxide to patients.

Hypothyroid patients are sensitive to CNS depressants and so these medications should be used carefully, with input from the patient's physician. For postoperative pain control, narcotic use should be limited, since there is greater susceptibility to these agents in patients with hypothyroidism. Patients with long-standing hypothyroidism may experience increased bleeding after trauma or surgery. The presence of excess subcutaneous mucopolysaccharides (due to decreased degradation) may impair the ability of small vessels to constrict if severed or traumatized, and this may result in increased postoperative hemorrhage from such infiltrated tissues, including mucosa and skin. Delayed wound healing may also occur due to decreased metabolic activity of the fibroblasts. However, a study of well-controlled primary hypothyroid patients who had been provided with dental implants demonstrated no significantly increased risk for implant failure when compared with matched normal controls.[98]

Hyperthyroidism

Hyperthyroidism can exacerbate the patient's response to dental pain and anxiety. Routine examination of the head and neck may disclose signs of thyroid disease, including changes in oculomotor function, protrusion of the eyes, enlargement of the thyroid, and so difficulty in swallowing, or of the tongue. The patient may demonstrate excessive sweating. The greatest concern is the development of thyrotoxicosis or a "thyroid storm," which includes symptoms of extreme irritability and delirium, hypotension, vomiting, and diarrhea.[99] It can be triggered by surgery, sepsis, and trauma. Emergency medical treatment is required for this condition. Epinephrine is contraindicated, and elective dental care should be deferred for patients who have hyperthyroidism and exhibit signs or symptoms of thyrotoxicosis.

Increased susceptibility to infection may develop as an adverse side effect of antithyroid agents, which can cause agranulocytosis or leukopenia. Propylthiouracil can also cause sialolith formation and can increase the anticoagulant effects of warfarin. Certain analgesics must be used with caution in these patients. Aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) may cause increased levels of circulating T4, leading to thyrotoxicosis. NSAIDs can also decrease the effect of beta blockers.[50] The use of epinephrine requires special consideration when treating hyperthyroid patients and those taking nonselective beta blockers.

DISORDERS OF THE ADRENAL GLANDS (CORTEX)

The normal adrenal glands weigh 6–11 g each, are located above the kidneys, and have their own rich blood supply.[100] Within the glands is the adrenal cortex, which produces three classes of corticosteroid hormones:

- Glucocorticoids (e.g., cortisol).
- Mineralocorticoids (e.g., aldosterone). Glucocorticoids and mineralocorticoids act through specific nuclear receptors, regulating aspects of the response to physiologic stress, and controlling blood pressure as well as electrolyte and glucose homeostasis.
- Adrenal androgen precursor (dehydroepiandrosterone [DHEA]) prohormones that are converted in peripheral target cells, principally the gonads, to become the sex steroids that, in turn, act via nuclear androgen and estrogen receptors. The sex steroids interact with androgen receptors that stimulate or control the development and maintenance of male characteristics, that is testosterone, or with the estrogen receptors, so regulating both the menstrual and the reproductive cycles.

Adrenal steroidogenesis occurs in a zone-specific fashion, with mineralocorticoid synthesis occurring in the outer zona

glomerulosa, glucocorticoid synthesis in the zona fasciculata, and adrenal androgen synthesis in the inner zona reticularis (Figure 22-12).

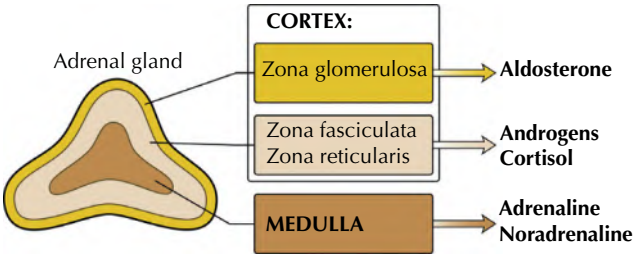

Figure 22-12 Adrenal steroidogenesis occurs in a zone-specific fashion. Mineralocorticoid synthesis (aldosterone) occurs in the outer zona glomerulosa. Glucocorticoid synthesis occurs in the zona fasciculate. Adrenal androgen synthesis occurs in the inner zona reticularis. The catecholamines (epinephrine and norepinephrine) are synthesized in the chromaffin cells of the adrenal medulla. *Source:* Kumar PJ, Clark ML (Eds.). *Kumar and Clark's Clinical Medicine*, 9th edn. Edinburgh: Saunders; 2017.

All the steroid hormones are derivatives of cholesterol (Figure 22-13). The steroidogenic pathway requires the import of cholesterol into the mitochondrion, a process initiated by the action of the steroidogenic acute regulatory (StAR) protein, which shuttles cholesterol from the outer to the inner mitochondrial membrane. Regulation of the production of glucocorticoids and adrenal androgens is under the control of the HPA axis (Figure 22-13).

Mineralocorticoids are regulated by the renin-angiotensin-aldosterone (RAA) system. Glucocorticoid synthesis is under inhibitory feedback control by the hypothalamus and the pituitary. Hypothalamic release of corticotrophin-releasing hormone (CRH) occurs in response to endogenous or exogenous stress. CRH in turn stimulates the release of ACTH by the cells of the anterior pituitary. ACTH is the pivotal regulator of cortisol synthesis, with additional short-term effects on mineralocorticoid and adrenal androgen synthesis. The release of CRH, and subsequently ACTH, occurs in a pulsatile fashion that follows a circadian rhythm, under the control of the hypothalamus. Reflecting this

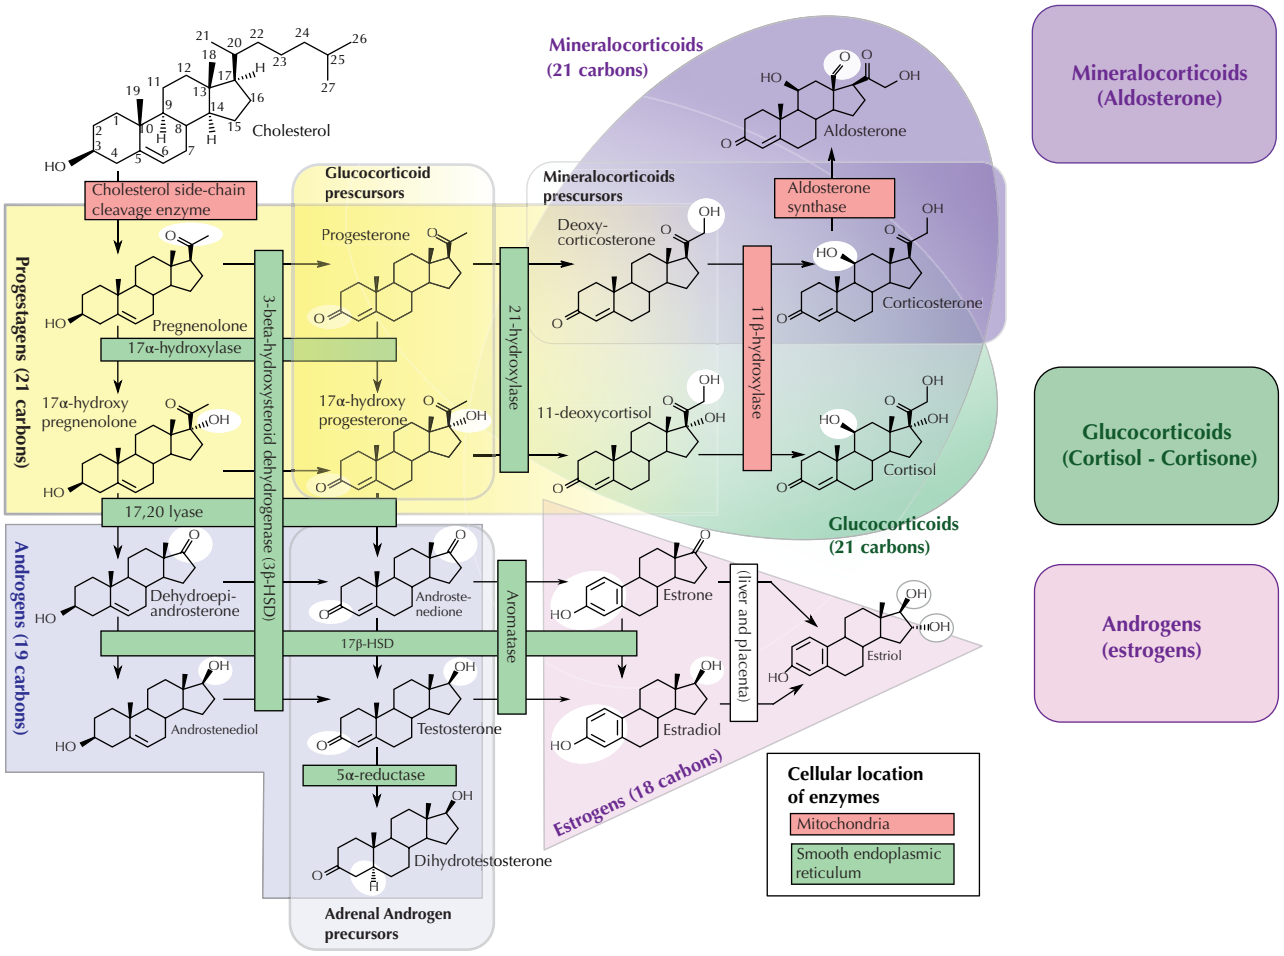

Figure 22-13 Adrenal steroidogenesis. Note how all the steroid hormones are derived from cholesterol. *Source:* https://commons.wikimedia.org/wiki/File:Steroidogenesis.svg. Creative Commons Attribution-Share Alike 3.0 Unported license.

pattern of ACTH secretion, adrenal cortisol secretion is also circadian, with peak levels in the morning and low levels in the evening

Diagnostic tests assessing the HPA axis makes use of the fact that it is regulated by negative feedback (Figure 22-1). Glucocorticoid excess is diagnosed by the dexamethasone suppression test. Dexamethasone, a potent glucocorticoid, suppresses CRH/ACTH and therefore lowers endogenous cortisol levels. If cortisol production is autonomous (e.g., from an adrenal adenoma), ACTH is already suppressed and the dexamethasone has little additional effect. If cortisol production is driven by an ACTH-producing pituitary adenoma, dexamethasone suppression is ineffective at low doses, but usually induces suppression at high doses. If cortisol production is driven by an ectopic source of ACTH, such as an ACTH-producing tumor, this is usually unaffected by dexamethasone suppression. Therefore, the dexamethasone suppression test is useful both in establishing the diagnosis of Cushing's syndrome (corticoid excess) and in differentiating the cause.[101] Conversely, to assess glucocorticoid deficiency, ACTH stimulation of cortisol production is used. The standard ACTH stimulation test involves administration of cosyntropin (Synacthen, a potent ACTH agonist) parenterally and the collection of blood samples at 0, 30, and 60 minutes to check the cortisol level.[102] A normal response is defined as a cortisol level >20 μg/dL or an increment of >10 μg/dL over baseline. Alternatively, an insulin tolerance test (ITT) can be used to assess adrenal insufficiency.

Mineralocorticoid production is controlled by the RAA regulatory cycle, which is initiated by the release of renin from the juxtaglomerular cells in the kidney, resulting in cleavage of angiotensinogen to angiotensin I in the liver. Angiotensin-converting enzyme (ACE) cleaves angiotensin I to angiotensin II, which binds and activates the angiotensin II receptor type 1 (AT1 receptor), resulting in increased aldosterone production and vasoconstriction. Aldosterone enhances sodium retention and potassium excretion, and increases renal arterial perfusion pressure, which in turn regulates renin release. As mineralocorticoid synthesis is primarily under the control of the RAA system, disorders of the hypothalamic-pituitary axis generally do not adversely affect adrenal gland synthesis of aldosterone.

Cushing's Syndrome (Glucocorticoid Excess)

Cushing's syndrome reflects a constellation of clinical features that result from the chronic effects of glucocorticoid excess, of any etiology and any source. Cushing's syndrome is rare, with an annual incidence of 1–2 per 100,000 population. The disorder can be ACTH dependent (e.g., pituitary corticotrope adenoma) or ACTH independent (e.g., adrenocortical tumor). Overwhelmingly, the medical use of glucocorticoids is the commonest cause of Cushing's syndrome. Only 10% of patients with Cushing's syndrome have a primary—that is, adrenal—cause of their disease.[103] The term "Cushing's disease" is specific to glucocorticoid excess caused by a pituitary adenoma secreting ACTH.

Ectopic ACTH production is predominantly caused by occult carcinoid tumors, most frequently in the lung, but also in the thymus or pancreas. Advanced small cell lung cancer can also cause ectopic ACTH production.[104]

Clinical Manifestations

Given that glucocorticoids (see Table 22-11) affect almost all cells of the body, the signs of cortisol excess impact multiple physiologic systems. In addition, excess glucocorticoid secretion overcomes the ability of a key kidney enzyme system (11 β-hydroxysteroid dehydrogenase type 2 or 11β-HSD2) to rapidly inactivate cortisol to cortisone. Cortisone has minimal mineralocorticoid activity, whereas cortisol has

Table 22-11 Major actions of glucocorticoids.

Organ/ Physiologic System	↑ Increased or Stimulated	↓ Decreased or Inhibited
Metabolic	↑ Gluconeogenesis ↑ Glycogen deposition ↑ Protein catabolism ↑ Fat deposition	↓ Protein synthesis
Renal (Kidneys) System	↑ Sodium retention ↑ Potassium loss ↑ Uric acid production	↓ Free water clearance
Hematologic System	↑ Circulating neutrophils	↓ Host response to infection, delayed hypersensitivity response ↓ Lymphocyte transformation, circulating lymphocytes, circulating eosinophils

some degree of mineralocorticoid action, which manifest as diastolic hypertension, hypokalemia, and edema. Excess glucocorticoids also interfere with central regulatory systems, leading to suppression of gonadotropins with subsequent hypogonadism and amenorrhea, and suppression of the hypothalamic-pituitary-thyroid axis, resulting in decreased TSH secretion.

The diagnosis of Cushing's syndrome should be considered when the following key clinical features are evident in the patient (see Figure 22-14): fragility of the skin, with easy bruising and broad (>1 cm), purplish striae, and signs of proximal myopathy, with the patient struggling to stand up from a chair (without the use of hands). Patients with Cushing's syndrome may develop marked hypercoagulopathy, so are at acutely increased risk of deep vein thrombosis and subsequent pulmonary embolism. Psychiatric symptoms of marked anxiety and/or depression are also common, but acute paranoia or frank psychosis may also occur.[101]

Overt untreated Cushing's syndrome is associated with a poor prognosis. In ACTH-independent disease, treatment consists of surgical removal of the adrenal tumor. In Cushing's syndrome, the treatment of choice is selective removal of the pituitary corticotrophic-producing tumor, usually via a transsphenoidal approach.

Conn's Syndrome (Mineralocorticoid Excess)

Hyperaldosteronism, the excessive release of the principal mineralocorticoid, aldosterone, typically presents as hypertension, given the adverse effects on the renin-angiotensin system that so powerfully controls renal perfusion and homeostasis, and blood pressure. The commonest cause is primary hyperaldosteronism, excess production of aldosterone by the adrenal zona glomerulosa, typically occurring with bilateral micronodular adrenal hyperplasia. Infrequently, Conn's syndrome occurs due to an adrenocortical carcinoma.

The clinical hallmark of mineralocorticoid excess is hypokalemic hypertension, but not hypernatremia, with the serum sodium tending to be normal due to the concurrent fluid retention, which in some cases can lead to marked peripheral edema. Severe hypokalemia can be associated with muscle weakness, overt proximal myopathy, or, in severe cases, hypokalemic paralysis, or tetany.[105] Diagnostic screening for mineralocorticoid excess is not currently recommended for all patients with hypertension, but should be considered in hypertensive patients younger than 40 years, treatment-refractory hypertension, hypokalemia, or the finding of an adrenal mass. The accepted screening test is concurrent measurement of plasma renin and aldosterone with subsequent calculation of the aldosterone–renin ratio, but the serum potassium needs to be normalized prior to testing.

With the diagnosis of hyperaldosteronism, CT imaging of the adrenal glands is needed. The treatment provided is dependent on the patient's age and fitness for surgery. Laparoscopic adrenalectomy is the preferred approach. Medical treatment, which can also be considered prior to surgery to avoid postsurgical hypoaldosteronism, is usually with the mineralocorticoid receptor antagonist spironolactone.[106]

Addison's Disease (Adrenal Insufficiency)

The US prevalence of adrenal insufficiency (Table 22-12) is 5 in 10,000 in the general population. Disorders of the hypothalamic-pituitary axis are more frequent, with a prevalence of 3 in 10,000, whereas primary adrenal insufficiency has a prevalence of 2 in 10,000, with about half of cases due to genetic causes (e.g., congenital adrenal hyperplasia). Primary adrenal insufficiency is most commonly caused by autoimmune destruction of the adrenal gland, with some 60–70% developing adrenal insufficiency as part of an autoimmune polyglandular syndrome (APS). APS1, an autosomal recessive disorder also termed APECED (autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy), is the underlying cause in 10% of patients affected by APS.[107] These patients invariably develop chronic mucocutaneous candidiasis, which usually manifests in childhood and precedes adrenal insufficiency by years or decades. Coincident autoimmune-induced endocrinopathies most frequently include thyroid autoimmune disease, vitiligo, and premature ovarian failure. Less commonly, T1DM and pernicious anemia (with consequent vitamin B_{12} deficiency) may occur. Rare causes of adrenal insufficiency involve destruction of the adrenal glands as a consequence of infection, with tuberculous adrenalitis still a frequent cause of disease in developing countries. Hemorrhage, or more rarely bilateral bulky metastatic infiltration with replacement of the adrenal glands, can also result in hypoadrenalism.

The commonest cause of adrenal insufficiency is iatrogenic, arising from suppression of the HPA axis as a consequence of exogenous glucocorticoid treatment (see Tables 22-13 and 22-14).[108] This has a reported prevalence of some 0.5–2% of the population in developed countries. Secondary adrenal insufficiency is the consequence of dysfunction of the hypothalamic-pituitary component of the HPA axis. Excluding iatrogenic impairment of the HPA axis (exogenous corticosteroid use), the majority of cases are caused by pituitary or hypothalamic tumors, or their treatment by surgery or radiotherapy.

In principle, the clinical features of primary adrenal insufficiency (Figure 22-15) are characterized by the loss of both glucocorticoid and mineralocorticoid secretion. In contrast, in secondary adrenal insufficiency only glucocorticoid deficiency is evident, as the adrenal itself is intact and can still be regulated by the RAA system. Adrenal androgen secretion is disrupted in both primary and

Table 22-12 Adrenal insufficiency (hypoadrenalism): classification.

Source: Data from Nicolaides NC, Pavlaki AN, Maria Alexandra MA, et al. Glucocorticoid therapy and adrenal suppression. Updated 2018. In: Feingold KR, Anawalt B, Boyce A, et al. (Eds.), *Endotext*. South Dartmouth, MA: MDText.com. https://www.ncbi.nlm.nih.gov/books/NBK279156/.

secondary adrenal insufficiency. Hypothalamic-pituitary disease can lead to additional clinical manifestations due to the involvement of other endocrine axes, or visual impairment with bitemporal hemianopia caused by compression of the optic chiasma. Iatrogenic adrenal insufficiency caused by exogenous glucocorticoid suppression of the HPA axis and its abrupt cessation can cause all of the symptoms associated with glucocorticoid deficiency, but the patient will appear cushingoid from the preceding "overexposure" to glucocorticoids.

Acute adrenal insufficiency usually occurs after a prolonged period of nonspecific complaints and is more frequently observed in patients with primary adrenal insufficiency, due to the loss of both glucocorticoid and mineralocorticoid secretion. The associated postural hypotension is a "red flag," as the patient may then progress to hypovolemic shock. Adrenal insufficiency may also mimic the features of an acute abdomen with abdominal tenderness, nausea, vomiting, and fever. An adrenal crisis can be triggered by an intercurrent illness, surgery, or other stress.[109]

The diagnosis of adrenal insufficiency is established by the short cosyntropin test (Synacthen), a safe and reliable tool with excellent diagnostic sensitivity. The ITT is an alternate, but can be hazardous to the patient, and requires supervision by a specialist physician.

Acute adrenal insufficiency requires immediate rehydration (1 L/hour of saline infusion) with cardiac monitoring and glucocorticoid replacement by bolus injection of 100 mg hydrocortisone, followed by further hydrocortisone supplementation (100–200 mg hydrocortisone over the course of 24 h). Mineralocorticoid replacement can wait until the daily hydrocortisone dose has been reduced to <50 mg, because at higher doses the hydrocortisone provides sufficient stimulation of the mineralocorticoid receptors.

Glucocorticoid replacement (Table 22-15) for the treatment of chronic adrenal insufficiency should be administered at a dose that replaces the physiologic daily cortisol production, typically orally administered hydrocortisone at a dose of 15–25 mg, in two divided doses: 10–20 mg in the mornings and 5 mg in the evenings, mimicking the natural circadian levels of cortisol.

Mineralocorticoid replacement in primary adrenal insufficiency is achieved by the use of 100–150 μg of fludrocortisone. Its efficacy is assessed by measuring the blood pressure, while both sitting and standing, to detect a postural drop indicative of hypovolemia, and assessing serum sodium, potassium, and plasma renin levels. Adrenal androgen replacement is an option for patients with a lack of energy, or with features of androgen deficiency, such as loss of libido.

Pheochromocytoma

This is an adrenal tumor that produces epinephrine, norepinephrine, or both catecholamines. Patients are hypertensive, with headache, sweating, tachycardia, palpitations, and pallor. Occasionally, these can be syndromic, as part of Multiple Endocrine Neoplasia Syndrome Type 2B (MEN2B) presenting with a marfanoid habitus, high arched palate, neuromas (of the tongue, buccal mucosa, lips, conjunctivae, and eyelids), and corneal nerve thickening. The diagnosis of pheochromocytoma is confirmed by measuring urinary and plasma catecholamine levels.[110]

Stomatognathic Manifestations and Complications of Disorders of the Adrenal Gland

Hyperadrenocorticism (Glucocorticoid Excess or Cushing's Syndrome)

The primary orofacial feature of Cushing's syndrome is a round, moon face due to muscle wasting and accumulation of fat. Surface capillaries in the face and other skin regions become fragile, rendering them readily susceptible to hematomas after mild trauma. The facial skin has a ruddy color that simulates "glowing health"; acne and excessive facial hair (hirsutism) are also commonly seen. Long-standing Cushing's syndrome in children produces delayed growth and development, including of the skeletal and dental structures. Many of the systemic findings of Cushing's syndrome are similar to those seen in patients on moderate- to high-dose glucocorticoid therapy, and these patients are considered to be immunosuppressed. Therefore, oral signs and symptoms of immunosuppression can be seen, including oral candidiasis, recurrent herpes labialis and herpes zoster infections, gingival and periodontal diseases, and impaired wound healing.

Hypoadrenocorticism (Glucocorticoid Deficiency or Addison's Disease)

The primary orofacial feature of Addison's disease is unusual skin pigmentation, most intensely of the sun-exposed areas due to ACTH stimulation of the melanocytes. Facial freckles and moles appear darker, in addition to the development of a tan-like complexion ("bronzing" of the skin and sometimes of the oral mucosa), which does not fade on cessation of sunlight exposure. The mucocutaneous junctions undergo increased pigmentation, including the lips, but hyperpigmentation can also involve the intraoral mucosal surfaces, such as the gingival margins, buccal mucosa, palate, and lingual surface of the tongue. The oral pigmentations appear as irregular spots that range from pale brown to gray or black.[111]

Dental Management of Patients with Adrenal Gland Disorders

Hyperadrenocorticism (Glucocorticoid Excess or Cushing's Syndrome)

Dental management of the patient with Cushing's syndrome must take into consideration concomitant medical conditions that can include hypertension and heart failure, depression or psychosis, as well as DM and osteoporosis. Patients will present with easy bruising of the skin, impaired wound healing, and the infective consequences of immunosuppression. Prophylactic antibiotic coverage should be considered prior to surgery (extractions) for active dentoalveolar infections.

Assessment of the ability to withstand stress is an essential component of treatment planning for patients with Cushing's syndrome and other patients who have been on long-term moderate- to high-dose glucocorticoid therapy (see Table 22-12). Stress may be induced by an invasive surgical procedure, the onset of infection, an exacerbation of an underlying disease, or a serious life event, such as the death of a family member.[112] When normal individuals undergo stress, the plasma cortisol levels can double, due to the inherent ability of the adrenal glands to significantly increase cortisol production. But, in a patient with adrenal insufficiency, adrenal function is inadequate to produce sufficient cortisol in response to stress. Consequently, the patient may experience severe hypotension, with cardiovascular events such as stroke, coma, and death. Patients with established severe adrenal insufficiency usually require premedication with oral or intramuscular glucocorticoids before an invasive procedure. Dosages must be agreed upon with the patient's physician; a frequent regimen is to double the daily dose of oral glucocorticoids the day before the surgery and on the day of surgery.[113]

Hypoadrenocorticism (Glucocorticoid Deficiency or Addison's Disease)

Dental management is similar to that for the patient who has taken long-term moderate to high doses of glucocorticoids (see earlier), since Addison's disease is frequently treated with exogenous glucocorticoids. The oral health practitioner must be able to recognize and provide initial management of an acute adrenal crisis (intramuscular or intravenous hydrocortisone) when treating these patients.[114]

Use of Replacement Corticosteroid Therapy ("Stress Steroids" or "Steroid Cover")

Cortisol (hydrocortisone) is essential to maintain vasomotor tone, and so normal blood pressure, by sensitizing the alpha-adrenergic receptors (alpha 1A, 1B, and 1D receptors) of the vasculature to circulating epinephrine and norepinephrine

Table 22-16 Dental procedures and recommended replacement corticosteroids.

Risk Category	Dental Procedure	Hydrocortisone	Prednisone	Dexamethasone
Negligible	• Nonsurgical & in chair +/- local anesthetic	Nil	Nil	
Mild	• Minor oral surgery • Minor periodontal surgery } in the dental chair			Nil
Moderate to severe	• Major oral or periodontal surgery—multiple extractions/implants • Procedure >60 mins • Significant blood loss • general anesthetic/intubation	50–100 mg day of surgery *and 24 hours* afterward	10–20 mg within 2 hours of procedure	~2–4 mg (long-acting) >48 hours
Monitoring	• BP (100/60) systolic >100; diastolic >60 ➔ if *lower* give fluids (5% dextrose saline)			

and increasing catecholamine release from the adrenal cortex. If insufficient cortisol is produced at times of marked physiologic stress, this can result in vasodilation, reduced cardiac return, and potential hypotensive cardiac shock, leading to collapse and death. Significant physiologic stressors include severe infection and/or injury; that is, surgery and intubation associated with general anesthesia.[115–117]

Iatrogenic adrenal insufficiency is caused by suppression of the HPA axis due to exogenous glucocorticoid therapy. The mean cortisol production rate is 5.7 mg/m^2/day, or about 10 mg/day (equal to 2.5 mg of prednisone or 0.5 mg of dexamethasone) (see Table 22-15).[118] Body surface area (BSA) is used to calculate the dose of a drug relative to the patient's "ideal" body weight, resulting in a dose per meter squared (m^2). The BSA is a better indicator of the patient's "ideal" body weight because it is less affected by abnormal adipose mass, and this is useful when giving drugs with a narrow therapeutic safety index, such as chemotherapy agents. Of the various formulations, the Mosteller equation is simpler and considered more accurate:

$$\mathrm{BSA}\left(\mathrm{m2}\right)=\frac{\sqrt{height\left(cm\right)\times weight\left(kg\right)}}{3600}$$

Therefore, exogenous glucocorticoids that exceed the mean level of cortisol production can result in suppression of the HPA axis, as well as atrophy of the adrenal glands. Consequently, at times of acute physiologic (and possibly psychologic stress), the now atrophied adrenal gland is unable to produce sufficient cortisol for the affected patient to respond appropriately to stress. Historically this resulted in the so-called Rule of Twos, in which a patient was thought to be susceptible to an impaired response to physiologic stress, due to adrenocorticoid suppression from exogenous corticosteroids used for the medical treatment of predominantly immune-related or inflammatory conditions. The Rule stated that if a patient had taken glucocorticoids in excess of 20 mg of cortisone, continuously for 2 weeks (or more), within 2 years of the date/day of their dental treatment, this patient needed supplementary steroids prior to their dental treatment.[119] What is now very clear is that the published evidence has concluded that supplementary steroids ("steroid cover") are not indicated for dental procedures done in the dental chair and facilitated by means of local anesthesia, for patients using therapeutic corticosteroids. The evidence for using such "stress steroids" is at best equivocal for more major dental (surgical) procedures. For patients who have recently (within 2 years) ceased supraphysiologic corticosteroid therapy, the evidence is again considered to be equivocal.

Thus, in assessing the need for a patient with hypoadrenalism to receive preprocedural supplemental corticosteroids (Table 22-16), the essentials still need to be applied: careful patient assessment and evaluation, including taking a detailed medical history, with particular attention to recent surgery and how the patient coped with the procedure.[120–122] However, for patients undertaking dental procedures utilizing oral or intravenous sedation with potent short-acting benzodiazepines (e.g., midazolam) to abrogate the psychologic stresses associated with invasive dental treatment, this intended blunting of the emotional stress response may blunt the physiologic stress response. Therefore, for those patients with primary hypoadrenalism or on long-term supraphysiologic doses of corticosteroids having dental treatment aided by means of oral or intravenous sedation, supplementary pre- or periprocedural "stress steroids" should be considered and possibly provided.[123]

GONADS AND GONADAL DYSFUNCTION

The gonads, like most other endocrine organs, are incorporated into an endocrine axis: the hypothalamic-pituitary-gonadal (HPG) axis. The physiologic function and regulation of the HPG axis, especially in women, is complex and

changes dramatically over a lifetime. The hypothalamic hormone in the HPG axis is gonadotropin-releasing hormone (GnRH). GnRH is released in a complicated pulsatile fashion that varies widely in a person's lifetime and is significantly different between men and women. The general principles of stimulation and feedback inhibition apply to the HPG axis (see Figures 22-4 and 22-5); however, this axis is complicated by two issues: GnRH is pulsatile, and the pituitary makes two hormones, LH and FSH. In the male, LH stimulates testosterone production from the Leydig cells of the testicles, and FSH stimulates sperm production by the Sertoli cells. In females, FSH stimulates maturation of the ovarian follicle, and LH causes "luteinization," or maturation of the follicle into a corpus luteum, as well as the production of ovarian estradiol.

For both males and females, the HPG axis is relatively dormant before the onset of puberty. The onset of puberty in girls occurs approximately 2 years before that of boys. In girls, the average age at which breast development starts is 10.5 years, and menses starts at about 12 years. In boys, the peak growth rate and beginning of voice change are about the age of 14 years, whereas facial hair appears on average at the age of 15 years. In men, from late puberty until about age 60 years, the serum testosterone levels are relatively constant and begin to decline gradually thereafter. In women, serum estradiol levels vary widely over the course of the menstrual cycle, but after the onset of menopause (which occurs on average at the age of 50 years), serum estradiol levels become very low and gonadotropin (LH and FSH) levels are elevated.

Precocious Puberty, Delayed Puberty, Hypogonadism, and Menopause

In both males and females, precocious puberty, delayed puberty, and hypogonadism are clinical diagnoses, made by early or late signs of secondary sexual differentiation or loss of sexual characteristics.[124] Pubertal development is measured clinically by a staging system developed by Tanner.[125] Puberty is generally considered precocious in boys if it starts before age 10 years and in girls before age 8.5 years, or delayed if there are no signs of sexual development by the age of 13 years in girls and 14 years in boys.[126]

Once a clinical diagnosis of gonadal dysfunction is established, the next step is to determine whether the pathophysiologic process is of the gonads (primary/end-organ disorder), pituitary (secondary endocrinopathy), hypothalamus (tertiary endocrinopathy), or, alternatively as in the case of precocious puberty, due to an ectopic (or exogenous) source of the hormone. Gonadal testing usually involves measuring the appropriate sex steroid (testosterone or estradiol) and the pituitary gonadotropins LH and FSH. The most common cause of precocious puberty in boys and girls is early onset of pituitary hormone production, termed "central precocious puberty." If the end-organ hormones are elevated and the gonadotropins are suppressed (gonadotropin-independent precocious puberty), this suggests primary (autonomous) gonadal dysfunction. Finally, the adrenal gland also produces androgens that can lead to early puberty in boys and masculinization in girls.

Premature ovarian failure heralded by the onset of menopause before the age of 40 years presents as "hot flushes." The most common associated problem is cessation or marked irregularity of the menstrual cycle. Hypogonadism in men presents with a loss of libido and decreased growth rate of facial hair, and can lead to osteoporosis and fractures; it is diagnosed by a low serum testosterone level. Premature ovarian failure is diagnosed by the early loss of menstrual cycles in the setting of an elevated serum FSH. Replacement of the primary gonadal steroid, testosterone or estradiol or one of its analogues, in men and women is straightforward. However, replacement of the missing hormone will not return fertility, which is often the major concern. If the gonad is still functional but disorder or loss of the relevant pituitary hormones leads to a loss of function, the pituitary hormones can then be replaced.

Oral Manifestations of Gonadal Disorders

Hypersecretion of female sex hormones commonly occurs in pregnancy. High levels of female sex hormones cause increased capillary permeability, increased susceptibility to the development of gingivitis (pregnancy gingivitis), gingival hyperplasia, and pyogenic granulomas (pregnancy tumor).[127] These factors may complicate preexisting periodontal disease. A decrease in gonadal hormones at menopause is associated with a decrease in salivary flow and salivary composition.[128] Postmenopausal women also have increased susceptibility to osteoporosis, so dental radiographs may demonstrate hypocalcified bone.[129]

Dental Management of Patients with Gonadal Disorders

Elective and stressful dental procedures should be avoided during the first trimester of pregnancy and the last half of the third trimester. The second trimester is the safest period to provide dental care during pregnancy. During this time, emphasis should be on prevention, maintenance of optimal oral health, and treatment of dental concerns that may lead to complications in late stages of pregnancy.[130] Injudicious use of medications should be avoided in pregnancy; choice of medication should be guided by FDA pregnancy classifications for prescription drugs to avoid those with possible teratogenic effects.[131]

Table 22-17 Type 1 versus type 2 diabetes mellitus (DM) characteristics.

	Type 1 DM	Type 2 DM
Prevalence (DM—all types)	<5–10%	>90–95%
Age (of onset)	Younger (<30 years of age)	Older (>30 years of age)
Weight	Lean	Overweight/obese
Symptom duration	weeks	Months/years/decades
Risk factors		
Ethnicity	Northern European	Asian, African, American Indian, Australian Aboriginal, Polynesian
Social/lifestyle	(?) uncertain	Obesity, sedentary lifestyle
Heredity	HLA-DR3 or DR4 (>90%)	No HLA linkage
Pathogenesis	Autoimmune disease	?
Ketonuria	Yes	No
Clinical	Insulin deficiency	Partial insulin deficiency, initially then increasing insulin resistance
	± ketoacidosis	± hyperosmolar state
	Insulin dependent	Need insulin with time as beta pancreatic cells fail
	Increased risk of hypoglycemia	Lower risk of hypoglycemia

DIABETES MELLITUS

DM encompasses a group of heterogeneous metabolic disorders with a common phenotype of persistent, abnormally elevated blood glucose levels (hyperglycemia) in association with dysregulation of carbohydrate, protein, and lipid metabolism (see Table 22-17). This persistent hyperglycemia (disordered glucose homeostasis) results from either a defect in the secretion of insulin from the pancreas, or resistance to the action of insulin by the body's cells, or both.[132] Hyperglycemia has been shown to affect almost all tissues in the body and is associated with significant complications of multiple organ systems, including the eyes, nerves, kidneys, and blood vessels. These complications are responsible for the high degree of morbidity and mortality seen in the diabetic population. In the United States (as in other Westernized countries), DM is the leading cause of end-stage renal disease (ESRD);[133] nontraumatic toe, foot, and lower limb amputation;[134] and adult blindness.[135]

Epidemiology

Worldwide, DM, in particular T2DM given that it accounts for 90–95% of all patients with DM, is now one of the most common noncommunicable diseases. It is the ninth leading cause of death in most high-income countries and there is substantial evidence that it is now also becoming epidemic in many low- and middle-income countries.[136] The main risk factor for DM, specifically T2DM, is obesity. Obesity is defined as a condition in which excess body fat has accumulated to the extent that it may have a negative effect on health, leading to reduced life expectancy and/or morbidity.[137–139] The incidence of DM rises as the population ages and the prevalence of obesity increases.[140,141] In the United States, for the period 2007–2010, the crude total prevalence of DM was estimated at 11.4% of the population over 20 years of age (data obtained by self-report of physician-diagnosed diabetes and exclude women who reported having diabetes during pregnancy).

Hormonal Control of Blood Glucose[142]

Plasma glucose levels are normally tightly regulated in health, confined to a range of 3.5–8.0 mmol/L (63–144 mg/dL), despite physiologic stressors of food, fasting, and exercise. The principal organ of glucose homeostasis is the liver, which absorbs and stores glucose (in the form of glycogen) in the postabsorptive state (after the intake of food), and releases glucose into the circulation between meals to meet the rate of glucose utilization (cellular respiration) by the peripheral tissues. The liver is also the site of gluconeogenesis ("new sugar formation"), whereby 3-carbon molecules

derived from the breakdown of fat (glycerol), muscle glycogen (lactate), and protein (e.g., alanine) are synthesized into the 6-carbon glucose molecule. About 200 g of glucose is produced and used each day. More than 90% of this is derived from the glycogen stores in the liver and from gluconeogenesis. The remaining 10% is derived from gluconeogenesis undertaken by the kidneys.

The brain is the major consumer of glucose, requiring up to 1 mg/kg bodyweight per minute (i.e., 100 g/daily in a 70 kg patient). Glucose uptake by the brain is obligatory and not dependent on insulin, with the glucose used for energy (cellular respiration) or oxidized to form carbon dioxide and water. Other tissues, namely the fat and muscle cells, are facultative consumers of glucose, which otherwise rely on fatty acid oxidation for their energy needs. Glucose taken up by muscle cells is stored as glycogen or broken down to lactate, which enters the circulation to become a major substrate for hepatic gluconeogenesis. Glucose is used by fat cells as a source of energy and as a substrate for triglyceride synthesis. Lipolysis is the breakdown of lipids by the hydrolysis of triglycerides into free fatty acids and glycerol. The resulting glycerol also serves as a substrate for hepatic gluconeogenesis.

Cell membranes, because of their polar lipid bilayer, are not readily permeable to glucose. Glucose transporters (GLUT) are a family of four, ubiquitous, specialized cell membrane proteins that facilitate the transport of glucose (and related hexoses) through the plasma membrane.[143] The glucose transporter responsible for the majority of glucose uptake by cells of the body is GLUT 4, which operates solely at the bidding of insulin. GLUT 4 is found on the cells of adipose tissue as well as skeletal and cardiac muscle, and glucose cannot enter these cells without the presence of insulin.

Insulin

Insulin is the key hormone involved in the storage and controlled release of the energy available from food. Insulin is a peptide hormone produced by the beta (islet) cells of the endocrine pancreas. After secretion, insulin enters the portal circulation and is transported to the liver, its prime target organ. Half of this insulin is taken up from the circulation and degraded by the liver, with the residue broken down in the kidneys.

Insulin is a major regulator of intermediate metabolism. Although its actions are modified by many other hormones, its importance lies in its differing actions in the fasting and postprandial states. In the fasting state insulin functions to regulate the release of glucose by the liver, and in the postprandial state it facilitates the uptake of glucose by fat and muscle. The effect of counter-regulatory hormones (namely glucagon, epinephrine, cortisol, and GH) is to cause a greater release of glucose from the liver and decrease the utilization of glucose by the fat and muscle cells, for a given level of insulin.

Glucagon

Glucagon is a peptide hormone synthesized and secreted from alpha cells of the islets of Langerhans, of the endocrine portion of the pancreas (Box 22-2). Glucagon acts to raise blood glucose levels (Figure 22-16), so the effect of glucagon is opposite to that of insulin (which lowers blood glucose levels). The pancreas releases glucagon when blood glucose concentrations fall critically low (Table 22-18). Glucagon generally elevates blood glucose levels by promoting gluconeogenesis and glycogenolysis in the liver. High blood glucose levels stimulate the release of insulin, which then allows glucose to be taken up and used by insulin-dependent tissues. Thus, glucagon and insulin are part of a feedback system that maintains blood glucose levels at a stable level. Glucagon also regulates the rate of glucose production through lipolysis.

Amylin

Amylin, or islet amyloid polypeptide (IAPP), is a 37-residue peptide hormone. It is co-secreted with insulin from the pancreatic beta cells at a ratio of approximately 100:1. Amylin functions as a synergistic partner to insulin. The overall effect is to slow the rate of appearance of glucose in the blood. After eating, amylin causes a coordinated slowing of gastric emptying, the inhibition of digestive secretions (gastric acid, pancreatic enzymes, and bile), and the induction of satiety that results in a reduction in food intake. Blood glucose levels are also reduced by inhibiting secretion of the gluconeogenic hormone glucagon. Collectively, these actions reduce the total demand for insulin. These actions are largely mediated by the glucose-sensitive part of the brain stem, the *area postrema*,

Box 22-2 Glucagon (Peptide Hormone) versus Glycogen (Polysaccharide)

Glucagon is secreted by the pancreas, is a peptide hormone that raises blood glucose levels, and its effect is *opposite that of insulin* (insulin lowers blood glucose levels).

Glycogen is a multibranched polysaccharide of glucose that serves as secondary energy storage (the primary energy stores being fats held in adipose tissue). Glycogen is made and stored primarily in the hepatocytes and the muscles.

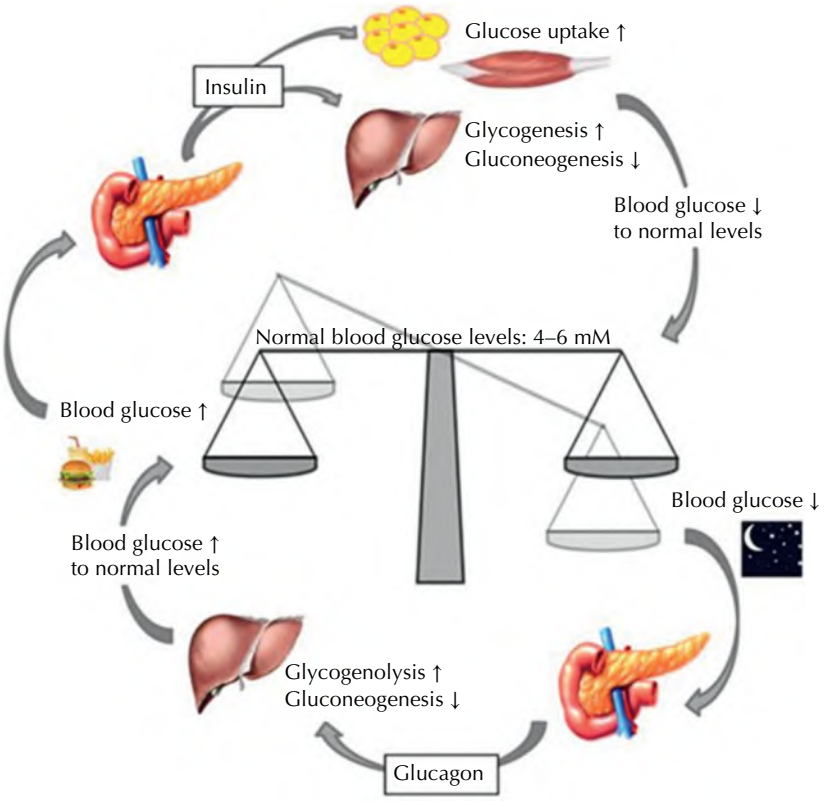

Figure 22-16 Maintenance of blood glucose levels by glucagon and insulin. When blood glucose levels are low, the pancreas secretes glucagon, which increases endogenous blood glucose levels through glycogenolysis. After a meal, when exogenous blood glucose levels are high, insulin is released to trigger glucose uptake into insulin-dependent muscle and adipose tissues as well as to promote glycogenesis. *Source:* Röder PV, Wu B, Liu Y, Han W. Pancreatic regulation of glucose homeostasis. *Exp Mol Med*. 2016;48(3):e219. Reproduced with permission.

Table 22-18 Regulation of glucagon.

↑ **Glucagon** secretion of glucagon is **stimulated by:**	• **Hypoglycemia** • Epinephrine • Arginine • Alanine (muscle-derived pyruvate/glutamate transamination • Acetylcholine • Cholecystokinin
↓ **Glucagon** secretion of glucagon is **inhibited** by:	• **Insulin (via GABA)** • Somatostatin • PPARγ/retinoid X receptor heterodimer • Increased free fatty acids and keto acids into the blood • Increased urea

but this control can be overridden during hypoglycemia. Both insulin and amylin are regulated by similar factors since they share a common regulatory promoter motif, with amylin being degraded in part by insulin-degrading enzymes and by peptidases in the kidney. A synthetic analogue of human amylin, pramlintide (Symlin®, AstraZeneca, Wilmington, DE, USA), is used in both T1DM and T2DM. Both insulin and pramlintide are injected separately, before a meal, to synergistically control the post-prandial glucose levels.[144]

Pathophysiology of Diabetes Mellitus

The pathophysiology of DM is mediated by alterations of carbohydrate metabolism and insulin action. After a meal, breakdown of carbohydrates leads to hyperglycemia, an elevation in blood glucose levels. Hyperglycemia stimulates insulin secretion from pancreatic beta cells because insulin is critical for glucose uptake by most cells (except in the brain). Insulin binds to specific cellular receptors and facilitates entry of glucose into the cell, which then uses the glucose for energy. The end result is a reduced blood glucose level and ultimately decreased insulin secretion. If insulin production and secretion are altered by disease, glucose entry into cells will be inhibited, resulting in sustained hyperglycemia.

Hyperglycemia can also ensue if insulin cannot function effectively, termed "insulin resistance." Following meals, the amount of glucose available often exceeds cellular demand for glucose. The excess glucose is stored in the liver in the form of glycogen, which serves as a ready reservoir of glucose for future use. When energy is required, glycogen stores in the liver are converted into glucose via glycogenolysis, elevating blood glucose levels and providing the needed cellular energy source. The liver also produces glucose from fat (fatty acids) and proteins (amino acids) through the process of gluconeogenesis. Glycogenolysis and gluconeogenesis

both serve to increase blood glucose levels. Thus, glycemia is controlled by a complex interaction between the gastrointestinal tract, the pancreas, and the liver. Insulin is the only hormone that lowers blood glucose levels. Counter-regulatory hormones such as glucagon, catecholamines, GH, thyroid hormone, and glucocorticoids all act to increase blood glucose levels, in addition to their other effects.

Type 1 Diabetes Mellitus

T1DM is characterized by idiopathic autoimmune destruction of pancreatic beta cells, usually leading to an absolute insulin deficiency (Tables 22-18 and 22-19).[4] It constitutes 5–10% of all DM cases. T1DM typically occurs before the age of 25 years in 95% of affected persons, but can occur at any age. It affects both sexes equally, and is more prevalent in Caucasians. The risk of developing T1DM is increased by a family history of T1DM, having gluten enteropathy (celiac disease), or other endocrine diseases. There are two distinct subclasses:

- *Immune-mediated form of T1DM*. This has a slow onset, with a subclinical prodromal period, characterized by cellular-mediated autoimmune destruction of the insulin-producing beta cell in the pancreatic islets. This may be triggered by a viral infection, but it is also associated with other autoimmune disorders, such as Hashimoto's thyroiditis, Addison's disease, vitiligo, or pernicious anemia.
- *Idiopathic T1DM*. This is acute in onset, and the cause of beta cell destruction is still unclear. It is prevalent among people of African or Asian origin and has a strong pattern of familial inheritance.[145]

Since the pancreas no longer produces insulin, a T1DM patient is completely dependent on exogenously administered insulin for survival. People with T1DM are highly susceptible to diabetic ketoacidosis. Although glucose is present, it is trapped in the circulation, but without insulin the cells are unable to take up the glucose. To meet cellular energy needs, fat is broken down through lipolysis, releasing glycerol and free fatty acids. Glycerol is converted to glucose for use by the cells. Fatty acids are converted to ketones, with an increase in the ketone levels in body fluids, which thus become increasingly alkaline (increased pH). Ketones are excreted in the urine, accompanied by large amounts of water. This accumulation of ketones in body fluids, increased pH, electrolyte loss, and dehydration from excessive urination, in addition to alterations in the bicarbonate buffering system, result in diabetic ketoacidosis. Untreated diabetic ketoacidosis can result in coma or even death. Many patients with T1DM are initially diagnosed following an episode of diabetic ketoacidosis.[146]

Table 22-19 American diabetes association diagnosis and classification of diabetes mellitus (DM).

1 Type 1 (Type 1 DM)	Formerly termed "juvenile diabetes" or "insulin-dependent diabetes"
2 Type 2 (Type 2 DM)	Formerly termed "adult-onset diabetes" or "non-insulin-dependent diabetes"
3 "Other"	A group of other types of DM caused by specific genetic defects of beta cell function or insulin action, diseases of the pancreas, or drugs or chemicals
4 Gestational diabetes	

Note: Arabic numbers are used instead of Roman numerals, thereby eliminating the confusion of type II, for example, as the number 11.

Type 2 Diabetes Mellitus

T2DM is the most common type of DM, constituting 90–95% of DM cases (Tables 22-18 and 22-19). It is characterized by insulin resistance in the peripheral tissues and/or defective insulin secretion by the pancreatic beta cells.[147] The etiology of T2DM is multifactorial, including genetic predilection, advancing age, obesity, and lack of exercise (Table 22-20).[10] Most T2DM patients are overweight, and most are diagnosed as adults.

Table 22-20 Risk factors for type 2 diabetes mellitus.

Diabetes-Related Risk Factors
Previously identified with: • impaired fasting glucose; or • impaired glucose tolerance; or • HbA1c of 5.7–6.4%
History of gestational diabetes or delivery of a baby >4 kg (9 lb)
Cardiovascular Risk Factors
History of cardiovascular disease
Hypertension (blood pressure ≥140/90 mmHg)
Dyslipidemia • high-density lipoprotein cholesterol level <35 mg/dL (0.90 mmol/L); and/or • triglyceride level >250 mg/dL (2.82 mmol/L)
Conditions/Diseases Associated with Development of Diabetes
Polycystic ovary syndrome
Acanthosis nigricans
Family History/Lifestyle Risk Factors
Family history of diabetes (i.e., parent or sibling with type 2 diabetes)
Race/ethnicity (e.g., African American, Latino, Native American, Asian American, Pacific Islander)
Obesity (body mass index [BMI] ≥25 kg/m^2)
Physical inactivity

The underlying pathophysiologic defect in T2DM does not involve autoimmune beta cell destruction, and is characterized by the following three features:

- Peripheral resistance to insulin, especially by the muscle cells.
- Increased production of glucose by the liver.
- Defective insulin secretion by the pancreatic beta cells.[5]

Increased tissue resistance to insulin generally occurs first, followed by impaired insulin secretion. The pancreas produces insulin, yet insulin resistance prevents its proper use at the cellular level. Glucose cannot enter target cells and accumulates in the bloodstream, resulting in hyperglycemia. The high blood glucose levels often stimulate an increase in insulin production by the pancreas; thus, people with T2DM often have excessive insulin production (hyperinsulinemia), but then, over several years, this drops to below normal levels.

In addition to hyperglycemia, patients with T2DM often have a group of disorders called "metabolic syndrome" comprising hyperglycemia, hypertension, dyslipidemia, atherosclerosis, and central or abdominal obesity (Table 22-20).[148] Obesity contributes greatly to insulin resistance and may explain the dramatic increase in the incidence of T2DM in the United States and worldwide in the past 10–20 years. Other risk factors include advancing age, high caloric intake, sedentary lifestyle, and low birth weight. People with impaired glucose tolerance, impaired fasting glucose, and gestational DM have a high risk of developing T2DM later in life, with these conditions being considered the preclinical stages of T2DM.

T2DM has a slow onset and may remain undiagnosed for years, given that some 50% of affected people are unaware of their disease. By the time many T2DM patients are diagnosed, diabetic complications and the consequent morbidity are already established. T2DM patients do not require exogenous insulin for survival since they still produce insulin. However, insulin is often an integral part of medical management for T2DM. Unlike patients with T1DM, those with T2DM are generally resistant to diabetic ketoacidosis, because their pancreatic insulin production is often sufficient to prevent ketone formation, although severe physiologic stress can still induce diabetic ketoacidosis in those with T2DM. Long periods of severe hyperglycemia can result in hyperosmolar nonketotic acidosis. This occurs when hyperglycemia results in the urinary excretion of large amounts of glucose, with attendant water loss. If this fluid is not replaced, dehydration can result in electrolyte imbalance and acidosis.

Gestational DM includes the development of T1DM or the discovery of undiagnosed asymptomatic T2DM during pregnancy.[8] Approximately 2–5% of pregnant women in the United States develop a mild degree of fasting hyperglycemia or glucose intolerance during the third trimester, which significantly increases perinatal maternal morbidity and mortality. Some 30–50% of women with gestational DM will develop T2DM within 10 years.

Diagnosis and Monitoring

The diagnosis of DM is based on specific laboratory findings, as well as the presence of clinical signs and symptoms. Diagnostic guidelines include testing of the fasting and nonfasting glucose levels. Diagnosis is not made until the patient has exceeded threshold glucose levels on two separate occasions. The classic signs of DM vary in number and order, but are typically described as (1) polyuria (frequent urination); (2) polydipsia (increased thirst); (3) polyphagia (increased hunger); (4) weight loss; and (5) either disturbed (blurry) vision or peripheral neuropathy.

Glycosylated Hemoglobin Assay

The glycosylated hemoglobin assay (HbA1c) allows the determination of blood glucose status over the 30–90 days prior to collection of the blood sample. It has now been officially recommended as one of the tests for the definitive diagnosis of DM, for screening of individual patients suspected to have DM, and for population screening. As glucose circulates in the bloodstream, it becomes attached to a portion of the hemoglobin molecule on red blood cells (like barnacles on a ship). The higher the plasma glucose levels are over time, the greater the percentage of hemoglobin that becomes glycosylated. The American Diabetes Association recommends that individuals with DM attempt to achieve a target HbA1c value of less than 7%. An HbA1c value of more than 8% suggests that a change in patient management may be needed to improve glycemic control.[4] The HbA1c can provide false-positive and -negative values in rare situations, such as patients with severe iron deficiency and those with any form of hemoglobinopathy, for example sickle cell disease.

Glucometers

The development of small, accurate, handheld glucometers has allowed the diabetic individual to take much greater control of their disease. Glucometers use a small drop of capillary blood from a finger-stick sample to assess glucose levels within seconds.[149]

Screening

The American Diabetes Association recommends screening all individuals >45 years every 3 years, and screening individuals at an earlier age if they are overweight (body mass index [BMI] >25 kg/m^2) and have one additional risk factor

for diabetes, as listed in Table 22-19. Dental healthcare providers are well placed to undertake screening of their patients for diabetes.[150–152]

Management

The primary treatment goals for DM are to achieve blood glucose levels as close to normal as possible and to prevent diabetic complications.[13] Secondary goals are to maintain normal growth and development, normal body weight, the avoidance of sustained hyperglycemia or symptomatic hypoglycemia, and the prevention of diabetic ketoacidosis and nonketotic acidosis. The other major aim is the prevention and management of the long-term complications of diabetes. Diet, exercise, weight control, and medications (Table 22-21) are the mainstays of diabetic care. Weight reduction and exercise improve tissue sensitivity to insulin and allow its proper use by target tissues.

Medications

Drugs used to treat DM lower glucose levels in the blood. With the exceptions of insulin, exenatide, liraglutide, and pramlintide, all are administered orally and are therefore also called oral hypoglycemic agents or oral antihyperglycemic *agents* (see Table 22-22).[153,154]

Gastric Banding and Gastric Bypass Surgery

These surgical treatments are indicated for patients with severe, morbid obesity who are unresponsive to 6 months' intensive attempts at dieting and graded exercise. FDA-recommended BMI thresholds for surgery range from 30–40 kg/m^2, with one or more obesity-related medical conditions: hypertension, heart disease, DM, or sleep apnea. The surgical risks and postoperative complications are frequent and potentially severe. Also, long-term intensive specialist care and follow-up are needed, including psychologic support and nutritional supplements (subsequent to bowel resection procedures). About one-third of DM patients have complete resolution of their disease, becoming medication free.[155,156] However, DM can still recur.

Insulin

All patients with T1DM use exogenous insulin, as do many with T2DM. Insulin is given via subcutaneous injection. Insulin infusion pumps deliver insulin through a subcutaneous catheter. Ideally, the use of exogenous insulin provides an insulin profile similar to that seen in a nondiabetic individual, with a continuous basal level of insulin availability augmented by increased availability following each meal (see Tables 22-21, 22-22, and 22-23).

Human insulin is only absorbed slowly, reaching a peak 60–90 minutes after subcutaneous injection, and its action tends to persist after meals, predisposing to hypoglycemia. Rapid-acting insulins (insulin lispro, insulin aspart, and insulin glulisine) enter the circulation more rapidly than human soluble insulin, but also disappear more rapidly and are of limited effectiveness.[157]

The action of human insulin can be prolonged by the addition of zinc or by the addition of protamine. The most widely used form is neutral protamine hagedorn (NPH or isophane insulin), which is a suspension of crystalline zinc insulin combined with protamine; this has an intermediate duration of action that is longer than that of regular insulin, but shorter than ultralente, glargine, or detemir. NPH has the advantage that it can be premixed with soluble insulin to form stable mixtures (biphasic insulins), of which the combination of 30% more readily soluble absorbable insulin with 70% NPH is most widely used. The intermediate-acting insulins (lente and NPH) take several hours after injection to begin having an effect. Peak activity varies among individuals and sites of injection, but generally occurs 4–10 hours after injection.

Long-acting insulins include insulin glargine. This form of insulin is soluble in the vial as a slightly acidic (pH 4) solution, but precipitates on subcutaneous injection, which prolongs its duration of action. Ultralente insulin is the longest-acting insulin. Commonly called "peakless" insulin, ultralente has a very slow onset of action, minimal peak activity, and a long duration of action. It is usually taken to mimic the basal metabolic rate of insulin secreted from a normally functioning pancreas (see Table 22-22).

Insulin Complications

The most common complication of insulin therapy is hypoglycemia, a potentially life-threatening emergency.[10] Intensified treatment of DM to achieve a tightly regulated blood sugar level increases the risk of hypoglycemia. One-third of severe hypoglycemic episodes result in seizure or loss of consciousness and 36% of episodes occur with no warning symptoms for the diabetic patient. The phenomenon known as "hypoglycemia unawareness" is more common in diabetic patients with good glycemic control than in those with poor control. Signs and symptoms of hypoglycemia are most common when blood glucose levels fall to <60 mg/dL, but they may occur at higher levels in diabetic patients with chronic poor metabolic control.[13] In people with hypoglycemia unawareness, glucose levels can fall to 40 mg/dL or lower before an individual feels or reports being unwell.[158]

Pancreas or Beta-Islet Cell Transplantation

Transplantation of the whole pancreas or just the pancreatic islet cells is an option for T1DM, particularly for patients with severe or poorly controlled disease.[159]

Table 22-21 Drug therapies used for diabetes mellitus.

Oral Agents

Insulin Sensitizers

Class	Actions	Generic Name	Trade Name(s)[a]	Advantages	Disadvantages/ Warnings
Biguanides	↓ Hepatic glucose production ↓ Intestinal absorption of glucose Improves insulin sensitivity by increasing peripheral glucose uptake and utilization	Metformin	Diabex Fortamet Glucophage Glumetza Riomet	Weight neutral No hypoglycemia	Lactic acidosis with metformin: risk increases with degree of renal impairment, patient's age, unstable/ acute congestive heart failure
Thiazolidinediones ("glitazones")	↑ Tissue sensitivity to insulin ↓ Hepatic gluconeogenesis ↓ Glucose use ↓ Blood glucose levels.	Rosiglitazone Pioglitazone	Avandia Actos	Lower insulin requirements No hypoglycemia	May increase risk of congestive heart failure and myocardial infarction
Insulin Secretagogues (Increase Insulin Release)					
Sulfonylureas (1st generation)	↓ Lowers blood glucose acutely	Tolazamide Tolbutamide	Tolazamide Orinase	?	Significant adverse side effects (relative to 2nd-generation sulfonylureas)
Sulfonylureas (2nd generation)	↑ Insulin by stimulating its release from pancreas	Gliclazide[b] Glimepiride Glipizide Glyburide	Diamicron[b] Amaryl Glucotrol DiaBeta Glynase	More potent, but fewer side effects or drug interactions	Hypoglycemia Increased risk of cardiovascular mortality
Nonsulfonylurea Insulin Secretagogues					
Meglitinides	↓ Lowers blood glucose ↑ Insulin by stimulating its release from pancreas	Nateglinide Repaglinide	Starlix Prandin	Acts similar to sulfonylureas but much shorter half-life	Hypoglycemia
Alpha-Glucosidase Inhibitors (Have No Effect on Insulin)					
α-Glucosidase Inhibitors	↓ Digestion and ingestion of glucose (in the form of starch) from the gastrointestinal tract	Acarbose Miglitol	Precose Glyset	Reduce postprandial hyperglycemia	Flatulence Inhibits hydrolysis of sucrose to glucose and fructose; use oral glucose (dextrose) instead of sucrose in treatment of mild–moderate hypoglycemia

(*Continued*)

Table 22-21 (Continued)

Oral Agents

Insulin Sensitizers

Class	Actions	Generic Name	Trade Name(s)[a]	Advantages	Disadvantages/ Warnings
Glycosuric Agents					
Sodium/glucose cotransporter 2 (SGLT2) Inhibitors	↓ Reabsorption of renally filtered glucose ↓ Lowers renal threshold for glucose, thereby increases urinary glucose excretion ↓ Glucose blood levels	Canagliflozin Dapagliflozin[b] Empagliflozin	Invokana Forxiga[b] Jardiance	Weight reduction Reduced blood pressure	Hypotension Hyperkalemia Genital mycotic infections, urinary tract infection, increased urination
Dipeptidyl Peptidase-4 Inhibitors					
Dipeptidyl peptidase-4 inhibitors	↓ Enzymic inactivation of incretin hormones, thereby increasing serum concentrations ↓ Fasting and postprandial glucose blood levels	Alogliptin Linagliptin Saxagliptin Sitagliptin Vildagliptin[b]	Nesina Tradjenta Onglyza Januvia Galvus[b]	No hypoglycemia	Angioedema
Parenteral Agents					
Insulin					
Short-acting Long-acting Combination (short- and long-acting)	↑ Glucose utilization (and absorption) ↓ Hepatic gluconeogenesis	Various (see Table 22-11)		Known and predictable safety profile	Parenteral: injection needed Weight gain (increases hunger) Hypoglycemia
Incretin Mimetics					
Gastric inhibitory peptide (GLP-1) agonists	↑ Insulin ↓ Glucagon	Exenatide	Bydureon (XR) Byetta	Slow gastric emptying and so increase satiety, leading to weight loss	Injection Hypoglycemia Nausea Pancreatitis
		Liraglutide	Victoza		
Amylin analogues	Modulation of gastric emptying ↓ Postprandial rise in plasma glucagon ↑ Satiety	Pramlintide	Symlin	Satiety ↓ Caloric intake → Potential weight loss Regulates food intake	Parenteral: injection needed Increased risk of insulin-induced severe hypoglycemia (especially in patients with type 1 diabetes mellitus)

↓, decreases; ↑, increases; →, leads to; ?, uncertain; XR, extended release

[a] Table entry refers to the single agent. Oral antidiabetic agents are often prescribed and supplied in combination with other antidiabetic agents.

[b] Not marketed in the United States.

Table 22-22 Types of insulin.

Type	Class	Onset of Activity (h)	Peak Activity (h)	Duration of Activity (h)
Lispro	Rapid-acting	0.25	0.5–1.5	<5
Insulin aspart (Novorapid)	Rapid-acting	0.25	0.67–1.5	3–5
Insulin glulisine (Apidra)	Rapid-acting	0.2	0.67–1.5	3–5
Regular	Short-acting	0.5–1.0	2–3	4–12
Lente	Intermediate-acting	3–4	4–12	16–20
Neutral protamine hagedorn	Intermediate-acting	2–4	4–10	14–18
Insulin detemir	Long-acting	Onset 2 h	No peak	6–24
Insulin glargine	Long-acting	Onset 2 h	No peak	20 to >24
Ultralente	Long-acting	6–10	12–16	20–30

Table 22-23 Common insulin regimens.

Insulin(s) Description	Frequency of Injection	Timing of Injection	Characteristics
intermediate-acting	Single (1×) daily	Morning early	• Peak insulin activity at midday • Can provide enough insulin for midday meal only • Hyperglycemia common upon rising, following breakfast and dinner
Mixture of intermediate-acting and regular or rapid-acting	Single (1×) daily	Morning early	• Peak insulin activity at both mid-morning (from regular or lispro insulin) and midday (from intermediate-acting insulin) can provide enough insulin for breakfast and midday meals Hyperglycemia common on rising and late afternoon to next morning
Intermediate-acting	Twice (2×) daily	Prior to breakfast Prior to dinner	• Peak insulin activity at both midday (from morning injection) and evening (from dinner injection) • Can provide enough insulin for lunch and sometimes dinner to prevent early-morning high blood glucose levels • Hyperglycemia common after breakfast and shortly after dinner
Mixture of intermediate-acting and regular or rapid-acting	Twice (2×) daily	Prior to breakfast Prior to dinner	• Peak insulin activity after breakfast (from morning regular or lispro insulin), after lunch (from morning intermediate-acting insulin), after dinner (from dinnertime regular or lispro insulin), and late evening or early morning (from dinnertime intermediate-acting insulin) • Can provide enough insulin for all meals • Prevents early-morning high blood glucose levels
Regular or rapid-acting and one injection of intermediate-acting	Three (3×) daily	Prior to each main meal	• Peak insulin activity after breakfast, lunch, and dinner (from regular or lispro insulin before each meal) and late evening or early morning (from dinnertime intermediate-acting insulin) • Can provide enough insulin for all meals • Prevents early-morning high blood glucose levels
	Single (1× daily)	Bedtime	• Provides better glycemic control than once- or twice-daily injection regimens
Ultralente and regular or rapid-acting	Once (morning)	Morning	• Peak insulin activity after breakfast, lunch, and dinner (from regular or lispro insulin before each meal), insulin activity in late evening or early morning (from morning Ultralente insulin)
	Three (3×) daily	Prior to each main meal	• Can provide enough insulin for all meals • Prevents early-morning high blood glucose levels • Provides better glycemic control than once- or twice-daily injection regimens
Infusion* regular or rapid-acting	Continuous with bolus (before meals)	See note	• Provides on-demand insulin with meals • Basal metabolic rate most closely mimics normal pancreatic function • Often (not always) provides best glycemic control

* Rate set to provide continuous low dose with bolus programmed to be given prior to each meal.

Complications of Diabetes Mellitus

Life expectancy is considerably reduced in patients with DM (Table 22-24). The major causes of death are cardiovascular complications, renal failure, and infection(s).[160,161] The pathophysiology is related to (1) nonenzymatic glycosylation of proteins such as hemoglobin, collagen, and tubulin in peripheral nerves, thus impairing their function and also leading to an accumulation of advanced glycosylated end-products, causing injury and inflammation;[162] and (2) disruption of the polyol pathway[163] of the vascular endothelium, with the metabolism of glucose being increased by intracellular aldose reductase, which leads to the accumulation of sorbitol and fructose that causes changes in vascular permeability, cell proliferation, and capillary structure.

Table 22-24 Complications of diabetes mellitus.

System/Organ	Presentation
Cardiovascular system	Macrovascular disease (accelerated atherosclerosis) leading to peripheral vascular disease, coronary artery disease and cerebrovascular disease, ischemic ulcers, andgangrenous feet
Nervous system	Sensory: peripheral neuropathy, cranial neuropathy affecting cranial nerves III, IV, VI, VII Autonomic: gastroparesis; changes in cardiac rate, rhythm, and dysfunction; postural hypotension; gastrointestinal neuropathy; urinary bladder atony; impotence
Kidney	Nephropathy, renal failure
Skin and oral mucosa Periodontium	Unusual infections, delayed wound healing Gingivitis and periodontal diseases
Eyes	Retinopathy, cataracts, blindness

Macrovascular Complications

Diabetes is a risk factor for the development of atherosclerosis (Table 22-25). Consequently, myocardial infarction is 3–5 times more likely for both diabetic men and women. Similarly, stroke is two times higher and foot amputation for gangrene is 50 times more likely to occur.

Microvascular Complications

Small blood vessels throughout the body are affected, but the disease process is of particular concern in three sites: retina, renal glomerulus, and nerves (specifically the nerve sheath), the latter resulting in a variety of sensory and autonomic neuropathies.

Infectious Complications

Infections in diabetics tend to be more frequent and generally more severe (Table 22-26), due to abnormalities of cell-mediated immunity and impaired polymorphonuclear leucocytes (neutrophil) function. Neutrophil chemotaxis and phagocytosis are diminished, because at high blood

Table 22-25 Macrovascular complications of diabetes and their management.

Risk Factor	Aim	Treatment/Intervention
Duration of diabetes mellitus	Maintenance of optimal glycemic control	Frequent monitoring, by patient and health professionals
Hypertension	Aggressive maintenance of target blood pressure	Usually requires a combination of antihypertensive agents: angiotensin-converting enzyme (ACE) inhibitors and/or angiotensin II receptor antagonists
Myocardial infarction/stroke		Aspirin (low dose): reduces macrovascular risk, but is associated with complications from bleeding
Proteinuria (including microalbuminuria)	Regular urinary analysis	Urine to be checked regularly (at least annually) for proteinuria Screening of younger patients for microalbuminuria
Dyslipidemia/ hyperlipidemia	Aggressive control of hypercholesterolemia	Statins: there is no "safe" cut-off for serum cholesterol, so the lowest achievable level seems best practice
Other factors (as per the general population): Aging Smoking Excessive alcohol intake Poor diet	Avoidable/modifiable	Consistent efforts should always be made to address modifiable risk factors

Table 22-26 Infectious complications in diabetic patients.

Site/Organ	Infectious Organism(s)	Clinical Entity
Skin	*Staphylococcal* spp.	Boils Abscesses Carbuncles
Mucosa	*Candida* spp.	Mucocutaneous candidiasis Vulvo-vaginal candidiasis
Oral cavity	Mixed bacterial infection	Periodontal disease
Bone	*Staphylococcal* spp.	Spontaneous spinal osteomyelitis
Lung	*Staphylococcal* spp. *Pneumococcus* spp. Gram-negative bacteria Tuberculosis	Pneumonia Pulmonary tuberculosis
Gastrointestinal tract	Mixed bacterial infection	Rectal and ischiorectal abscesses
Urinary tract	Mixed bacterial infection	Urinary tract infections (in women) Pyelonephritis Perinephric abscess

glucose concentrations neutrophil superoxide generation is impaired, and there is reduced tissue vascularity (reduced microcirculation/number of vessels and capillaries in the tissues). Reduced tissue vascularity results in hypoxia and ischemia that limit the access of neutrophils and any antibiotic given to the patient to sites of infection. Hyperglycemia also aids in the colonization and growth of *Candida* and other fungi, and of select bacterial species. Conversely, all types of infections may lead to impaired glycemic control and are a common cause of ketoacidosis. Insulin-treated patients need to increase their insulin dose(s) by up to 25% when infection occurs, and non-insulin-dependent diabetics may need insulin to be instituted during the course of the infection.[164] Apart from increased frequency and severity of common infections, there are district rare infections of diabetic populations: malignant, invasive otitis externa, usually secondary to *Pseudomonas aeruginosa*, which can lead to osteomyelitis and even meningitis; emphysematous (gas-forming) bacterial infections of the gall bladder and urinary tract; and rhinocerebral mucormyositis of the sinuses.[165]

Stomatognathic Manifestations and Complications of Diabetes Mellitus

Dentists also must be prepared to provide, sometimes highly invasive, surgical treatment for patients with DM, which may include the use of general anesthesia (Table 22-27). Good oral health, especially the prevention and treatment of infections, such as the various forms of candidiasis, periodontal disease, and odontogenic-related soft tissue infections and cellulitis, is essential for the maintenance of glycemic control, and the diabetic patient's overall wellbeing and health.[166]

Medical History and Review of Physiologic Systems

The focus of a thorough medical history and review of systems is to determine both the severity and stability of the medical condition(s). Stability of DM is the more critical concern. It can be readily assessed by reviewing the patient's ongoing glycemic control, such as their self-assessment of fasting and nonfasting blood glucose levels using a home glucometer, or arranging testing of HbA1c, which serves as a useful assessment of glycemic control for the last three months. Other important clues to glycemic control are the number and severity of the known complications of DM. These include the state of their cardiovascular health, which is critical to safe dental treatment, the frequency of hypoglycemic episodes, or the length of time since the patient's last hypoglycemic episode. For T2DM patients, the number of medications they use, recent adjustments in the dose or frequency of their medications, and whether they require insulin as part of their management regimen are also highly informative in determining the level of their glycemic control. A favorable outcome of recent dental extractions and surgery within the past 3–6 months is also indicative of a favorable outcome for any dental surgery needed in the immediate future.

The most likely and serious complication is inadvertent hypoglycemia, in a patient taking their normal medication, especially insulin, but failing to eat, either because of a dental problem associated with discomfort and pain, or the

Table 22-27 Oral and dental findings with diabetes mellitus.

Clinical Finding (Sign)	Description	Etiology/Pathophysiology
Extraoral Findings		
Sialosis	Bilateral diffuse swelling of the parotid glands, in the absence of any other identifiable cause of bilateral parotid sialoadenopathy	Autonomic neuropathy
Angular cheilitis	Unilateral, but typically bilateral moist fissuring of the corners of the lips/mouth (commissures)	Infection (secondary to impaired immunity): *Candidal* spp. with coinfection from staphylococcal bacterial species resident on the perioral skin.
Intraoral Findings		
Hyposalivation	Clinical evident decrease in total volume of unstimulated and stimulated salivary flow Smooth surface dental caries Atrophy and desiccation of mucosal surfaces Atrophy of papillae of dorsal tongue	Autonomic neuropathy Dehydration secondary to polyuria
Candidiasis		Infection (secondary to impaired immunity) with contributory factors including hyposalivation, and increased presence in saliva of glucose
Oropharyngeal candidiasis	White, adherent, small plaques that on removal leave a red, superficially bleeding area scattered over the oral and oropharyngeal mucosa	
Atrophic candidiasis	Erythematous, atrophic oral mucosa, particularly of the hard palate	
Denture stomatitis	Markedly erythematous, atrophic oral mucosa of the denture-fitting surfaces of the oral mucosa (particularly the palate)	
Medium rhomboid glossitis	Erythematous, well-demarcated, somewhat rhomboid-shaped area of mucosa of the central dorsal surface of the tongue	
Periodontal disease(s)	Localized or generalized periodontal changes, with gingival erythema, presence of increased tooth mobility, and bleeding on periodontal probing, with associated alveolar bone loss, evident radiographically	Infection secondary to impaired immunity, due to accumulation of dental plaque and impaired neutrophil response (deficient chemotaxis and bacterial killing)
Poor oral hygiene	Bacterial plaque deposits and/or calculus readily evident on tooth surfaces, with gingivitis and easy bleeding of gingiva	Impaired manual dexterity, secondary to sensory and autonomic neuropathy affecting hands/fingers
Oral lichen planus/ lichenoid mucositis	Striae: fine white-gray lines on erythematous background, typically bilateral, involving buccal or latero-ventral surfaces of tongue, with similar-colored discrete plaques and/or mucosal ulceration and/or desquamative gingivitis	Lichenoid drug reaction to oral hypoglycemic agents (e.g., chlorpropamide)

mistaken belief in the need to fast prior to a dental procedure. Odontogenic-related infections (periapical periodontitis) that result in either in a collection in the adjacent soft tissues or cellulitis can trigger ketoacidosis. Therefore, a simple precaution before undertaking highly invasive dental surgical procedures is to check the patient's blood glucose level by means of an inexpensive, compact, point-of-care glucometer. A hypoglycemic patient can be provided with replacement sugar. For a conscious patient, this can be in the form of a glucose drink of 150 mL carbonated lemonade, two teaspoons of table sugar (sucrose), or preferably glucose (dextrose) in water. The clinician should check for patient recovery and recheck their blood glucose level.

For patients with a deteriorating level of consciousness, this represents an evolving medical emergency, requiring the prompt institution of first aid, and if necessary intramuscular administration of 1 mg glucagon (see later).

Oral Candidiasis

When DM patients present with candidiasis in any of its clinical forms, it is indicative of impaired glycemic control. Therefore, patients' random blood glucose and hemoglobin HbA1c should be checked. The treatment of oral fungal infections in DM patients is similar to that for standard patients, with the added consideration that topical antifungal medications need to be sugar free.

Periodontal Disease

Periodontal disease has been referred to as the sixth sign[167] or complication of DM, and the longer the duration of DM, the greater the likelihood of developing severe periodontal disease.[168,169] Severe periodontitis has also been suggested to be a risk factor for poor glycemic control.[170,171] Since glycemic control is connected to periodontal disease and progressive alveolar bone loss,[172] periodontal treatment must be in parallel with DM treatment.[173–177] There is firm evidence of improvement in glycemic control in diabetic patients that receive treatment of their periodontal disease. There is a modest, but significant, improvement in glycemic control, reflected by a 0.4% reduction in glycated hemoglobin levels.[178] Importantly, this modest benefit in the glycated hemoglobin level, as a result of periodontal therapy, when combined with other interventions, such as diet modification and exercise, may be sufficient to prevent or at least limit the number of medications required for good diabetic control, thereby limiting the cost to the patient and/or the healthcare system.[179,180]

Edentulism

Rates of tooth loss in patients with DM are not only higher compared with nondiabetic patients, but also more rapid, resulting in higher rates of edentulism at a younger age.[181] The main causes of tooth loss are predominantly due to dental caries and periodontal disease. It appears that diabetes per se does not directly contribute to tooth loss, but the combined effects of hyposalivation and peripheral neuropathy that affect manual dexterity are significant contributing factors, because they promote the formation, persistence, and growth of dental plaque. It is also important to note that the same causal lifestyle factors for T2DM—poor levels of health education, personal neglect, poor lifestyle choices, reflected in poor dietary choices—are also contributing factors to dental disease, with poorer levels of oral hygiene seen in this same group of patients.[182]

Dental Implants

DM is not a contraindication for dental implants. Although there is concern that implant survival may be reduced, a long-term cohort study demonstrated that smoking was independently a more significant and adverse factor for implant survival than DM. The study also showed that excellent frequent and regular implant maintenance was a significant factor to ensure and improve long-term implant survival.[183] As in all patients irrespective of diabetic status, appropriate patient selection and eradication of comorbidities such as poor oral hygiene, cigarette smoking, and periodontitis are critical to implant success. For patients with DM, one study demonstrated that stabilization of glycemic control HbA1c at around 7% and prevention of infection increased the success of dental implants to a satisfactory rate of 85–95%. The use of antibiotics at the time of implant placement for patients with DM is still debatable, as there is limited evidence that it may provide some benefit.

Dental Treatment Planning Considerations

Appointment Scheduling

Generally, the best time for dental treatment is either before or after periods of peak insulin activity. This reduces the risk of perioperative hypoglycemic reactions, which occur most often during peak insulin activity. The greatest risk would occur in a patient who has taken the usual amount of insulin or oral hypoglycemic agent but has not eaten prior to dental treatment. Patients with poor long-term glycemic control and patients with a history of severe hypoglycemic episodes are at greater risk of future hypoglycemia. Often it may not be possible to plan dental treatment in a way that will avoid peak insulin activity. This is particularly true for patients who take frequent insulin injections; these patients have greater risks of developing perioperative hypoglycemia. Pretreatment blood glucose level can be measured with a glucometer, and there should be a readily available source of carbohydrates in the dental office.[173]

Treatment Aims

For patients with sub-optimally controlled DM, treatment should be focused on addressing any active infection, and likely sources or sites of infection in the immediate future, such as periodontally compromised teeth with questionable prognosis. Odontogenic infections should also be aggressively addressed, by extracting the offending tooth or with root canal therapy (if appropriate), with an emphasis on excellent postoperative analgesia by using long-acting local anesthetics and opiate-containing analgesics. This may require aggressive surgical management with drainage of collections in the adjacent soft tissues, and antibiotic coverage. Hospital admission to stabilize the patient's blood glucose levels, and manage infection by surgery and intravenous antibiotics, may be merited. Extensive, elective dental treatment should be delayed until the patient's diabetes is better controlled.

For diabetic patients, it is important to ensure that the patient is able to eat and/or drink to replenish their glucose levels. Hypoglycemia can occur as a consequence of fasting, and happens more easily and more rapidly, so is a more critical concern than hyperglycemia. This can be best addressed by rechecking the patient's postoperative blood glucose level, providing supplementary glucose in the form of a drink (lemonade, orange juice), and ensuring that the patient travels home by private transport and that someone is at home to care for them on discharge from the clinic.

As to the specifics of patient positioning in the dental chair, patients with long-standing DM may have developed some degree of autonomic neuropathy with associated orthostatic hypotension. Thus it is vital to slowly and carefully raise the patient from the supine to the upright or standing position.

Drug Use and Adverse Drug Interactions

There are few significant drug interactions in DM (Table 22-28). The exception is metformin with radiographic iodine contrast, in which case temporary cessation of the metformin to allow time for the contrast to be administered and the imaging completed is recommended.

Table 22-28 Diabetic drugs—interactions with drugs relevant to dentistry/oral medicine.

Insulin Sensitizers					
Class	**Generic Name**	**Trade Name(s)[a]**	**Drug Interaction***		**Comment**
Biguanides	Metformin	Diabex Fortamet Glucophage Glumetza Riomet	Iodinated radiographic contrast	**S**	Recommendation is for temporary discontinuation of metformin
Insulin Secretagogues (Increase Insulin Release)					
Sulfonylureas (1st generation)	Tolazamide	Tolazamide	Hypoglycemic effects potentiated by NSAIDs and miconazole	?	
	Tolbutamide	Orinase			**
Sulfonylureas (2nd generation)	Gliclazide[b]	Diamicron[b]			
	Glimepiride	Amaryl	Hypoglycemic effects potentiated by NSAIDs, some azoles (miconazole, fluconazole)	?	**
	Glipizide	Glucotrol			
	Glyburide	DiaBeta Glynase			
Nonsulfonylurea Insulin Secretagogues					
Meglitinides	Nateglinide	Starlix	NSAIDs and CYP2C9 inhibitors: fluconazole, miconazole, may potentiate hypoglycemia	?	
	Repaglinide	Prandin	CYP3A4 and/or CYP2C8 inducers: carbamazepine, CYP3A4 inhibitors: erythromycin and OATP1B1 inhibitors: itraconazole, ketoconazole, clarithromycin	?	
Insulin					
Short-acting Long-acting Combination (short- and long-acting)	Various (see Table 22-14)		Epinephrine Corticosteroids	? S	
Incretin Mimetics					
Amylin analogues	Pramlintide	Symlin	Do not administer with agents that alter gastrointestinal motility (e.g., anticholinergic agents such as atropine) and pilocarpine (cholinergic agonists)	**S**	

[a] Table entry refers to the single agent. Oral antidiabetic agents are often supplied combined with other agents.
[b] Not marketed in the United States
* Corticosteroids all cause loss of glycemic control, but generally not mediated by adverse interaction with drugs used for the management of diabetes mellitus, except for insulin.
** Only isolated case reports of severe hypoglycemia with coadministration of miconazole.
CYP, cytochrome (superfamily of proteins found in hepatocytes and responsible for metabolism of organic substances); NSAID, nonsteroidal anti-inflammatory drugs; OATP, organic anion-transporting polypeptide, membrane transport proteins that mediate the transport of mainly organic anions across cell membranes; S, serious; ?, theoretical risk with no or limited case reports documenting adverse interaction.

Epinephrine (in Local Anesthetics)

Epinephrine is not contraindicated in diabetic patients per se, because it helps promote better dental anesthesia and significantly lowers the amounts of endogenous epinephrine released in response to pain and stress. However, in a patient with concomitant cardiovascular or renal disease, the level of epinephrine may need to be reduced to two or fewer carpules of local anesthetic containing 1:100,000 epinephrine. Two small-scale studies compared DM patients to controls and found no significant alteration in blood glucose levels after dental treatment, such as extractions, which required administration of local anesthetic with epinephrine.[184,185]

Corticosteroids

Topical and systemic corticosteroids have established value in a range of oral dermatoses; however; because of their physiologic actions rather than their drug interactions, dysregulation of glycemic control may ensue. Corticosteroids profoundly affect carbohydrate and lipid metabolism, designed to protect the glucose-dependent tissues (and their cells) such as the heart (cardiac myocytes) and brain (neurons) from starvation. Corticosteroids increase blood glucose levels by stimulating the liver to form glucose from amino acids and glycerol, and to store glucose as glycogen. In the periphery, corticosteroids increase protein breakdown and activate lipolysis. All these contribute to increased blood glucose levels that worsen glycemic control in patients with overt diabetes and precipitate the onset of hyperglycemia in susceptible patients, potentially leading to frank DM. Corticosteroids should be used with caution in collaboration with the patient's physician. If systemic corticosteroids are required, an adjustment of DM drugs may be necessary. Regular monitoring of glucose levels will be paramount to ensure good glycemic control.

Major Surgery, General Anesthesia, and Hospital Admission

Type I Diabetes Mellitus

Recommendations for those with T1DM undergoing general anesthesia and surgery:

- Long-acting and/or intermediate insulin should be stopped the day before surgery, with soluble insulin substituted.
- Diabetic patients should be first on the morning appointment list.
- Infuse glucose, insulin, and potassium during surgery. The insulin can be mixed into the glucose solution or administered separately by syringe pump. (The standard combination is 16 U of soluble insulin with 10 mmol potassium chloride in 500 mL 10% glucose, infused at 100 mL/h.) Any other intravenous fluids needed must be given through a separate intravenous line so as not to interrupt the glucose/insulin/potassium infusion.
- Postoperatively the infusion is maintained until the patient is able to eat.
- Glucose levels are checked every 2–4 hours and potassium levels are monitored and, if necessary, adjusted by provision of replacement insulin, dextrose, and/or potassium.

Type 2 Diabetes Mellitus

Patients with mild hyperglycemia (fasting blood glucose below 8 mmol/L [144 mg/dL]) can be treated as nondiabetics. For patients reliant on oral antidiabetic agents for management of their DM, they should stop medication two days before surgery. Moreover, these oral agents are of concern if the patient is fasting (in particular the risk of hypoglycemia with sulfonylurea agents). Those type 2 diabetics with poorly controlled diabetes can be managed with an insulin infusion or subcutaneous long-acting insulin plus preprandial, short-acting insulin.

Managing the Diabetic Emergency in the Dental Office

Hypoglycemia is a potentially life-threatening situation that must be recognized and treated expeditiously. Signs and symptoms include confusion, sweating, tremors, agitation, anxiety, dizziness, tingling or numbness, and tachycardia. Severe hypoglycemia may result in seizures or loss of consciousness. Prevention starts with the practitioner being familiar with the general medical risks for hypoglycemic events (Table 22-29) and assessing the patient's risk for developing hypoglycemia (Table 22-30). Every dental office that treats DM patients (see Table 22-31) should have readily available sources of oral carbohydrates (e.g., fruit juice, nondiet soda, hard candy). As soon as a patient

Table 22-29 General management considerations for the patient with diabetes.

Assess level and stability of glycemic control
Refer patients with signs and symptoms suggestive of undiagnosed or uncontrolled diabetes to physician for diagnosis and treatment
Obtain medical consultation if systemic complications are present
Use a glucometer to help avoid emergencies related to diabetes
Treat acute oral infections aggressively
Place patients on frequent recall visits to monitor and treat oral complications and maintain optimal oral hygiene and diet

Table 22-30 Determining risk of hypoglycemia: questions for the dental patient.

1. Have you ever had severe hypoglycemia?
2. How often do you have hypoglycemic reactions?
3. What diabetic medication(s) do you take?
   Did you take them today?
   When did you take them?
   Is that the same time as usual?
   How much of each medication did you take?
   Is this the same amount you normally take?
4. What did you eat today before you came to the dental office?
   Is that when you normally eat?
   Did you eat the same amount you normally eat for that meal?
   Did you skip a meal?

Table 22-31 Treatment of hypoglycemia in the dental office.

Patient Condition	Treatment
Patient is awake and able to take food by mouth	• Give 15 g oral carbohydrate • 4–6 oz (125–175 mL) fruit juice or soda (nondiet) • 3–4 tsp (equal to 15–20 mL) Table sugar (hard candy, cake frosting)
Patient is unable to take food by mouth and intravenous line is in place	• Give 25–30 mL D50 (50% dextrose solution) or • 1 mg glucagon
Patient is unable to take food by mouth and intravenous line is not in place	• Give 1 mg glucagon subcutaneously or intramuscularly at almost any body site

experiences signs or symptoms of possible hypoglycemia, the dentist should check the blood glucose with a glucometer, which has a typical response time of less than 15 seconds. Rapidly absorbed oral carbohydrates are preferable, particularly if the dentist is not trained or equipped to administer intravenous, intramuscular, or subcutaneous glucagon or dextrose. Following treatment, the signs and symptoms of hypoglycemia should resolve in 10–15 minutes, and the patient should be carefully observed for 30–60 minutes after recovery. A second evaluation with a glucometer should be done to ensure that a normal blood glucose level has been achieved.

A medical emergency from hyperglycemia is less likely to occur in the dental office since it develops more slowly than hypoglycemia. Emergency care entails protecting the airway and administering oxygen. Circulation and vital signs should be monitored, and the patient should be transported to a hospital as soon as possible. However, under some instances, severe hyperglycemia may present with symptoms mimicking hypoglycemia. If it is an actual hyperglycemic event, the small amount of extra glucose delivered will not have any deleterious effect. Nevertheless, emergency measures that will elevate serum glucose should not be delayed or withheld from a DM patient even if hyperglycemia is wrongly suspected in a patient who is actually hypoglycemic. This delay may result in severe adverse outcomes.[186]

Table 22-32 World Health Organization (Who) classification of obesity.

WHO Classification	Body Mass Index (BMI; kg/m^2)	Risk of Comorbidities
Overweight	25–30	Mildly increased
Obese	>30	
Class I	30–35	Likely
Class II	35–40	Very likely
Class III	>40	Very likely and severe
$\text{BMI} = \frac{\text{Weight (in kilograms)}}{\text{Height (in meters)}^2}$		

OBESITY

Obesity is defined as an abnormal or excessive fat accumulation such that it impairs health. It is commonly measured by calculating an individual's BMI (Table 22-32).[187]

The prevalence of obesity and the associated comorbidities, particular T2DM, has dramatically increased and has been termed an "obesity epidemic."[188] In the United States, 17% of children and more than 33% of adults are obese, so the problem is common and on the rise (Table 22-33).[188] Although there is ongoing contention as to the etiology of obesity, which includes genetic factors and disturbances of the gut microbiotome, the main factor is an energy imbalance; that is, excessive food intake and insufficient energy expenditure. The comorbidities and complications, including premature death from obesity, are established, with higher rates of DM, coronary heart disease, and cerebrovascular disease.

Metabolic Syndrome

Metabolic syndrome (also known also as "syndrome X" and "insulin resistance"; Table 22-34), in a patient with established obesity, is defined by five factors for increased risk of atherosclerotic cardiovascular disease (which includes consequent coronary heart disease and stroke):

- Atherogenic dyslipidemia comprising elevations in plasma triglycerides and apolipoprotein B (apo B), and reductions in high-density lipoproteins (HDL).
- Hypertension.
- Prediabetes or frank diabetes.
- A prothrombotic state with abnormalities in coagulation factors and blood platelets.
- A proinflammatory state resulting from inflammatory mediators acting on a variety of tissues.

Table 22-33 US data on prevalence of being overweight and of obesity among adults and children.

Prevalence	Class	Body Mass Index (BMI) (kg/m^2)
33%	of adults are overweight	25 to ≤30
36%	of adults are obese	≥30
6%	of adults are morbidly obese	≥40
17%	of children are obese*	25 to ≤30
*BMI for age and sex 95th percentile		
Target BMI is 18.5 to ≤25.0 BMI ≥30.0 + a comorbidity = morbid obesity		
Comorbidities • Hypertension; coronary heart disease; stroke • Sleep apnea • Type 2 diabetes mellitus; dyslipidemia • Osteoarthritis • Reduced fertility • Select cancers		

The contribution of each of these components to cardiovascular risk undoubtedly varies among individuals, but in combination they double the risk for atherosclerotic-related cardiovascular disease and are associated with a fivefold increased risk for diabetes.[189]

Stomatognathic Manifestations and Complications of Obesity[190,191]

Obesity: Clinical Implications

There is a contention that obesity is associated with an increased risk of periodontal disease. The chronic proinflammatory state associated with obesity may increase a patient's susceptibility to periodontal disease, although the published evidence is somewhat contradictory. There is a probable association between obesity and periodontal disease, but not a clear causal relationship. As obesity is associated with a higher intake of sugar, it has been suggested that this may be associated with higher rates of dental caries. Again, the reported studies have yielded contradictory results. There are case reports of higher rates of caries in patients post bariatric surgery, given their need for small, more frequent meals.[192] Dental erosion is related to increased rates of gastroesophageal reflux disease seen in patients with obesity, which is also a known complication of bariatric surgery, but the evidence consists of case reports only.

Concurrent Medical Comorbidities

Obese patients in general and those with metabolic syndrome are known to have a far greater likelihood of hypertension, cardiovascular disease, and T2DM. If these conditions are not identified as being managed by a physician in the course of taking the patient's medical history, it

Table 22-35 STOP-bang questionnaire: a practical approach to screen for Obstructive Sleep Apnea (OSA).

S	1	Snoring	Do you snore loudly?*	Yes/No
T	2	Tired	Do you often feel tired, fatigued, or sleepy during daytime?	Yes/No
O	3	Observed	Has anyone observed you stop breathing during your sleep?	Yes/No
P	4	Pressure—BP	Do you have or are you being treated for high blood pressure?	Yes/No
B	5	BMI	BMI >35 kg/m^2	Yes/No
A	6	Age	Age ≥50 years of age?	Yes/No
N	7	Neck circumference	Neck circumference ≥40 cm?	Yes/No
G	8	Gender	Male gender?	Yes/No
High risk of OSA: answering yes to 3 or more items				
Low risk of OSA: answering yes to fewer than 3 items				

* E.g., louder than talking or loud enough to be heard through closed doors?
BMI, body mass index; BP, blood pressure.

may be prudent to undertake screening for these conditions before considering highly invasive surgical procedures. Obesity is highly predictive for OSA. The exact interaction between obesity and OSA is unclear. The buildup of adipose tissue in the upper airway predisposes it to collapse and narrowing; however, OSA may itself predispose individuals to worsening obesity due to sleep deprivation, daytime somnolence, and disrupted metabolism. Regardless, OSA is a contraindication to dental sedation; for all patients for whom sedation is being considered, clinicians should employ the STOP-Bang questionnaire (Table 22-35),[193] but particularly so for obese patients.

Weight-Loss Drugs and Potential Drug Interactions

Increasing numbers of patients are using medication to facilitate their weight loss (see Table 22-36). Of these the most notable in the recent past was the advent of the fenfluramine–phentermine (fen–phen) combination, which was associated with valvular heart disease and required affected patients to take antibiotic prophylaxis to limit the risk of infective endocarditis following invasive dental procedures.[194,195]

Orlistat (trade name Xenical®, Roche, Nutley, NJ, USA) is a reversible inhibitor of gastric and pancreatic lipases, thus it inhibits the absorption of dietary fats by 30%.[196] Orlistat can interfere in the absorption and uptake of fat-soluble vitamins, including vitamin K, and consequently can potentiate the anticoagulant effect of warfarin. An update of the patient's international normalized ratio (INR) prior to invasive dental procedures should be considered. Supratherapeutic INR (>4.0) and subtherapeutic INR (<2.0) needs attention by the treating physician.[197]

Lorcaserin (Belviq®, Arena Pharmaceuticals, San Diego, CA, USA) appears to have no major adverse effects and no significant drug interactions. The phentermine–topiramate combination (Qsymia®, Vivus, Campbell, CA, USA) consists of an amphetamine derivative and an antiseizure agent, respectively. Concurrent use of benzodiazepines (and other CNS depressants) with the phentermine–topiramate combination may potentiate CNS depression and should be avoided without medical consultation. With naltrexone–bupropion (Contrave®, Currax Pharmaceuticals, Morristown, NJ, USA), due to the antagonistic effect of naltrexone on endogenous opioid receptors, the analgesic effect of opioid agents is reduced. If opioid analgesia is required in such patients, then temporary cessation of Contrave must be considered.

Issues with Service Delivery

All oral healthcare clinicians have a role in screening for systemic disease and lifestyle factors that are proven to be harmful to a patient's wellbeing, for example smoking and obesity. However, there is a reluctance by dentists to undertake screening and to offer advice regarding the need for and value of weight loss,[198] and so further training and education on how to offer appropriate and acceptable health advice about obesity, and the need for weight loss, may address this concern.

Obesity presents a number of practical challenges to service delivery. The first is the need for longer appointment times, and the consequent increased cost of service delivery. Increased appointment times are attributed to reduced patient mobility as well as increased difficulty for the dentist

Table 22-36 Weight loss medications: major side effects and drug interactions.

Generic Name	Trade Name	Site and Mechanism of Action	Major Side Effects	Drug Interactions
Orlistat	Xenical	• GIT • Lipase inhibitor • Inhibits uptake of dietary fats by 30%	• Steatorrhea • Flatulence	Warfarin
lorcaserin	Belviq	• CNS • Serotonin agonist (5-HT2C receptor agonist) • Increased satiety so reduced food intake	• Headache • Dizziness • Nausea	Benzodiazepams
Phentermine/ topiramate	Qsymia	• CNS • Stimulator of noradrenaline, dopamine, and serotonin release, augmenting the activity of γ-aminobutyrate • Appetite suppression	• Dry mouth • Paresthesia • Constipation • Insomnia • Dizziness	Carbamazepine (decreased topiramate levels)
Naltrexone/ bupropion	Contrave	• CNS • Naltrexone is an opioid antagonist • Bupropion, a relatively weak inhibitor of the neuronal reuptake of dopamine and norepinephrine. • Affects areas of the brain involved in the regulation of food intake: the hypothalamus (appetite regulatory center) and the mesolimbic dopamine circuit (reward system)	• Nausea • Headache • Constipation • Dizziness • Vomiting • Dry mouth • Dysgeusia	Opioid analgesics (less effective)
Liraglutide	Saxenda	• GIT and CNS • Daily subcutaneous injection • Acylated human GLP-1 analogue with 97% homology to human GLP-1 • Like human GLP-1 it increases satiety, decreases key hunger signals, with transient inhibition of gastric emptying	• Nausea • Hypoglycemia • Diarrhea • Constipation • Vomiting	

CNS, central nervous system; GIT, gastrointestinal tract; GLP-1, glucagon-like peptide-1.

Figure 22-17 Image of Barico dental chair at Westmead Centre for Oral Health, suitable for all patient groups up to 454 kg. Note the width of the chair (black arrow), especially at the shoulders (white arrows), which makes access to the patient's oral cavity by the treating dentist more difficult. Malik Z. Special needs dental management of the class 3 obese patient. *Case Rep Dent.* 2019;2019:7976531. Reproduced with permission.

in accessing the oral cavity in the larger, obese patient. The other aspect is the need to have equipment that is safe for obese patients. Body weights in excess of 140 kg may exceed the weight limitations of motorized dental chairs.[199–201] Consequently, there are increased costs required to purchase special-purpose and safe bariatric dental chairs (Figure 22-17) and wheelchairs as well as supplementary equipment, including hoists.

DISORDERS OF BONE AND MINERAL METABOLISM

Bone is a specialized connective tissue serving three major functions:

- *Mechanical*: attachment for muscles for movement and structure.
- *Metabolic*: providing the body's primary store of calcium, including a highly active role in calcium homeostasis and also in phosphate levels, as well as serving as a reservoir for sodium, magnesium, and other critical ions.

- *Protective*: of the vital organs as well as enclosing the marrow, containing the essential hematopoietic stem cells that produce all the cells found circulating in the blood (red blood cells, leukocytes, and platelets).

Bone comprises cells and a matrix of organic protein and hydroxyapatite crystal. Type I collagen is the main protein, forming parallel lamellae of differing density, which impair the propagation of cracks with trauma. Noncollagen proteins that are also found in bone include osteopontin, osteocalcin, and fibronectin. In cortical bone, concentric lamellae form around a central blood supply, and this collectively is termed the Haversian system, with transverse branches (termed Volkmann's canals). The long bones (e.g., femur, tibia, humerus) and flat bones (e.g., skull, scapula) are variably composed of:

- *Compact or cortical bone*, which forms the shaft of long bones and the outer shell of flat bones. Formed of concentric rings of bone, it is strong and is particularly resistant to the mechanical strain associated with flexure.
- *Trabecular or cancellous bone*, found at the ends of long bones and inside flat bones, is constituted by a network of interconnecting rods and plates of bone that provides great strength against compressive forces. It is the main site of bone turnover needed for mineral homeostasis.
- *Woven bone* lacks an organized structure. It appears in the first few years of life and at the sites of fracture repair, as well as in bone disorders associated with high turnover, such as Paget's disease. Woven bone is eventually remodeled to be organized and structurally sound bone.
- *Lamellar bone*, in which the collagen fibers are arranged in parallel bundles, forms much of the bone found in adults.

Bone Cells

Osteoblasts are of mesenchymal origin and are initially found on the surface of newly forming bone. The osteoblast secretes an organic matrix, which then is mineralized, encasing the cell, which is then termed an *osteocyte*; however, the osteocytes remain connected with each other, as well as with their blood supply, through a fine network of canaliculi, distributed throughout the bone. The vast majority of the cells found in bone are osteocytes, which serve to regulate bone formation and resorption and also serve as mechanosensors, signaling the osteoblasts and their progenitors through the canalicular network. Mineralization of the matrix, both in trabecular bone and in the osteones (of the Haversian system) of compact cortical bone, begins soon after the matrix is secreted and is termed primary mineralization, but it is not completed for several weeks or even longer by the process of secondary mineralization. Mineralization is a carefully regulated process that is dependent on the activity of osteoblast-derived alkaline phosphatase, and importantly the very high, near-saturation concentrations of calcium and phosphate present in the serum. Hormones such as parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D (1,25(OH)2D) activate receptors expressed by osteoblasts so as to regulate mineral homeostasis.

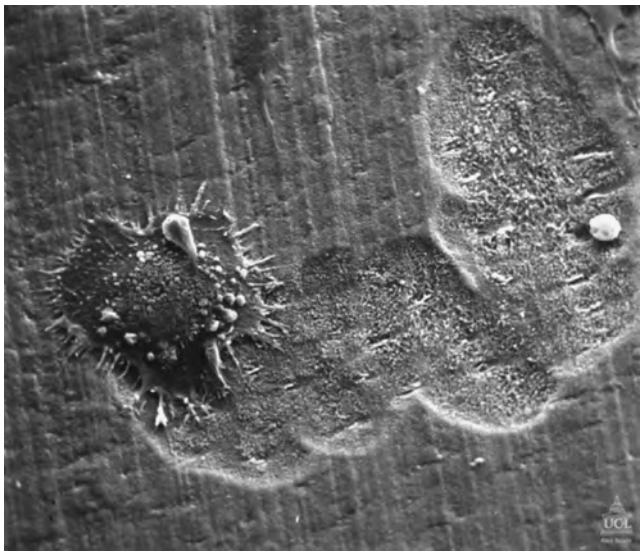

Figure 22-18 Osteoclast. *Source:* Bone Research Society, https://boneresearchsociety.org/resources/gallery/19/. Reproduced with permission.

Osteoclasts (Figure 22-18) serve to resorb bone, and are multinucleated cells that are formed by the fusion of cells derived from the same common precursor of macrophages. Multiple factors regulate osteoclast development and function. Macrophage colony-stimulating factor (M-CSF) plays a critical role during several steps in the pathway and ultimately leads to the fusion of osteoclast progenitor cells to form multinucleated, active osteoclasts. RANK (receptor activator of nuclear factor kappa-B) ligand is a member of the tumor necrosis factor (TNF) family, expressed on the surface of osteoblast progenitors and stromal fibroblasts. In a process involving cell–cell interactions, RANK ligand binds to the RANK receptor on the osteoclast progenitors, stimulating osteoclast differentiation and activation. Alternatively, a soluble decoy receptor, referred to as osteoprotegerin (OPG), can bind the RANK ligand and so inhibits osteoclast differentiation. OPG, also known as osteoclastogenesis inhibitory factor (OCIF), is a cytokine receptor and also a member of the TNF receptor superfamily. Several growth factors and cytokines can also modulate osteoclast differentiation and function (e.g., interleukins 1, 6, and 11, TNF, and interferon γ); they may also have role in the bone loss seen

in periodontal disease. Most hormones that influence osteoclast act indirectly, by influencing M-CSF and RANK ligand signaling of the osteoblasts. Both PTH and 1, 25(OH)2D increase osteoclast number and activity, whereas estrogen decreases osteoclast number and activity. Calcitonin, in contrast, binds directly to its receptor on the basal surface of osteoclasts and so inhibits osteoclast function. Osteoclast-mediated resorption of bone takes place in scalloped spaces (Howship's lacunae) where the osteoclasts are attached through a specific αvβ3 integrin to components of the bone matrix, such as osteopontin.[202]

Bone Growth and Remodeling

In the embryo and the growing child, bone develops by remodeling and replacing previously calcified cartilage, termed endochondral bone formation, or bone is formed without a cartilage matrix anlage, by means of intramembranous bone formation. Longitudinal growth occurs at the epiphyseal growth plate, a cartilaginous structure between the epiphysis and the metaphysis. Cartilage production is tightly regulated, with growth arrest and the subsequent mineralization occurring between the ages of 18 to 21 years, when the epiphysis and metaphysis plates fuse.

In adults, bone is constantly being remodeled, to repair microdamage and for the release of the calcium and phosphate needed for homeostasis. Signals regulating the initiation of remodeling include changes in osteocytes (apoptosis or altered signaling of sclerostin, prostaglandins, and other molecules), resulting in altered balance of RANK ligand and OPG expression by adjacent osteoblasts. Remodeling is carried out by the basic multicellular unit (BMU). Normal bone remodeling is a coupled process, with bone formation typically following resorption. New bone formation without resorption may, however, occur in the adult skeleton in response to anabolic therapy such as PTH peptides or estrogen (in both sexes), which is particularly involved by promoting the survival of osteocytes and inhibiting the formation of new osteoclasts.

Calcium Homeostasis

Over 99% of the 1–2 kg of calcium normally present in the adult human body resides in the skeleton, where it provides mechanical stability (in the form of hydroxyapatite) and also serves as a reservoir for maintenance of extracellular fluid (ECF) calcium concentration (Figures 22-19 and 22-20; Table 22-37). Only some 0.5–1% of the skeletal calcium is

Modulation of osteoclast differentiation and function by the new members of the tumor necrosis factor receptor and ligand families. *Endocr Rev*. 1999;20:345.

freely exchangeable; that is, in chemical equilibrium with the calcium found in the ECF. The concentration of ionized calcium in the ECF is maintained within a strict narrow range, because of the critical role it plays in numerous critical cellular functions, particularly neuromuscular activity, secretion, and signal transduction. In the blood, total calcium concentration is normally 2.2–2.6 mM (8.5–10.5 mg/dL), of which some 40% is ionized and physiologically active. The remaining 60% is bound to negatively charged proteins (predominantly albumin and immunoglobulins) or loosely complexed with phosphate, citrate, sulfate, or other anions. Alterations in serum protein concentrations (e.g., hypoalbuminemia) directly affect the total blood calcium concentration, but the ionized calcium concentration tends to remain stable.

Control of the ionized calcium concentration in the ECF is regulated by the effects of PTH and 1,25(OH)2D3 acting on the gastrointestinal tract, kidney, and bone. Ionized calcium in the circulation both directly suppresses PTH secretion by stimulating the calcium-sensing receptors present in the parathyroid glands, and indirectly suppresses PTH secretion via effects on vitamin D_2 (1,25(OH)2D) production. Active calcium uptake from the gut by means of highly regulated, energy-dependent transportation across the gut epithelium accounts for up to 95% of the daily calcium intake needed. This occurs mainly in the proximal small bowel (duodenum and proximal jejunum). Calcium absorption may also be impaired in disease states such as pancreatic or biliary insufficiency, in which ingested calcium remains bound to unabsorbed fatty acids or food debris, conditions associated with gastrointestinal malabsorption, such as in celiac disease and in patients who have had an extensive bowel resection. At high levels of calcium intake, synthesis of 1,25(OH)2D is reduced and this then decreases the rate of active intestinal calcium absorption.[203]

Daily net calcium absorption is generally constant at 5–7.5 mmol/day (equal to 200–400 mg/day), regardless of variations in the daily dietary calcium intake. This daily load of absorbed calcium is excreted by the kidneys in a tightly regulated manner, with approximately 8–10 g/day of calcium being filtered by the glomeruli, of which only 2–3% appears in the urine. Most filtered calcium (65%) is reabsorbed in the proximal tubules via a nonregulated, passive, paracellular

Table 22-37 Investigation of bone and calcium disorders.

Test	Normal Values	Interpretation/Considerations
Total serum calcium (corrected) (Ca^{2+})	2.2–2.6 mmol/L	Total serum calcium (corrected) • 40% is ionized and physiologically active Note: ionized calcium is difficult to measure; in practice total calcium is measured and the value corrected to allow for protein binding (using established formula)
24-hour urinary calcium	F: 2.5–6.25 mmol/24 h M: 2.5–7.5 mmol/24 h	Indications: hypercalcemia ↑ Renal tubular reabsorption of Ca^{2+} is decreased ↑ Hypercalcemia: exception with familial hypocalciuric hypercalcemia—genetic defect leads to inappropriately reduced calcium excretion
Plasma phosphate (PO_4^{3-}) levels	0.8–1.4 mmol/L	↑ [PO_4^{3-}] • Renal failure and hypoparathyroidism ↓ [PO_4^{3-}] • Primary hyperparathyroidism • Hypophosphatemic rickets • Osteomalacia • Disorders of reduced renal tubular phosphate reabsorption
Serum alkaline phosphatase (ALP)	• Bone-specific isoenzyme of ALP can be measured (marker of bone formation), but there is overlap with the liver isoenzyme	↑ ALP • Bone growth • Fracture repair • High bone turnover states
Vitamin D	• Best assessed using serum 25-(OH)D3 Note: 1,25(OH)2D3 has a short half-life and does not reflect true vitamin D status	
Parathyroid hormone	• Measures intact hormone	
NTX or CTX—serum or urine levels	• N-terminal (NTX) and C-terminal (CTX) cross-linked telopeptides ➔ Reflect bone resorption activity	↓↑ Changes rapidly in response to antiresorptive drugs or in disease states
Bone mineral densitometry (BMD)	• Dual-energy X-ray absorptiometry (DXA): uses low-dose radiation to measure areal bone density—mineral per surface area (rather than true volumetric density) • Sites: lumbar spine, proximal femur	Note: Gold standard for the diagnosis of osteoporosis • Young adult mean value (T score) is the standard • Spinal values may be artefactually elevated with osteophytes, spinal deformity, and vertebral fractures (so interpret with caution in the elderly)

route that is coupled to concomitant sodium chloride (NaCl) transporter. The remaining 35% requires active reabsorption in the thick loop of Henle and distal tubule.

Vitamin D Metabolism

The primary source of vitamin D in humans is photoactivation in the skin of 7-dehydrocholesterol to cholecalciferol, which is then converted, first in the liver to 25-hydroxyvitamin D (25(OH)D3) and then subsequently in the kidney (by the enzyme 1α hydroxylase) to the active form, 1,25(OH)2D3. Regulation of the latter step is by PTH, phosphate, and feedback inhibition by 1,25(OH)2D3 itself.

The mounting concern about sun (ultraviolet, UV) exposure and the development of skin cancer has led to increased reliance on dietary sources of vitamin D. The third National Health and Nutrition Examination Survey (NHANES) revealed that vitamin D deficiency is widely prevalent in the United States. Vitamin D deficiency can be a result of deficient production of vitamin D in the skin (insufficient UV exposure), lack of dietary intake, accelerated losses of vitamin D, impaired vitamin D activation, or resistance to the biologic effects of 1,25(OH)2D. The elderly and nursing home residents are particularly at risk for vitamin D deficiency, since both the efficiency of vitamin D synthesis in the skin and the absorption of vitamin D from the intestine

decline with age. Long-standing vitamin D deficiency results in hypocalcemia accompanied by secondary hyperparathyroidism, impaired mineralization of the skeleton—termed osteopenia; that is, decreased bone mineral density (BMD)—with a resultant increased risk for progression to osteoporosis.

Parathyroid Hormone

PTH, an 84 amino acid hormone, is secreted from the chief cells of the parathyroid glands, which bear calcium-sensing and vitamin D receptors. PTH increases renal phosphate excretion and increases plasma calcium by four principal effects: increasing osteoclastic activity—a rapid response; increasing intestinal absorption of calcium—a slow response; increasing 1α-hydroxylation of vitamin D (the rate-limiting step); and increasing renal tubular reabsorption of calcium. Hypomagnesemia can suppress the normal PTH response to hypocalcemia.

Calcitonin

Calcitonin is produced by C cells in the thyroid gland. Although calcitonin inhibits osteoclastic bone resorption and increases the renal excretion of calcium and phosphate, neither excess calcitonin (e.g., from an MTC) nor its deficiency (following thyroidectomy) appears to have any significant effect on the skeleton or bone density. Calcitonin is a useful agent to suppress bone resorption in Paget's disease and osteoporosis and in the treatment of hypercalcemia of malignancy.

Sclerostin

Sclerostin is a glycoprotein secreted by osteocytes. Sclerostin has been shown to be a potent inhibitor of bone formation by means of a catabolic effect on bone, increasing osteoclast numbers and activity by augmented osteocyte expression of the RANK ligand. Significant research interest in this signaling pathway led to the evolution of antisclerostin agent; that is, inhibitory therapeutic antibody, romosozumab. Of note is that a decline in RANK ligand signaling could explain, in part, the sustained decreases in bone resorption markers observed in recent trials with antisclerostin therapies.[204]

The role of sclerostin in the modulation of the Wnt/β-catenin dependent pathway came from the study of sclerosteosis and van Buchem disease, two rare genetic disorders associated with abnormally high levels of bone density and consequently a significantly lower risk of bone fractures.[205] Both diseases were traced to mutations impacting a single gene, *SOST*, which is mainly expressed from osteocytes. The Wnt signaling pathway is a crucial, ancient, and evolutionarily conserved pathway that regulates key aspects of cell fate determination, cell migration, cell polarity, neural patterning and organogenesis during embryonic development. The Wnt signaling pathway has a significant interaction with a transmembrane lipoprotein receptor-related protein, LRP5. The *LRP5* gene was initially identified as a determinant of bone mass in the 1990s from studies into osteoporosis pseudoglioma syndrome, an autosomal recessive hereditary disorder (characterized by low bone mass and abnormal eye vasculature), due to an inactivation mutation of *LRP5*.[206] In contrast, gain-of-function *LRP5* mutations are linked to the autosomal dominant condition of high bone mass, excessive bone formation, bone thickening, and reduced risk of fracture.[207] These findings were confirmed in mouse models of defective Wnt signaling. *LRP5*-deficient mice manifested an osteoporotic phenotype with impaired bone formation, while bone resorption remained unaffected. In contrast, mice carrying an gain-of-function mutation within the *LRP5* gene developed thick abnormal bone (osteosclerosis).[208,209] Sclerostin production by osteocytes is inhibited by PTH, mechanical loading, and select cytokines, such as prostaglandin E2. Sclerostin production is increased by calcitonin. Thus, osteoblast activity is self-regulated by a negative feedback system involving sclerostin.[210,211]

Based on genetic and rat studies, a monoclonal antibody directed against sclerostin has been developed. Romosozumab (marketed as Evenity® in the United States; Amgen, Thousand Oaks, CA, USA) gained FDA approval in April 2019, albeit with black box warning of increased risk for myocardial infarction, stroke, and cardiovascular-related death and that the drug should not be taken by patients who had experienced a cardiovascular event within the previous year.[212] Romosozumab is given by monthly subcutaneous injection and has shown great promise, with one large trial indicating significant benefit in reducing vertebral fractures in osteoporotic women.[213] However, two cases of osteonecrosis of the jaws (ONJ) occurred in the romosozumab-treated cohort of 3321 women (0.06%) over the course of 12 months.[214]

PARATHYROID GLAND AND DISORDERS OF CALCIUM HOMEOSTASIS

PTH is secreted by four parathyroid glands found within the thyroid gland in the anterior neck. Secretion of the PTH is in response to the level of serum ionized calcium. Low serum ionized calcium stimulates PTH secretion, whereas high serum ionized calcium suppresses PTH secretion. Another major regulator of PTH is the active form of vitamin D_3 (1,25-dihydroxyvitamin D_3 or calcitriol). It suppresses PTH

synthesis by its ability to promote intestinal calcium absorption. PTH protects the body from chronic low serum calcium (hypocalcemia); therefore, an individual with chronic hypocalcemia and vitamin D deficiency may develop parathyroid gland hyperplasia.

Hyperparathyroidism

Hyperparathyroidism is chronic excessive secretion of the PTH by the parathyroid glands. It results in uncontrolled chronic high serum calcium (hypercalcemia). The condition occurs in 0.1% of adult patients, is more common in the third to fifth decades of life, and is three times more prevalent in women than in men. The vast majority (90%) of patients with hypercalcemia have either primary hyperparathyroidism or hypercalcemia of malignancy.

Primary hyperparathyroidism is the term that refers to excessive PTH secretion arising from one or more of the parathyroid glands. Commonly it is caused by a solitary adenoma (80% of cases), whereas 15% are due to parathyroid hyperplasia and 1% are due to carcinoma of the parathyroid glands. Postmenopausal women are more commonly affected by primary hyperparathyroidism.[215]

Secondary hyperparathyroidism occurs with compensatory parathyroid gland enlargement in response to persistent hypocalcemia induced by renal failure (see later), or metabolic disorders of deficiency of 1,25(OH)2D, or malabsorption of calcium found in rickets and some forms of osteomalacia. PTH secretion from enlarged parathyroid glands may become autonomous (secreting without control or response to feedback inhibition), leading to *tertiary hyperparathyroidism*.[216]

Many cases of hyperparathyroidism may be asymptomatic and only detected incidentally by serum analysis during routine serologic evaluation. Clinically, patients may have manifestations of skeletal and renal disorders and hypercalcemia. They complain of a classic quintet of complaints, namely "bones, stones, abdominal groans, psychic moans, and psychic overtones." Skeletal presentations include bone demineralization that manifests as a reduction in bone mass (osteopenia). Bone radiographs show well-circumscribed unilocular or multilocular radiolucent lesions, known as "brown tumors" of hyperparathyroidism, but brown tumors are now rare because of early detection of hyperparathyroidism. Due to routine screenings and early detection of hypercalcemia, skeletal presentation is now commonly just as osteopenia. Renal presentations include polyuria and polydipsia as a result of hypercalcemia-induced DI, and 10–15% of patients may develop kidney stones consisting of calcium phosphate or calcium oxalate. Nonspecific presentations of hypercalcemia include "abdominal groans" of constipation, indigestion, weight loss, nausea, vomiting, peptic ulceration, and pancreatitis, as well as "psychic moans" of lethargy, fatigue, depression, loss of memory, paranoia, neuroses, change in personality, confusion, stupor, and coma.

The most common laboratory finding is high alkaline phosphatase in patients with bone lesions. Serum calcium is elevated (>10.5 mg/dL), but phosphate may vary from low-normal (<3.5 mg/dL) to low (<2.5 mg/dL). Serum PTH is often elevated, and the level of 1,25(OH)2D may also be high due to the stimulatory effect of PTH on 1-α-hydroxylase. Imaging should be undertaken to assess for the presence of a parathyroid adenoma. For symptomatic primary hyperparathyroidism, definitive treatment is surgical parathyroidectomy, which has a 95% success rate. Medical management may involve use of vitamin D when associated with vitamin D deficiency, as well as bisphosphonates and calcimimetics and the calcium-sensing receptor agonist cinacalcet (Sensipar®, Amgen). As postmenopausal women are commonly affected by hyperparathyroidism, high-dose estrogen replacement therapy is often needed to treat bone lesions and reduce serum calcium, but it does not reduce the PTH level.

Hypoparathyroidism

Hypoparathyroidism is a deficiency in the production, secretion, or action of PTH and is the most common cause of hypocalcemia. It usually results when parathyroid glands are surgically removed to correct primary hyperparathyroidism or during thyroidectomy. Radiation to the neck, metastatic cancer, infection, and magnesium deficiency are other unusual causes of hypoparathyroidism. Damage to the parathyroid glands by heavy metals, for example copper in Wilson's disease or iron in hemochromatosis, and from transfusion hemosiderosis is also an unusual cause of hypoparathyroidism. The parathyroid glands may be underdeveloped or completely absent in DiGeorge syndrome (now more accurately known as 22q11.2 deletion syndrome), a developmental abnormality of the third and fourth pharyngeal pouches.[217] *Pseudohypoparathyroidism* is a term used to describe a group of disorders that cause hypocalcemia as a result of renal resistance to PTH despite high levels of PTH. Other causes of hypocalcemia in addition to hypoparathyroidism are vitamin D deficiency, hyperphosphatemia, malabsorption of calcium, and chronic renal failure.[218]

Hypocalcemia

Hypocalcemia is often asymptomatic; however, acute hypocalcemia produces symptoms that result from neuromuscular irritability or excitability. This leads to muscular and mental manifestations that include paresthesia of hands, feet, and

circumoral muscles; electroencephalographic abnormalities; anxiety; confusion; and depression. A positive Chvostek's sign may be elicited by tapping on the facial nerve in the preauricular region, which causes twitching of the facial muscles. Patients may develop tetany characterized by tonic–clonic seizures, carpopedal spasm, and severe laryngospasm. In DiGeorge syndrome, tetany is usually noticed in infancy, but may remain undetected until adulthood. Laboratory findings are low PTH and low serum calcium levels, but serum phosphate is elevated and alkaline phosphatase is normal. Most patients with hypocalcemia can be treated with oral calcium and vitamin D supplements, although acute cases may require intravenous calcium infusions.

Chronic Renal Failure

Impaired production of 1,25(OH)2D by the diseased kidneys is thought to be the principal factor that causes calcium deficiency, secondary hyperparathyroidism, and bone disease. Treatment entails dietary changes, with the restriction of phosphate in the diet, avoidance of aluminum-containing phosphate-binding antacids to prevent the problem of aluminum intoxication, adequate calcium intake orally, usually 1–2 g/day, and supraphysiologic amounts of vitamin D or calcitriol, despite the fact that the uremic state also causes impairment of intestinal absorption of vitamin D. The aim is to restore normal calcium balance to prevent osteomalacia and severe secondary hyperparathyroidism.

Stomatognathic Manifestations of Parathyroid Gland Disorders

Hyperparathyroidism

The primary clinical orofacial signs and symptoms of hyperparathyroidism are reflections of the systemic effects of hypercalcemia. Long-standing hypercalcemia causes generalized osteoporosis, which is visible on dental radiographs. Patients develop cortical resorption and rarefactions, loss of trabeculation presenting as "ground-glass" appearance, partial or total loss of lamina dura, lytic lesions, and metastatic calcifications.[219] The rarefactions occur secondary to generalized osteoporosis when fine trabeculae disappear later in the disease process, leaving a coarse pattern. Alveolar bone is particularly sensitive to increased levels of PTH from either primary or secondary hyperparathyroidism.[220] Thinning and eventual loss of the cortical bone of the maxilla and mandible may occur, especially on the lower border of the mandible. Severe cases may result in spontaneous mandibular fracture.[221]

Stomatognathic Manifestations and Dental Management

Children with rickets/osteomalacia may present with delayed tooth eruption, loss of lamina dura, and enamel and dentine hypoplasia that may progress to periapical infections. Malocclusion and hypoplastic teeth increase the risks of dental caries; therefore, regular oral health evaluation is necessary to monitor dental and periodontal health.

OSTEOPOROSIS

Osteoporosis is defined as "a disease characterized by low bone mass and micro-architectural deterioration of bone tissue, leading to enhanced bone fragility and an increase in fracture risk."[222] The World Health Organization (WHO) defines osteoporosis as a bone density of 2.5 standard deviations (SDs) below the young healthy adult mean value (T score ≤ -2.5) or lower. Values between -1 and -2.5 SDs below the young adult mean are termed "osteopenia."

Fractures due to osteoporosis are a major cause of morbidity and mortality in elderly populations and a major contributor to rising health costs. Osteoporotic fractures of the spine cause severe, acute pain or deformity and postural back pain. The risk of fracture increases exponentially with age, with 1 in 2 women and 1 in 5 men aged 50 years having an osteoporotic fracture during their remaining lifetime (Table 22-38). Caucasian and Asian races are particularly at risk.

Osteoporosis occurs from increased bone breakdown by osteoclasts and decreased bone formation by osteoblasts, leading to loss of bone mass. Bone mass decreases with age, but will depend on the "peak" mass attained in adult life (at about the age of 40–45 years) and on the rate of loss in later life. The main risk factor for osteoporosis is estrogen deficiency. In the elderly, vitamin D insufficiency and consequent hyperparathyroidism are of greater importance. Hyperparathyroidism, hyperthyroidism, and malabsorption all increase the lifetime risk of a person having a low bone mass and low BMD. Additional risk factors associated with increased bone loss, or with increased bone fragility, include

Table 22-38 Hip fractures per 1000 patient-years.

World Health Organization Category	50–64 Years of Age	>64 Years of Age	Overall
Normal	5.3	9.4	6.6
Osteopenia	11.4	19.6	15.7
Osteoporosis	22.4	46.6	40.6

Source: Cranney A, Jamal SA, Tsang JF, Josse RG, Leslie WD. Low bone mineral density and fracture burden in postmenopausal women. *Canadian Med Assoc J*. 2007;177(6):575–580.

glucocorticoid therapy and smoking. Falls increase the risk of fracture, on top of the risk associated with the particularly low bone mass. Osteoporosis is asymptomatic, except subsequent to a fracture. Bone density assessment by use of dual-energy X-ray absorptiometry (DXA) is the gold standard for the diagnosis of osteoporosis.

Prevention and Treatment of Osteoporosis (and Consequent Fractures)

Exercise

Life-long weight-bearing exercise, as little as 30 minutes, three times a week, may increase BMD. Gentle exercise in the elderly reduces the risk of falls and improves the protective reflexes needed with falling.

Smoking Cessation

This should be strongly encouraged, as smoking is associated with lower BMD and increased fracture risk.

Reduced Alcohol Intake

Alcohol intake of >3 units/day should be avoided.

Fall Reduction

This can be assisted with physiotherapy and assessment of home safety, with installation of hand rails and nonslip floor surfaces, especially in wet areas such as the bathroom and toilet.

Vitamin Supplementation

Calcium

Research has established that optimal calcium intake reduces bone loss and suppresses bone turnover. For men and women aged 19–50 years the recommended daily intake is 1000 mg/day, and for adults 51 years and older this should be increased to 1200 mg/daily. The best sources are dairy foods, but many patients require calcium supplementation.

Vitamin D

The US Institute of Medicine recommends 200 IU/daily for adults <50 years of age, 400 IU/daily for those 50–70 years, and 600 IU for those >70 years.

Pharmacologic Interventions

See Table 22-39.

Estrogen(s)/Hormone Replacement Therapy

Given the adverse effects of an increased risk for breast cancer and cardiovascular disease risk, hormone replacement therapy (HRT) is a second-line option for osteoporosis, except in younger postmenopausal women at high fracture risk.

Selective Estrogen-Receptor Modulators

Raloxifene 60 mg daily is a selective estrogen-receptor modulator (SERM) that has the advantage of having no stimulatory effect on the endometrium, but activates estrogen receptors in bone. It prevents BMD loss of bone from the spine and hip in postmenopausal women. It also reduces the incidence of estrogen-receptor-positive breast carcinoma in women treated for up to 4 years. Leg cramps and flushing may occur and the risk of thromboembolic complications is also increased, including stroke, to a degree similar to that seen with HRT.

Antiresorptive Agents

Bisphosphonates

These synthetic analogues of bone pyrophosphate adhere to hydroxyapatite and inhibit osteoclasts (Tables 22-40 and 22-41). Alendronate, risedronate, and ibandronate are approved for the prevention and treatment of postmenopausal osteoporosis in the United States. Aclasta® (zoledronic acid; Novartis Europharm, Frimley, UK) infusion is approved for use in the treatment and prevention of osteoporosis in the United Kingdom and Europe. Risedronate and alendronate are approved for the treatment of steroid-induced osteoporosis. Bisphosphonates are generally well tolerated, but the orally given agents are associated with upper gastrointestinal side effects, such as esophagitis. Bisphosphonates given as an infusion negate the gastrointestinal side effects and ensure patient compliance, thus they are increasingly popular for the management of osteoporosis, apart from their established role in malignancy-associated bone diseases (hypercalcemia, bony metastases, and multiple myeloma). The optimal duration of bisphosphonate therapy is unknown, with prolonged suppression of bone turnover having adverse effects, including atypical, low-impact, femoral fractures, and ONJ. Current recommendations are to reassess the need for ongoing bisphosphonate treatment after 3–5 years, although the benefits appear to exceed the risk of these complications.

Denosumab

Sold as Prolia® (Amgen) when used for osteoporosis (in contrast to Xgeva® [Amgen] when used in the setting of malignancy), this is a fully human monoclonal antibody to RANK ligand. It is given twice yearly by subcutaneous administration for osteoporosis. Randomized controlled trials in postmenopausal women with osteoporosis have shown it to increase BMD in the spine, hip, and forearm and reduce vertebral, hip, and nonvertebral fractures over a 3-year period by 70%, 40%, and 20%, respectively. Fracture risk reduction is equivalent to bisphosphonates. Interestingly, the risk for osteonecrosis is equivalent to that seen with the more potent bisphosphonates, comparable with the use of zoledronic acid, in the setting of malignancy.

Table 22-39 Drug therapies used for osteoporosis.

Oral Agents

Class	Actions	Generic Name	Trade Name(s)[a]	Indications	Disadvantages/ Warnings
Minerals and Vitamins					
Calcium	• Essential for bone mineral formation	Calcium carbonate Calcium citrate	Various (plus, various combinations with vitamin D)	Aids in prevention and treatment of osteoporosis	
Vitamin D3	• Maintenance of skeletal calcium • Promotes calcium absorption from gastrointestinal tract • Maintains calcium and phosphate levels for bone formation • Proper function of parathyroid hormone (PTH)	Cholecalciferol (vitamin D3) Calcitriol (1,25-dihydroxy-vitamin D3), active form of D3	Various (plus various combinations with calcium)	Aids in prevention and treatment of osteoporosis	• Hypervitaminosis D (daily allowance:15 µg/d (600 IU/d • Excess of vitamin D: → hypercalcemia → overcalcification of the bones, soft tissues, heart and kidneys → Damage to kidney → Kidney stones
Estrogen/Estrogen-Related Agents					
Hormone replacement therapy	• Effect of estrogen is to inhibit bone resorption • With estrogen deficiency, the osteoclasts live longer and are therefore able to resorb more bone	Conjugated estrogens	Premarin	Prevention of postmenopausal osteoporosis	Risks: ↑ Myocardial infarction ↑ Stroke ↑ Pulmonary embolism (PE) and deep vein thrombosis (DVT) ↑ Breast cancer ? Dementia
Selective estrogen-receptor modulators	• Acts as estrogen agonist in bone ↓ Decreases bone resorption ↓ Bone turnover ↓ Decreases fracture incidence ↑ Bone mineral density	Raloxifene	Evista	Treatment and prevention of osteoporosis in postmenopausal women Reduction in risk of invasive breast cancer	Risks: ↑ DVT, PE ↑ Stroke ↑ Major coronary event
Antiresorptive Agents					
Bisphosphonates (amino-bisphosphonates)	• At the cellular level, preferential localization to sites of bone resorption, specifically under osteoclasts	Alendronate Risedronate Ibandronate	Fosamax Binosto Actonel Atelvia Boniva	Treatment and prevention of osteoporosis in postmenopausal women, men, and glucocorticoid-induced osteoporosis Paget's disease	• Optimal duration of use not determined • Patients at low risk for fracture, consider drug discontinuation after 3–5 years • Osteonecrosis of the jaw (ONJ)

Parenteral Agents (Intravenous, Intramuscular, and/or Subcutaneous)

Class	Actions	Generic Name	Trade Name(s)[a]	Indications	Disadvantages/ Warnings
Antiresorptive Agents					
Bisphosphonates	• in vitro, zoledronic acid inhibits osteoclastic activity and induces osteoclast apoptosis	Zoledronic acid	Reclast	Treatment and prevention of postmenopausal osteoporosis, for men, and glucocorticoid-induced osteoporosis Paget's disease 5 mg every 1–2 years	• ONJ
Denosumab	• Prolia binds to receptor activator of nuclear factor kappa-B (RANK) ligand • Protein essential for formation, function, and survival of osteoclasts ↓ Osteoclast formation, function, and survival, thereby decreasing bone resorption and increasing bone mass and strength	densumab	Prolia	Treatment and prevention of postmenopausal osteoporosis, for men, and glucocorticoid-induced osteoporosis 60 mg subcutaneously (SQ) every 6 months	• Prevention of skeletal-related events in patients with cancer: 120 mg SQ every 4 weeks • ONJ (incidence similar to that of zoledronic acid)
Calcitonin	• Hormonal bone resorption inhibitor; action on bone has not been fully established	Calcitonin (salmon rDNA) Intranasal/ intramuscular/SQ	Fortical Miacalcin	Treatment of postmenopausal osteoporosis in women >5 years post menopause in conjunction with Ca^{2+} and vitamin D	
Teriparatide (Forteo) Recombinant human PTH	↑ New bone formation by stimulation of osteoblastic activity over osteoclastic activity ↑ Skeletal mass ↑ Markers of bone formation and resorption ↑ Bone strength	20 µg daily SQ		Treatment of postmenopausal women with osteoporosis, men with primary or hypogonadal osteoporosis, and glucocorticoid-induced osteoporosis for patients at high risk for fracture	• Not to be prescribed for patients who are at increased baseline risk for osteosarcoma (including those with Paget's disease)

→ leads to; ↑, increases; ↓ , decreases; ?, uncertain.

Table 22-40 Bisphosphonates: indications and usage.

Usage	Indication	Comments	Incidence of MRONJ
>90%	Osteoporosis (>90% usage)	• Postmenopausal • Corticosteroid induced/related • "Male" age-related osteoporosis • Renal osteodystrophy • Male hypogonadism	
~1%	Other/rare conditions	• Paget's disease • Osteogenesis imperfecta • Reflex sympathetic dystrophy (complex regional pain syndrome) • Heterotopic ossification with spinal cord injury • Total hip replacement • Giant cell tumor of bone	<10%
5–10%	Malignancy	Skeletal (bony) metastases (from solid malignancies • Breast cancer • Lung cancer • Prostate cancer Multiple myeloma Hypercalcemia	>90%

MRONJ, medication-related osteonecrosis of the jaws.

Table 22-41 Amino-bisphosphonates and their potency ratings.

Nitrogenous (N-Containing) Bisphosphonates

Generic Name	Trade Name	R2 Group	Potency
Pamidronate	Aredia	Amino	100
Alendronate	Fosamax	Amine	1000
Ibandronate	Bondronate	Long-chain nitrogen	10 000
Risedronate	Actonel	Cyclic nitrogen	10 000
Zoledronate	Zometa	Cyclic nitrogen	>10 000

Potency is calculated on the agents' antiresorptive effect on bone, i.e., the decline in bone resorption.
Source: Adapted from Licata AA. Discovery, clinical development, and therapeutic uses of bisphosphonates. *Ann Pharmacotherapy*. 2005;39(4):668–677.

Calcitonin

Calcitonin preparations are approved by the FDA for Paget's disease, hypercalcemia, and osteoporosis in women more than 5 years post menopause. Calcitonin suppresses osteoclast activity by direct action on the osteoclast calcitonin receptor. Calcitonin produces small increments in bone mass of the lumbar spine. A nasal spray (Fortical®, Upsher-Smith Laboratories, Minneapolis, MN, USA) containing calcitonin (200 IU/day) is available for treatment of osteoporosis in postmenopausal women and as an injectable form (Miacalcin®, Mylan Pharmaceuticals, Canonsburg, PA, USA).[223]

Teriparatide

Teriparatide (Forteo®, Eli Lilly, Indianapolis, IN, USA) is recombinant human parathyroid hormone (rhPTH) peptide 1–34, an anabolic agent that stimulates bone formation. Teriparatide reduces vertebral and nonvertebral fractures in postmenopausal women with established osteoporosis, although data on hip fracture are not yet available. It is given by daily subcutaneous injection in a dose of 20 μg for 18–24 months. rhPTH therapy is indicated in severe cases of vertebral osteoporosis or in women who fail to respond to other therapies.[224]

Antisclerostin Antibody Agents

Romosozumab only gained FDA approval in April 2019. It is given as a monthly subcutaneous injection (see earlier).

Glucocorticoid-Induced Osteoporosis

Iatrogenic osteoporosis is a recognized major complication of the therapeutic use of glucocorticoids. The risk of fractures depends on the dose and duration of glucocorticoid therapy, although data now suggest that there may be no completely safe dose.

Patients needing continuous oral glucocorticoid therapy for 3 months or more (at any dose) should be assessed for coexisting risk factors (age, previous fracture, and hormone status). Postmenopausal women and men aged over 50 years, as well as any individuals who have sustained a fracture, should receive treatment for the prevention of osteoporosis

and its progression, without waiting for BMD assessment. To date, only bisphosphonates have been demonstrated in large clinical trials to reduce the risk of fractures in patients being treated with glucocorticoids. Calcium and vitamin D supplementation also needs to be given.

MEDICATION-RELATED OSTEONECROSIS OF THE JAWS

Medication-related osteonecrosis of the jaws (MRONJ) is a clinical entity in which patients develop localized areas of bone necrosis involving the jawbones, predominantly the mandible, and the maxilla (Figures 22-21 and 22-22).[225] The necrosis, which is the key feature seen with MRONJ, entails cell and tissue injury, resulting in unexpected, premature cell death by an as yet unclear process, although necrosis usually results from trauma, infection, and/or toxins within otherwise unaffected, vital, normal bones of the jaws. Hence, the abbreviated term *osteonecrosis of the jaws* (ONJ) is also used.

There are select medications that have been established to be strongly associated with MRONJ. Of these, the drugs with the greatest and most frequently described associations are those that act to inhibit bone resorption, termed antiresorptive agents. They include the following drugs (or classes of drug):

- Amino-bisphosphonate agents.
- Denosumab, a monoclonal antibody directed against the RANK ligand found on osteoclasts.
- Romosozumab, the first of a new class of antisclerostin antiresorptive agents.[226]
- Antiangiogenic agents, which interfere with the formation of new blood vessels (angiogenesis) that is essential for cancer growth and development. A number of these agents alone, but more commonly when given concurrently with antiresorptive agents, have been associated with the development of MRONJ (Table 22-42).[227–229]

Of note is that other agents that affect bone remodeling and turnover—that is, teriparatide (the humanized recombinant form of human PTH) and strontium ranelate (never marketed in the United States because of the significant adverse risks of heart attacks and blood clots)—are not associated with MRONJ. Strontium ranelate has a dual action stimulating both osteoclastic and osteoblastic activity, and teriparatide is known to have a similar effect, given its anabolic effect on bone turnover. Of interest is that teriparatide has in a small number of case reports shown to be of benefit in established MRONJ.[234–239]

Evolution of the Nomenclature

Until the advent of the antiresorptive agent denosumab in 2010,[240] and reporting of the association between denosumab and ONJ,[241] ONJ was exclusively associated with bisphosphonate agents, and specifically the newly introduced, more potent amino-bisphosphonates. The initial bisphosphonate with a side chain containing nitrogen, termed an amino-bisphosphonate, was pamidronate, which was approved for medical use in 1987.[242] Subsequently, further modification of the nitrogen-containing side groups resulted in newer, highly potent agents with regard to their ability to prevent bone resorption by their interference in that action

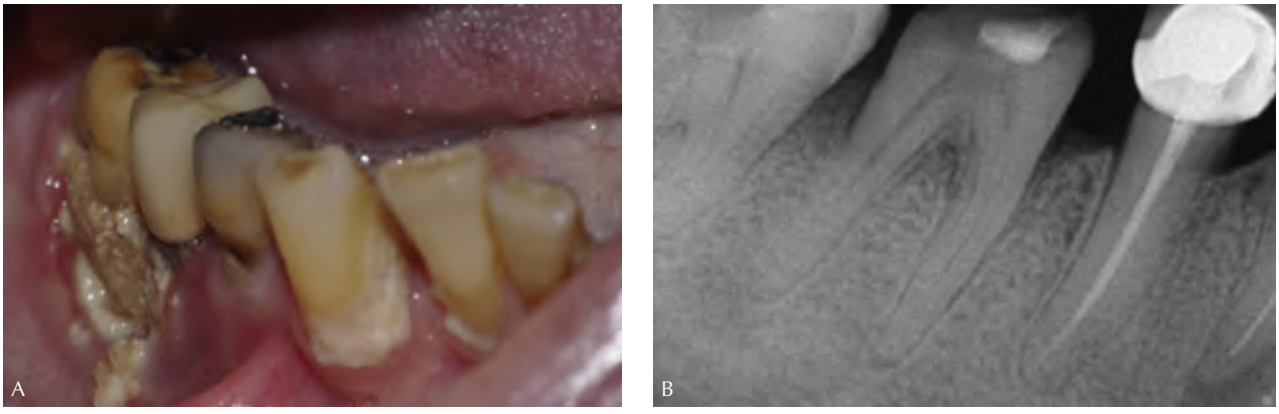

Figure 22-21 Example of exposed medication-related osteonecrosis of the jaw. A patient receiving high-dose denosumab presented with pain of 6 months' duration on the right lower first molar. He was receiving antibiotics. (A) Exposed bone and purulence were observed on the buccal alveolar bone area of the tooth consistent with osteonecrosis of the jaw, exposed type, before dental extraction. (B) Panoramic radiography disclosed alveolar bone loss around the molar tooth. Medicinrelateret osteonekrose i kæberne—oversigt og retningslinjer. *Tandlægebladet*. 2015;119:918–930. Published with the permission of the Danish Dental Journal.

and also reducing the number of osteoclasts. Hence there is now widespread use of these potent amino-bisphosphonate agents to treat and prevent osteoporosis, which is caused by relatively excessive bone resorption by osteoclasts that is not matched by bone formation by osteoblasts. Of the amino-bisphosphonates, the most potent is zoledronic acid (zoledronate), marketed as Zometa® and Reclast® (Novartis Pharmaceuticals, East Hanover, NJ, USA), which was introduced in 2001.[243] MRONJ was first reported in 2003.[244] Given that up to 2010 the only drugs shown to be consistently associated with ONJ were bisphosphonates, the term bisphosphonate-related osteonecrosis of the jaws (BRONJ) was adopted, including variations such as bisphosphonate-associated osteonecrosis of the jaws (BAONJ), bisphosphonate-associated osteonecrosis (BON), osteochemonecrosis of the jaws (OCNJ), and "bis-phossy jaw." However, the term medication-related osteonecrosis of the jaws is now preferred and MRONJ has replaced BRONJ, since it has been recognized that ONJ is associated with other agents besides bisphosphonates, including the newer antiresorptive agent denosumab and antiangiogenic agents used in the treatment of various cancers.

Case Definition

The case definition and established diagnostic features of MRONJ are as follows:

- Current or previous treatment with bisphosphonates and/or denosumab, as well as select antiangiogenic agents. However, generally MRONJ occurs when these select antiangiogenic agents have been used concurrently with an antiresorptive agent.
- A localized area of exposed bone, or bone that can be readily probed through fistula, which can be intraoral or extraoral (i.e., through the skin overlying the mandible or maxilla, the nasal cavity of adjacent maxillary sinuses) and has been present or persistent for more than 8 weeks.
- No history of prior radiation therapy to the jaws.
- Exclusion of obvious metastatic disease or deposits of the jaws.

Table 22-42 Antiangiogenic agents associated with medication-related osteonecrosis of the jaws (MRONJ).

Drug	Mechanism of Action	Primary Indication	
Sunitinib (Sutent)	• Tyrosine kinase inhibitor (TKI) • Sunitinib inhibits cellular signaling by targeting multiple receptor tyrosine kinases, including: – Platelet-derived growth factor receptors (PDGFR) – Vascular endothelial growth factor receptors (VEGFRs), which play a role in tumor angiogenesis and cell proliferation[230]	GIST RCC pNET	Gastrointestinal stromal tumor Renal cell carcinoma Pancreatic neuroendocrine tumor
Sorafenib (Nexavar)	• TKI • Sorafenib is a protein kinase inhibitor with activity against many protein kinases, including: – VEGFR – PDGFR – RAF kinases (three serine/threonine-specific protein kinases related to retroviral oncogenes)[231]	HCC RCC	Hepatocellular carcinoma Renal cell carcinoma
Bevacizumab (Avastin)	• Bevacizumab is a recombinant humanized monoclonal antibody that blocks angiogenesis by inhibiting: – Vascular endothelial growth factor A (VEGF-A)[232]	mCRC NSCLC Glio mRCC	Metastatic colorectal carcinoma Nonsquamous non-small-cell lung carcinoma Glioblastoma Metastatic renal cell carcinoma
Sirolimus (Rapamune)	• Mammalian target (mTor) of rapamycin pathway • Downregulates the expression of these VEGFs by decreased expression of both the proteins and mRNA: – VEGF-A/VEGFR-2 and VEGF-C/VEGFR-3,which are closely involved in angiogenesis and lymphangiogenesis[233]	Prevention of rejection in renal transplantation	

Source: Adapted from Ruggiero SL, Dodson TB, Fantasia J, et al. American Association of Oral and Maxillofacial Surgeons position paper on medication-related osteonecrosis of the jaw—2014 update. *J Oral Maxillofac Surg*. 2014;72(10):1938–1956.

The case definition has evolved, with the recognition that metastatic disease or deposits of the jaws are important differential diagnoses that need to be considered and excluded, which is best done by histopathologic assessment following biopsy.[245] Caveats apply to this case definition, including increasing recognition of cases in which exposed bone for protracted periods is not necessarily the presenting feature of MRONJ.[246–247]

Staging

The American Association of Oral and Maxillofacial Surgeons staging system of 2014[227] serves to define cases and the severity of the MRONJ identified, but stage-specific treatment approaches have a sound and growing evidence base as to their effectiveness (Table 22-43).[248]

Definitions of High-Dose versus Low-Dose Antiresorptive Therapy

The epidemiology for MRONJ has clearly established that 90% of cases occur in patients with cancer receiving *high-dose* therapy; that is, intensive dosing regimens of intravenous, high-potency bisphosphonates, mainly zoledronic acid (4 mg every 3–4 weeks) or subcutaneous denosumab (120 mg every 4 weeks). Data from prospective studies demonstrated that properly adjudicated MRONJ occurred in 1.3% of cancer patients treated with zoledronic acid and in 1.1% of patients with cancer treated with denosumab.[249] Furthermore, the evidence demonstrates that the increase in the cumulative dose of antiresorptive agent is associated with an increasing incidence of MRONJ. Among patients

Table 22-43 Staging of medication-related osteonecrosis of the jaws (MRONJ).

Stage	Findings
Patients at risk	No apparent necrotic bone in asymptomatic patients who have been treated with intravenous or oral antiresorptive or antiangiogenic therapy
Stage 0 (Nonexposed bone variant)	Patients with no clinical evidence of necrotic bone, but present with nonspecific symptoms or clinical and radiographic findings: **Symptoms** • Odontalgia not explained by an odontogenic cause • Dull, aching bone pain in the body of the mandible, which may radiate to the temporomandibular joint region • Sinus pain, which may be associated with inflammation and thickening of the maxillary sinus wall • Altered neurosensory function (patients may complain of altered sensation of the lips) **Clinical findings** • Loosening of teeth not explained by chronic periodontal disease • Periapical/periodontal fistula not associated with pulpal necrosis due to caries **Radiographic findings** • Alveolar bone loss or resorption not attributable to periodontal disease • Changes to bony trabecular pattern: – Dense woven bone – Persistence of unremodeled bone in extraction sockets • Regions of osteosclerosis involving the alveolar bone and/or the surrounding basilar bone • Thickening/obscuring of periodontal ligament: – Thickening of the lamina dura – Decreased size of the periodontal ligament space[150]
Stage 1 (Asymptomatic)	• Exposed and necrotic bone or fistulae that on probing contacts bone, in patients who are asymptomatic and have no evidence of infection. **Radiographic findings**: as seen in Stage 0, may also be present that are localized to the alveolar bone region
Stage 2 (Symptomatic)	• Exposed and necrotic bone *and/or* • Fistulae that on probing contacts bone, with evidence of infection • Patients are symptomatic • **Radiographic findings**: as seen in Stage 0, may also be present that are localized to the alveolar bone region
Stage 3	Exposed and necrotic bone, or fistulae that probe to bone, with evidence of infection and one or more of the following: • Exposed necrotic bone extending beyond the region of alveolar bone – to the inferior border and ramus in the mandible – maxillary sinus and zygoma in the maxilla • Pathologic fracture • Extraoral fistula • Oral antral/oral nasal communication • Osteolysis extending to the inferior border of the mandible or sinus floor

Source: Adapted from Ruggiero SL, Dodson TB, Fantasia J, et al. American Association of Oral and Maxillofacial Surgeons position paper on medication-related osteonecrosis of the jaw—2014 update. *J Oral Maxillofac Surg*. 2014;72(10):1938–1956.

with advanced breast cancer with bony metastases, the incidence of MRONJ at years 1, 2, and 3 was 0.5%, 1.2%, and 1.4%, respectively in those patients who received zoledronic acid, and 0.8%, 1.9% and 2.0%, respectively in those treated with denosumab. The risk of ONJ among patients with cancer exposed to antiresorptive or antiangiogenic medications is about 1%, but ranges between 0.2% and 6.7%.[250] Overall, the benefit provided by antiresorptive therapy outweighs the

risk of development of MRONJ in the settings of both osteoporosis and oncology.

Low-dose antiresorptive medication regimens are those typified by the dosing regimens for osteoporosis in postmenopausal women, which includes oral and intravenous bisphosphonates, with an example of the latter being zoledronic acid (5 mg every 12 months) and denosumab at a dose of 60 mg every 6 months.[251] Such low-dose regimens dominate the use, dose, and frequency of antiresorptive agents for all of their approved indications, *except* in the setting of patients with cancer. It is estimated that over 90% of patients taking antiresorptive agents are receiving low-dose regimens. The risk of ONJ among patients who are managed for osteoporosis using antiresorptive medications is about 0.1% (range 0.004%–0.2%), but this increase, as seen with patients taking oral bisphosphonates to manage osteoporosis with the risk of ONJ after tooth extraction, is estimated to be 1 in 200 (0.5%).[252] However, as has been established, it is not only the intensity of the antiresorptive dosing regimen that affects the rate of MRONJ, it is the overall cumulative dose. For patients receiving oral bisphosphonate therapy to manage osteoporosis, the prevalence of ONJ increases over time from near zero to 0.2% after 4 or more years of bisphosphonate exposure, with ONJ being seen at a median duration of oral bisphosphonate exposure of 4.4 years. Although there is less published data, the same phenomenon was seen in osteoporotic subjects taking denosumab. After 2 years of exposure, the incidence of ONJ was 0.09%, but this doubled to 0.2% after 6 years of exposure to denosumab.[253]

The significance of this epidemiologic evidence regarding the risk and duration of antiresorptive treatment associated with the development of MRONJ is as follows:

- In the majority of patients taking antiresorptive agents, these are low-dose regimens associated with a modest to significantly lower risk of MRONJ occurring.
- Regardless of which antiresorptive agent is involved, patients who are taking these drugs in the setting of cancer have a significantly greater risk of developing MRONJ, >1%, and this risk increases with the greater cumulative dose of the agent taken.
- There are definite "window periods" in which patients on low-dose antiresorptive drug regimens remain at a very low risk for MRONJ, which appears to be up to 4 years of treatment with low-dose antiresorptive agents. In this period, invasive dental procedures such as extractions (and implant placement) can be undertaken with a low risk of MRONJ occurring.

For dentists, this represent a critical period in which patients need to be made as dentally fit as possible, providing patients on such antiresorptive agents with a sustainable and easily maintainable dentition that negates the need for future dental extractions.

Window Periods for Patients on High-Dose Antiresorptive Therapy

The epidemiologic data indicate that up to 4 years of treatment with a low-dose antiresorptive treatment regimen, whether it be an oral or intravenous bisphosphonate agent or denosumab, is associated with very low risk of MRONJ occurring, even with the undertaking of invasive procedures, namely extractions. These data can be extrapolated and applied to patients who are on high-dose antiresorptive therapy in the setting of cancer. The cumulative 4-year low-dose regimen of any specific antiresorptive agent is indicative of the cumulative dose at which the risk of MRONJ substantially increases. This, by way of specific examples, is 20 mg of zoledronic acid (equal to 4 years of treatment at 5 mg per annum) and 480 mg for denosumab (equal to 4 years of treatment at 120 mg per annum; 60 mg given every 6 months). In the setting of cancer, patients will be exposed to 20 mg of zoledronic acid after 15 weeks. The standard dosing regimen for zoledronic acid used in cancer patients is 4 mg every 3 weeks, therefore it will take 15 weeks (~3.5 months) for a dose of 20 mg to be reached. For patients taking denosumab in the setting of cancer, it will take 16 weeks to reach a dose of 480 mg, as denosumab is given at 120 mg every 4 weeks. Note that in a setting of hypercalcemia of malignancy, "loading" doses of 120 mg of denosumab are to be given on days 8 and 15 within the initial 4 weeks, so shortening the tine to reach 480 mg to just 4 weeks; that is, one month. At 4 weeks a patient will have taken 240 mg, with 120 mg of denosumab given on days 0 and 28 and an extra 240 mg (2×120 mg) on days 8 and 15.

This extrapolation of the data suggests that for patients needing zoledronic acid or denosumab for the prevention of skeletal-related events of bony metastases or of the progression of the bony lytic lesions of multiple myeloma, but not when denosumab is used to treat hypercalcemia of malignancy, there is a potential window period of up to 3 months. Within this 3-month window, invasive dental procedures can be undertaken in an effort to make the patient dentally fit and so preventing the need for extractions after the 3-month window expires. However, there is no direct evidence in the form of patient-based studies that have established this premise, which is based on first principles.

Risk Factors

The overriding factor for the assessment of the risk of MRONJ developing is cumulative exposure of the patient to bisphosphonates or denosumab, considering both the dose per treatment and the number of administrations given from the start of the treatment.[254] A secondary consideration should be the relative potency of the agents used. Although to date no clear threshold dose below which MRONJ does

not occur has yet been identified, consensus is emerging in the setting of patients receiving low-dose antiresorptive medication for osteoporosis: some experts argue that the risk of MRONJ is significant after 3 years of therapy,[245] while the American Academy of Oral and Maxillofacial Surgery has stated that for patients who have received 4 years of low-dose antiresorptive treatment, the risk of MRONJ occurring subsequent to invasive dental procedures is low.[227]

The other major risk factors are the presence of infection, since typically MRONJ develops following a local infection and/or trauma to bone or soft tissues, as occurs with invasive dental procedures, namely extractions. Recent data have shown that localized periodontal or dental disease may precede the appearance of MRONJ.[37] Furthermore, alveolar bone necrosis has been documented at the time of dental extraction and the bacterial microbiotome within the necrotic bone is consistent with that seen in periodontal disease.[255,256] Dentists should be aware of the risk of MRONJ when considering invasive procedures (e.g., tooth extraction or implant placement), in cases of pressure sores from ill-fitting dentures, and when there is significant inflammation/infection.[112–114] Other factors have also been associated with an increased risk of MRONJ, including the use of other cancer therapies and/or previous or concurrent corticosteroid use, smoking, poor oral hygiene, and comorbidities, such as diabetes mellitus and renal failure. In particular, the concomitant use of antiresorptives with agents that inhibit angiogenesis—that is, the formation of new blood vessels as part of tumor growth and spread—has been documented to increase the likelihood of MRONJ occurring.[83]

Treatment Goals

The major goals of treatment for patients at risk of developing or who have MRONJ are as follows:

- Education and engagement with patients and their physicians regarding the risks of MRONJ, how these risks can be ameliorated, and keeping them apprised of when MRONJ occurs and how it can be best managed.
- Prioritization and support of the ongoing treatment for oncology patients requiring high-intensity antiresorptive agents and/or antiangiogenic drugs and those on long-term antiresorptive drugs for osteoporosis (that is, beyond 4 years of treatment). It should be noted that oncologic patients and osteoporotic patients obtain significant therapeutic benefit from antiresorptive therapy by controlling bone pain and lowering the incidence of other skeletal complications and osteoporotic-related fractures.
- For patients on antiresorptive agents that have not exceeded the window periods, prioritizing their dental care, removing all immediate and potential likely sources of dental-related infection, and ensuring these patients have a dentition that is sustainable and maintainable, so limiting the need for dental extractions in the future, beyond the designated window periods.

Prevention

Poor dental health—that is, active periodontal disease, and/or infectious and inflammatory complications of caries-induced pulpitis—is an established risk factor for the development of MRONJ in patients on long-term antiresorptive therapy. The converse also applies, in that excellent levels of dental health, supported by preventative dental health measures, have been shown to significantly limit the risks of development of MRONJ, even in patients receiving antiresorptive therapy in the setting of malignancy. This concept needs to be extended, with dental practitioners needing to be mindful of providing a dentition that patients are best able to maintain and that negates the need for future invasive dental procedures, such as extractions or implant placement, given that patients will be in receipt of antiresorptive therapy for long durations (in excess of 5 years) until their BMD score is normalized. For patients who need invasive dental treatment, the risk of such treatment needs to be carefully balanced against the possible risks of such patients developing MRONJ; however, deferring extractions of teeth with a poor to dismal prognosis that are otherwise unrestorable, or unmaintainable, is also associated with risk. In such situations, the presence of ongoing infection and associated inflammation in itself increases the risk of MRONJ occurring, with "spontaneous" cases of MRONJ having been well documented, occurring in 30% of patients without any invasive dental treatment having been undertaken. Patients will continue to receive further antiresorptive treatment for their osteoporosis, as the risks of serious bone fracture and its morbid and possible fatal complications outweigh the risks and complications, such as ONJ.

The risk of MRONJ is now thought to occur in a dose-dependent manner; that is, the greater the dose, the greater the risk of MRONJ occurring. Therefore, it may serve the patient better to undertake the necessary extractions in a planned, preemptive fashion, whereby the risk of MRONJ may be mitigated, than to await a time that extraction becomes inevitable or severe infection develops. Methods to mitigate MRONJ from occurring include the use of a course of pre- and postprocedural antibiotics, with frequent use of antibacterial (chlorhexidine-containing) mouthwashes, a "gentle"—that is, as atraumatic as practical—extraction or oral surgical technique, and primary closure. Such measures may not prevent MRONJ from developing, but may see only MRONJ stage 0 or 1 developing, which is highly amenable to conservative and modest surgical interventions.

Tables 22-44, 22-45, 22-46, and 22-47 estimate and attempt to stratify the risk of MRONJ occurring with invasive dental

Table 22-44 Duration of antiresorptive therapy (in cancer) that is equal to 4 years of treatment for osteoporosis.

Agent	Route of Administration	Osteoporosis Dose Regimen	Total Dose at 4 years	Cancer Dosing Regimen	Duration of Antiresorptive Treatment That Reaches 4-year Total Dose (as for Osteoporosis)	
Zoledronate (Aclasta)	IV	5 mg/year	20 mg	4 mg every 3 weeks	• 20 mg/4 mg = 5 doses • 5 doses given every 3 weeks = 15 weeks **= 3.5 months**	**3 months**
Ibandronate (Bondronat)	IV	3 mg every 3 months	48 mg	6 mg every 4 weeks	• 48 mg/6 mg = 8 doses • 8 doses given every 4 weeks = 32 weeks **= 7 months**	**7 months**
Ibandronate (Bondronat)	Oral	150 mg every month	200 mg	50 mg every day	• 200 mg/50 mg = 144 doses • 144 doses daily = 20 weeks **= 4.6 months**	**4 months**
Pamidronate (Aredia, Pamisol)	IV	60 mg every month	880 mg	90 mg every 3 weeks	• 880 mg/90 mg = 32 doses • 32 doses every 3 weeks = 96 weeks **= 22 months**	**22 months**
Denosumab (Prolia)	SQ	60 mg every 6 months	480 mg	120 mg every 4 weeks	• 480 mg/120 mg = 4 doses • 4 doses every 4 weeks = 16 weeks **= 3.6 months**	**3 months**

IV, intravenous; SQ, subcutaneous.

Table 22-45 Bisphosphonates and estimated "window periods" for substantively increased risk of medication-related osteonecrosis of the jaws (MRONJ) with invasive dental procedures.

Name	Generic Name	Route of Administration	Indication	Window Period: Duration of Bisphosphonate Therapy (in Months)*
Zometa	Zoledronic acid	Intravenous	Malignancy-related skeletal events	3
Bondronat	Ibandronate	Intravenous		7
Aredia Pamisol	Pamidronate	Intravenous		22
Bondronate	Ibandronate	Oral		4
Didronel	Etidronate	Oral	Paget's disease; heterotopic ossification with spinal cord injury; total hip replacement	36–48
Zometa	Zoledronic acid	Intravenous	Osteoporosis (noniatrogenic) treatment/ prophylaxis	>36–60?
Aredia Pamisol	Pamidronate			
Actonel	Risedronate	Oral		
Fosomax	Alendronate			

* In which invasive treatment (dental extractions/oral surgery) can be undertaken with a relative lower risk of complications, but not with no risk—risk of MRONJ still is present.
?, uncertain.

procedures. For moderate-risk patients, all the interventions suggested in Table 22-48 should be undertaken and, of course, extensive consultation with the patient's treating physician, and the patient themselves, including providing detailed and informed consent of the risks of MRONJ occurring. For patients stratified (Table 22-46) as being at high risk for developing MRONJ, the risks of the development of MRONJ, versus the benefits of addressing active pain or infection arising from the involved tooth/teeth, need to be outlined. Furthermore, referral of such patients to clinicians and/or specialized centers experienced in the management of MRONJ should be considered.

There also remains considerable doubt regarding the value of "drug holidays" for patients with established MRONJ.[257] However, on discussion with the patient's treating physician, an inquiry regarding the use of non-antiresorptive agents with no known risk for ONJ associated with their use (e.g., teriparatide) may prompt consideration of such alternate agents, especially in those patients with a high risk of developing MRONJ, or who have established MRONJ but still require further invasive dental procedures, such as extractions.

Unfortunately, to date there appear to be no reliable investigations for determining the optimal time to proceed with invasive dental procedures in patients taking antiresorptives. Biochemical markers of bone remodeling, such as CTx and NTx—the cleaved ends of strands of type 1 collagen that are present in the blood and can be assessed on serology, and are indicative of bone turnover—but this test has not been shown to be reliable in determining the risk for MRONJ occurring; therefore, preprocedural serum testing is not presently recommended.[258–262]

Established Medication-Related Osteonecrosis of the Jaws

See Table 22-49. Initially conservative measures only should be undertaken, namely observation. If signs of infection are evident, such as active suppuration or the development of facial swelling, in keeping with an abscess or collection with marked regional lymphadenopathy, then provide the patient with antibiotics: amoxicillin in combination with metronidazole, or a macrolide (e.g., roxithromycin) with metronidazole or clindamycin. Clindamycin has the advantage of coverage of both gram-positive streptococci and anaerobic bacterial species and good bone penetrance. Tetracyclines also have excellent bone penetrance, but bacterial resistance is common, limiting these agents' effectiveness. Frequent use of topical antibacterial mouthwashes, such as chlorhexidine-containing mouthwashes, should also be instituted.

Table 22-46 Risk assessment for medication-related osteonecrosis of the jaws (MRONJ).

Patient-Related Factors	Procedural (Surgical) Factors
Amino-bisphosphonate • Potency • Route of administration • Duration • Clinical indication/ usage **Comorbidities** • Age • Diabetes mellitus (poorly controlled) • Immunosuppression	• One or more surgical sites • Contiguous teeth or multiple separate sites • Extent of surgery • Mandibular posterior (molar) teeth • Proximity of tori
Low-risk patient • Low-dose antiresorptive therapy (e.g., osteoporosis) • For no more than 4 years	**Low-risk procedure** • Routine dental extraction • Facilitated by local anesthetic in the dental chair • Up to 3 contiguous teeth
High-risk patient • Patient on long-term/ high-dose antiresorptive therapy related to malignancy: – Solid cancer metastases (breast, prostate) – Multiple myeloma • Concurrent administration of antiangiogenic agents • Patients aged >70 years • Immunosuppression • Recent (within 2 weeks) cytotoxic chemotherapy (with resultant leukopenia) • High-dose corticosteroid administration • Diabetes mellitus (poorly controlled)	**High-risk procedure** • Extensive oral surgery • Extensive number of dental extractions – 5 teeth or more – >1 dental quadrant • Surgical extraction of mandibular molar teeth with risk of impinging lingual cortical plate and/or the mylohyoid ridge • Surgery with risk of impinging of maxillary or mandibular tori

Table 22-47 Risk calculator for medication-related osteonecrosis of the jaws (MRONJ).

Risk	Patient-Related Risk Factors	+	Surgical Procedure Risk Factors	
Minimal	Low-risk patient	+	Low-risk procedure	• Provide dental treatment required • If undertaking extractions/oral surgery, monitor regularly for development of MRONJ
Significant	Low-risk patient	+	High-risk procedure	• **Seek expert guidance** of an oral and maxillofacial surgeon (OMFS) or an oral oncology center with experience in the management of patients with MRONJ
	High-risk patient	+	Low-risk procedure	
Highly significant	High-risk patient	+	High-risk procedure	• **Refer the patient** to an OMFS or an oral oncology center with experience in the management of patients with MRONJ

DISORDERS OF INTERMEDIATE METABOLISM

Inheritable Disorders of Connective Tissue: Skeletal Dysplasia

These include a large group of heterogeneous disorders of collagen adversely affects the proper development of bone and the connective tissues. All have considerable stomatognathic manifestations and complications.

Marfan's Syndrome

Marfan's syndrome (MFS) is one of the most common autosomal dominant inherited disorders of connective tissue, affecting approximately 1 in 5000 of the population worldwide, with some 25% of individuals having developed MFS as a consequence of a new mutation.[263] It causes cardiovascular problems, especially of the heart, with sufferers developing aortic aneurysms and dissection, which can be fatal, mitral valve prolapse, and a typical body habitus consisting of a tall thin body, with long arms, legs, and fingers; scoliosis and problems with their eyes, such as dislocated lenses and retinal detachment.

Investigations

Investigations are centered on the cardiovascular system and the heart:

- Imaging: chest X-ray may be normal, but often there are signs of aortic aneurysm, widening of mediastinum, and pneumothorax is a common complication, as is scoliosis. Computed tomography (CT) is useful to detect aortic dilatation and for monitoring its progression.
- Echocardiography demonstrates mitral valve prolapse and mitral regurgitation in the majority of patients.
- Electrocardiography (ECG): 40% of patients usually have arrhythmia, with premature ventricular tachycardia and atrial arrhythmias.

Table 22-48 Interventions to mitigate the risk of medication-related osteonecrosis of the jaws (MRONJ).

Antibacterial mouthwashes	Pre- (up to 7 days) and postprocedural (up to 7 days), frequent (daily) and after meals
Antibiotics	Pre- (up to 7 days) and postprocedural (up to 7 days)
Antibiotic regimens	
Amoxicillin 500 mg 3 times/day) + metronidazole 400 mg 3 times/day	
Roxithromycin 150 mg twice/day + metronidazole 400 mg 3 times/day	
Clindamycin 300 mg daily (5 days only)	

Management

- Beta blocker therapy slows the rate of dilatation of the aortic root.
- Sedentary activities are encouraged because of the potential adverse effects of exertion on the heart, pain and potential deformities of the joints, and risk of retinal detachment and lens displacement.
- Annual or more frequent echocardiograms to monitor aortic root dilatation. If the aortic root diameter exceeds 5 cm, this is an indication for aortic root replacement surgery.

Stomatognathic Manifestations and Complications

- Hypermobility with dislocation of the temporomandibular joint.

Table 22-49 Stage-specific treatment for medication-related osteonecrosis of the jaws (MRONJ).

Staging of MRONJ		Recommended Treatment/Treatment Provider	
Stage 0	• No clinical evidence of necrotic bone *but* • Nonspecific clinical findings, radiographic changes, and symptoms	• Antibacterial mouth rinse • Quarterly follow-up/review • Patient education and review of indications for continued antiresorptive therapy • Symptomatic treatment with oral antibiotics and antibacterial mouth rinse • Pain control • Debridement to relieve soft tissue irritation and infection control	• By dentist
Stage 1	• Exposed and necrotic bone or fistulas that probe to bone in patients who are asymptomatic and have no evidence of infection		
Stage 2	• Exposed and necrotic bone or fistulas that probe to bone associated with • Infection as evidenced by pain and erythema in the region of exposed bone with or without purulent drainage	• Antibacterial mouth rinse • Antibiotic therapy and pain control • Surgical debridement or resection for longer-term palliation of infection and pain	• Seek expert guidance of an oral and maxillofacial surgeon (OMFS) or an oral oncology center with experience in the management of patients with MRONJ
Stage 3	• Exposed and necrotic bone or a fistula that probes to bone in patients with pain, infection, and one of the following: • Exposed and necrotic bone extending beyond the region of alveolar bone (i.e., inferior border and ramus in mandible, maxillary sinus, and zygoma in maxilla) • Resulting in pathologic fracture, extraoral fistula, oral antral or oral nasal communication, or osteolysis extending to inferior border of the mandible or sinus floor		• Refer the patient to an OMFS or an oral oncology center with experience in the management of patients with MRONJ
Regardless of MRONJ stage, mobile segments of bony sequestrum should be removed without exposing uninvolved bone. Extraction of symptomatic teeth within exposed necrotic bone should also be considered because it is unlikely that extraction will exacerbate the established necrotic process			

Source: Adapted from Ruggiero SL, Dodson TB, Fantasia J, et al. American Association of Oral and Maxillofacial Surgeons position paper on medication-related osteonecrosis of the jaw—2014 update. *J Oral Maxillofac Surg*. 2014;72(10):1938–1956.

- High and narrow palatal vault, severe malocclusions with maxillary retrognathy, and micrognathia and marked tooth crowding.
- Sleep apnea.

Ehlers–Danlos Syndrome

Ehlers–Danlos syndrome (EDS) is a highly heterogeneous group of disorders of collagen, with 10 different subtypes recognized associated with varying degrees of skin fragility, skin hyperextensibility, and joint hypermobility.[264]

- *Types I, II, and III*: autosomal dominant inheritance. The biochemical basis to these forms of EDS are yet to be determined.
- *Type IV* (vascular type): autosomal dominant. It involves the arteries, the bowel, and the uterus, as well as the skin. Mutations in the *COL3A1* gene produce abnormalities in the structure, synthesis, and secretion of Type III collagen.
- *Type VI*: inheritance is autosomal recessive.
- *Type VII*: an autosomal dominant disorder in which there is a defect in the conversion of procollagen to collagen; *COL1A1* and *COL1A2* mutations delete the N-proteinase cleavage sites.

There are also other rare forms of EDS.

Osteogenesis Imperfecta

Osteogenesis imperfecta (OI) is a heterogeneous group of mainly autosomally dominant inherited disorders.[265] There are four main types of OI (I–IV), with other clinical subtypes also described (V, VI, and VII). The major clinical feature is bone fragility, but other collagen-containing tissues are also involved, such as tendons, the skin, and the eyes, and of course the teeth, as dentinogenesis imperfecta.

- *Type I*: mild bony deformities, blue sclerae, defective dentine, early-onset deafness, hypermobility of joints, and heart valve disorders.
- *Type II*: perinatal death.
- *Type III*: severe bone deformity, blue sclerae.
- *Type IV*: fewer fractures, normal sclerae, normal lifespan.

Treatment involves bisphosphonates (particularly intravenous pamidronate), given from an early age, that is stopped at about 18–21 years with growth arrest, and this has considerably improved bone cortical thickness and skeletal development. Overall prognosis is still variable and dependent on the severity of the disease. To date no cases of ONJ with the use of bisphosphonates in this clinical setting have been reported.

Achondroplasia ("Dwarfism")

Achondroplasia is an autosomal dominant disease, but spontaneous mutations can also occur.[266] The condition is caused by a defect in the fibroblast growth factor receptor-3 gene. The trunk is of normal length, but the limbs are very short and broad due to abnormal endochondral ossification. The vault of the skull is enlarged, the face is small, and the nose bridge is flat. Intelligence is unaffected. Diagnosis is usually made by fetal ultrasound by progressive discordance between the femur length and the head circumference and diameter. Dental malocclusion is common.

Neurologic Diseases

Eric T. Stoopler, DMD, FDSRCS, FDSRCPS
Michael L. McGarvey, MD

Neurologic diseases currently impact over 100,000 million Americans, with a similar prevalence world-wide, resulting in years lost to disability and economic impact greater than all other categories of disease.[1] Thus, oral healthcare providers will encounter patients who have a neurologic disease diagnosis. The signs and symptoms, as well as the complications, of these disorders and their treatment can have significant impact on oral health, as well as dental management decisions. This chapter focuses on common neurologic diseases, especially those with greater impact on the orofacial region and/or dental treatment.

CEREBROVASCULAR DISEASE

Epidemiology and Etiology

Cerebrovascular disease refers to disorders of the cerebral blood vessels that cause impaired cerebral circulation. Stroke is an impairment in blood flow to the brain due either to lack of blood flow (ischemia) or hemorrhage, resulting in cell injury and death, causing loss of neurologic function, including loss of motor, sensory, visual, and cognitive function, depending on the location of the injury. Ischemic stroke

Burket's Oral Medicine, Thirteenth Edition. Edited by Michael Glick, Martin S. Greenberg, Peter B. Lockhart, and Stephen J. Challacombe.

accounts for 85% of all strokes, while cerebral hemorrhage accounts for the remaining 15% and can be further divided into primary intracerebral hemorrhage (ICH), subarachnoid hemorrhage (SAH), subdural hematoma, and epidural hematoma. Transient ischemic attack (TIA) is defined as an acute, short-duration, focal neurologic deficit, typically lasting less than 1 hour, without evidence of infarction on brain imaging.[2]

Stroke is the second most frequent cause of mortality world-wide[3] and the fifth most frequent in the United States,[4] with a prevalence of 2.6% in those over 20 years of age, despite a decrease in the incidence of stroke and stroke mortality over the past 30 years.[5,6] Stroke disproportionately affects the elderly, ethnic minorities, and those of lower educational achievement.[7] In 2013, the total estimated cost of stroke was estimated to be $75.2 billion in the United States alone and these costs will continue to increase due the aging population.[8] Risk for stroke increases with age, with a crude age-adjusted rate per 1000 persons of 0.5 for ages 18–44 years, 2.5 for ages 45–64 years, 6.9 for ages 65–74 years, and 12.4 for ages 75 years and older.[9] Approximately 20% of all strokes are heralded by a TIA; the short-term risk of stroke after TIA is 10% at 90 days, with the highest risk being in the first 24 hours;[10–12] 80% of all strokes following TIA are preventable. Within 1 year of a TIA, 12% of patients die.[13,14]

Impaired cerebral blood flow leading to ischemia and energy failure is the common pathogenic mechanism for stroke. A 50% decrease in blood flow to the brain for as few as 3–4 minutes can result in irreversible brain injury. Following infarction, edema and excessive neurotoxic excitation contribute to further regional tissue injury and death. Ischemic strokes occur through three mechanisms: (1) primary thrombosis of artery or vein; (2) embolism of debris to the central nervous system (CNS) from a proximal site; or (3) systemic hypoperfusion.[15] Thrombotic stroke occurs due to primary occlusion of a blood vessel supplying the CNS. They can be further divided into large vessel or small vessel strokes. Large vessel stroke includes the carotid and vertebral arteries and their major branches. The major cause of primary occlusion of these vessels is atherosclerosis, but dissection, trauma, and vasculitis are other etiologies.[15] Strokes are characterized by extensive downstream ischemia, usually due to a thromboembolic event along the distribution of these vessels. Small vessel or lacunar strokes result from obstruction of the small (<5 mm diameter) penetrating arterioles supplying the basal ganglia, anterior limb of the internal capsule, and (less commonly) deep cerebral white matter. Age and uncontrolled hypertension are the greatest predisposing factors.[16,17] Symptoms usually include unilateral motor or sensory deficit without visual field changes or disturbances of consciousness or language. Embolic strokes result from debris that originates from a source outside the CNS, typically the heart or aorta. Sources include atrial fibrillation, valvular heart disease, ventricular thrombus, heart failure with low cardiac function, patent foramen ovale, infectious endocarditis, hypercoagulability, and aortic atherosclerosis.[18] Strokes may occur due to periods of sustained systemic hypoperfusion resulting in decreased cerebral perfusion in conditions such as cardiac arrythmias or arrest.

Approximately 15% of strokes result from hemorrhagic events leading to infarction, most often related to hypertension, trauma, substance abuse, or aneurysmal rupture.[19] Primary cerebral ICH typically occurs from rupture of small arteries in the subcortical brain tissue, resulting in a hematoma that expands slowly until it is stopped by intracranial pressure. The most common cause is chronic or acute hypertension, but trauma, sympathomimetic drug abuse, amyloid angiopathy (cortical ICH), or vascular malformations are other causes.[20] Headache, nausea, and decreased consciousness typically accompany neurologic deficits coinciding with the location of the ICH. The major cause of SAH is rupture of arterial intracranial aneurysms, but other etiologies include trauma, vascular malformations, and amyloid angiopathy. The aneurysmal rupture releases blood into the cerebral spinal fluid surrounding the brain under arterial pressure, which results in a sudden increase in intracerebral pressure with abrupt changes in consciousness, severe headache, and focal neurologic deficits. The aneurysmal SAH may occasionally be preceded by a subtle bleeding episode with headache only, called a sentinel hemorrhage.[21] Acute interventional treatment with catheter-based or open surgical clipping of aneurysm is often required to prevent rebleeding of the aneurysm, which is frequently fatal.

Clinical Manifestations

The hallmark of stroke is a sudden loss of brain function. The clinical manifestations of stroke vary depending on the size and location of the affected brain region. The most common signs and symptoms include sensory and motor deficits, changes (paresis) in extraocular muscles and eye movements, visual defects, sudden headache, altered mental status, dizziness, nausea, seizures, impaired speech or hearing, and neurocognitive deficits such as impaired memory, reasoning, and concentration.[19,22,23]

Diagnosis

Stroke should be considered whenever a patient experiences the clinical manifestations described above, with the additional goals of ensuring medical stability and identifying the cause of the deficits. Other nonstroke causes for these signs and symptoms, particularly when focal, may include seizures, hypoglycemia, intracranial tumors, trauma, infection,

encephalitis, multiple sclerosis (MS), and prolonged migrainous aura.[22] In addition to a thorough neurologic and cardiovascular examination, anatomic and functional brain imaging is central to the diagnosis of stroke. Time is of the essence for instituting treatment to manage acute stroke due the potential to employ reperfusion strategies, which are now the standard of care in ischemic stroke. Intracranial hemorrhage must be quickly excluded before life-saving thrombolytic therapy can begin. While brain magnetic resonance imaging (MRI) provides greater anatomic detail and sensitivity for detection of early infarction, noncontrast computed tomography (CT) scan is the first line of imaging because of its speed, low cost, and availability (see Figures 23-1 and 23-2).[24–26] Laboratory evaluation of the stroke patient includes compete blood count, comprehensive metabolic panel, urinalysis, coagulation profile, and, when indicated, blood culture, echocardiography, and lumbar puncture.[22]

Treatment

The outcome of stroke and TIAs is significantly affected by the timeliness of treatment. Early intervention is critical to prevention, treatment, and recovery. The critical issue in treatment of ischemic TIA is identification of the cause, as large number of strokes following TIAs or minor strokes are preventable. This evaluation includes laboratory work to exclude anemia, erythro/thrombocytosis, coagulopathies, and hypoglycemia that can mimic stroke; as well as cardiac evaluation with electrocardiogram (ECG), long arrhythmia monitoring, and echocardiogram to exclude atrial fibrillation and other cardiac sources of embolism. Vascular imaging of neck and head with ultrasound, CT, or magnetic resonance angiography (MRA) will identify large vessel sources of stroke such as carotid stenosis. Structural brain imaging with CT or MRI is also necessary to rule out mimics such as brain tumors. TIAs are treated by reduction in hypertension (lifestyle changes such as diet, exercise, smoking cessation, and stress reduction; medical therapy for hypertension; and anticoagulant or antiplatelet medications), or large vessel revascularization.[27] The reader is referred to Chapters 14 and 18 in this textbook that describe more thoroughly anticoagulant and antihypertensive therapies.

The core principle of acute stroke care is recanalization of occluded vessel (reperfusion of ischemic tissue that can be saved, known as the penumbra), optimization of collateral flow, and avoidance of secondary brain injury. Management of acute stroke includes medical therapy to reduce bleeding or thromboembolic occlusion, medical therapy to reduce brain edema and neurotoxicity/nerve injury, and surgical interventions (revascularization, hemorrhage control).[22,23,27]

Figure 23-1 Noncontrast head computed tomography demonstrating a left parietal lobe intracerebral hemorrhage.

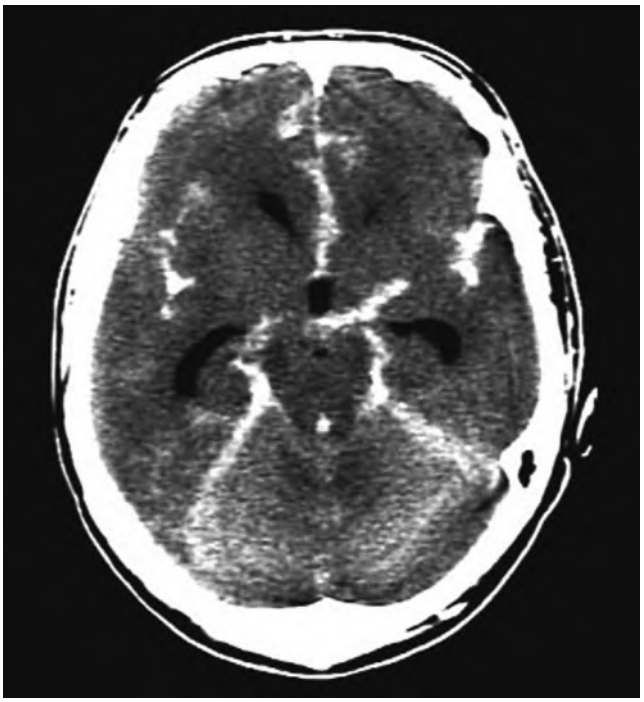

Figure 23-2 Noncontrast head computed tomography demonstrating a diffuse subarachnoid hemorrhage resulting from acute rupture of an anterior cerebral aneurysm.

Once intracranial hemorrhage has been excluded as the source of acute cerebral ischemia, thrombolysis with intravenous tissue plasminogen activator (t-PA) can improve reperfusion, minimize infarction, and reduce disability.[28] The American Heart Association and American Stroke Association advisory statement recommends administration of t-PA from 3 to 4.5 hours after stroke onset.[29,30] Advance perfusion imaging techniques now enable identification of patients who may benefit from treatment of ischemic stroke up to 24 hours after, utilizing catheter-based mechanical thrombectomies for large cerebral occlusions where brain tissue can be still be rescued.[31] No neuroprotectant agent has been found for acute stroke, although extensive investigation continues to develop and test new neuroprotective drugs to minimize neurotoxicity, reduce edema, and correct ischemia, mostly among excitatory amino acid antagonists, free radical scavengers, and cytokine inhibitors.[23,27] Once acute stroke management is complete, etiologic evaluation of ischemic stroke follows a similar pathway to that of TIA and identification of cause is critical to preventing recurrent stroke.

Primary hemorrhagic stroke is typically managed conservatively, although SAH, subdural, and epidural hemorrhages may require surgical intervention aimed at treating the specific mechanism or lesion.

Oral Health Considerations

Following stroke, patients may experience several oral problems (see Table 23-1). These problems can lead to impairment of food intake, poor nutrition, and weight loss due to diminished taste satisfaction, chewing capacity, and swallowing; choking; and gagging.[32–34] Diminished motor function of masticatory and facial muscles may also reduce food clearance from the mouth and teeth and, alone or combined with the presence of diminished dexterity of the arms or hands, may adversely affect oral hygiene and increase the risk for caries and periodontal disease.[34,35] Creative and effective use of adjuvant oral hygiene techniques and devices (oral antimicrobial rinse, oral irrigation, floss holders, etc.) represents an important approach to oral health promotion and disease prevention, supported by frequent recall examination and prophylaxis. Replacement of missing teeth and adequacy of removable and fixed prostheses are essential to effective chewing and diet.

Table 23-1 Orofacial findings associated with stroke.

Extraoral	Intraoral
• Sensory/motor deficits • Weakness in extraocular muscles/ocular movements • Visual defects • Sudden headache • Impaired speech • Muscle paralysis – Facial muscles – Masticatory muscles • Sensory impairment/loss • Calcified carotid artery atheroma on panoramic imaging may be associated with stroke risk	• Sensory impairment/loss – Taste – Touch • Gag reflex impairment • Dysphagia • Poor oral hygiene, due to diminished manual dexterity and/or above factor(s) – Increased risk of periodontal disease – Increased risk of dental caries

Dental management of the patient with a history of TIA or stroke presents several challenges.[32–34,36] Physical limitations secondary to stroke, such as hemiplegia or paralysis, must be assessed to determine practical aspects of delivering oral healthcare. Ambulatory patients may require assistance getting into the dental operatory and transferring to the dental chair.[37] These patients may also require chair modifications, such as commercially available pillow and wedge support devices, to maintain an upright position and comfort during dental treatment.[37] If the patient is in a wheelchair, it must be determined whether transfer to the dental chair is feasible.[37,38] The dental team should be familiar with various transfer techniques to ensure the safety of all those involved in the process.[38] Dental treatment may need to be administered to patients in wheelchairs if they are not able to transfer, which can pose various challenges to oral healthcare providers.[38]

Stroke prevention through routine monitoring of blood pressure is an important step in hypertension risk, detection, and reduction through referral and effective management. Identification of calcified carotid artery atheroma (CCAA) in the neck on panoramic imaging may represent findings associated with stroke risk. CCAA-related calcifications occur in the common carotid artery at the bifurcation of the internal carotid artery and the external carotid artery, located lateral and inferior to the hyoid bone or in either branch (see Figure 23-3).[39] These radiographic findings provide reasonable accuracy in the detection of vessel stenosis, but do not infer the presence of hemodynamically significant disease related to risk of stroke.[39] Patients with identified CCAA on panoramic imaging should be informed of the findings and referred to a medical provider for further evaluation. Prior history of TIA or stroke increases the risk of a future or second stroke, with the highest risk during the first 90 days.[13,14,40,41] A comparative retrospective study[42] examining complications of invasive dental treatment following acute stroke found no evidence to support the historical intuitive guideline to defer elective dental treatment for 6 months following a stroke or for a patient with active TIAs. With optimal medical monitoring and poststroke care, patients can safely undergo invasive dental treatment, with appropriate consideration for stress reduction, medication interactions,

Figure 23-3 Panoramic radiograph. adverse effects, neurologic deficit management, and control of underlying cardio/cerebrovascular risk factors.[42]

Use of antiplatelet and anticoagulant medications is common in patients with a history of stroke and TIAs. This includes oral aspirin, oral antiplatelet drugs, such as ticlopidine and clopidogrel, subcutaneous low molecular weight heparin, and warfarin. These medications, taken in therapeutic dosages, and for warfarin with an international normalized ratio (INR) ≤3.5, rarely require dose modification before routine dental and minor oral surgical treatment.[43–47] Novel anticoagulants, such as factor Xa inhibitors—that is, apixaban (Eliquis), rivaroxaban (Xarelto), edoxaban (Savaysa)—and direct thrombin inhibitors (DTIs)—that is, dabigatran (Pradaxa)—are now commonly used in stroke prevention. Current evidence suggests that these medications should not be discontinued for basic dental treatment and minor invasive dental procedures due to risk of a thromboembolic event.[48] Bleeding complications arising in patients using these medications are typically managed with local measures, including pressure, topical hemostatic agents, and primary closure.[48,49] However, an individualized approach should be considered in all cases of patients taking these medications who undergo invasive dental procedures, accounting for type of procedure, risk of bleeding, and risk of embolism.[50] For additional information regarding management of patients taking antiplatelet and anticoagulant medications, the reader is referred to Chapter 14 in this textbook. Concomitant use of nonsteroidal anti-inflammatory drugs (NSAIDs) may increase the risk for bleeding, and their long-term use may reduce the protective effect of aspirin. Potential drug interactions of note include, but are not limited to, use of metronidazole, erythromycin, and tetracycline, which may alter the bioavailability of warfarin.

Stress reduction and confidence building for the patient during dental visits are important behavioral goals to make the patient comfortable and minimize anxiety-related elevation in blood pressure. Epinephrine-containing impression cord should not be used.[36,42] Blood pressure should be monitored at every visit and during a visit if long and stressful.

MULTIPLE SCLEROSIS

Epidemiology and Etiology

MS is a disorder of variable clinical features resulting in deficits in cognitive, sensory, motor, and bladder function. It is characterized pathologically by inflammation, axonal injury, and demyelination of the CNS.[51] The typical presentation of MS is of recurrent, focal neurologic deficits that typically improve over several weeks or months, but over time these recurrent episodes evolve into progressive loss of neurologic function. In Western societies, MS is second only to trauma as a cause of neurologic disability in early to middle adulthood.[51] The age at onset is typically between 20 and 31 years; rarely does MS appear clinically before the age of 10 or after age 60.[51,52] MS is more common among women than men (2.3:1 ratio); however, in patients with later onset of MS, the sex ratio tends to be more even.[53] The concept that the prevalence of MS increases with increasing distance from the equator has been disproved.[54] When racial differences are correlated with prevalence rates for MS worldwide, white populations are at greatest risk and both black and Asian populations have a low risk of disease.[52]

The cause of MS is unclear, and the most widely accepted theory is that MS is an inflammatory autoimmune disorder

caused by autoreactive lymphocytes resulting in demyelination of axons in the CNS.[55] Myelin is critical for the propagation of nerve impulses and when it is destroyed in MS, slowing and/or complete block of impulse propagation is manifested by abnormal muscular and neurologic signs and symptoms. While loss of myelin is a hallmark of disease, it appears that neuronal and axonal loss is also important in disease progression.[56,57] This results in brain lesions called plaques. MS lesions or "plaques" vary in size and are characterized by perivenular cuffing with inflammatory mononuclear cells, predominantly macrophages and T cells, which is generally limited to the white matter and periventricular areas of the CNS.[58] Studies have established that demyelinated lesions are also commonly found in the cortical gray matter and meningeal inflammation is prominent in early MS.[59] Plaques may be found in both the brain and the spinal cord, and within the plaques there is variable destruction of myelin and neuronal axons, with preservation of the ground structure.[52] Uniform areas of incomplete myelination are called shadow plaques and may be evident in chronic lesions of MS.[51] Although an inflammatory and autoimmune mechanism is involved in the disease, it is unclear whether this is a primary process or a reaction to an infectious agent or underlying primary neurologic degeneration.[60]

Substantial evidence suggests that autoimmune mechanisms are involved in the pathogenesis of MS.[61] Myelin basic protein (MBP) is an important T-cell antigen that is critical in the development of experimental allergic encephalomyelitis (EAE) in animals. Certain forms of EAE are pathologically similar to MS and activated MBP-reactive T cells are often found in the blood or cerebrospinal fluid (CSF) of MS patients, supporting the autoimmune theory of MS pathogenesis.[61] Increased levels of immunoglobulin G (IgG) and cytokines such as tumor necrosis factor are commonly detected in the CSF of patients with MS.[62] A genetic susceptibility to MS clearly exists, and it is thought that an initial trigger leads to autoimmune mechanisms causing demyelination. The major histocompatibility complex (MHC) on chromosome 6p21 (*HLA-DRB1* gene) has been identified as one genetic determinant for MS.[63] The MHC encodes the genes for the human leukocyte antigen (HLA) system, and susceptibility to MS lies with the class II alleles, particularly the class II haplotypes DR15, DQ6, and Dw2.[52]

Epidemiologic evidence supports the role of an environmental exposure in MS, and two common infectious agents to be implicated in the pathogenesis of this disease are Epstein–Barr virus and human herpesvirus 6.[64] Other viruses that have been implicated in the pathogenesis of MS include measles, mumps, rubella, *Chlamydia pneumoniae*, parainfluenza, vaccinia, and human T-lymphotropic virus 1.[52,64] There does appear to be a relationship between a lack of sun exposure and low serum vitamin D levels with the risk of MS.[65] This finding initially led to the belief that MS was more prevalent in northern latitudes, but more recent data have not supported this finding. There has been no association with vaccination and MS.[66]

Clinical Manifestations

The onset of MS may be insidious or abrupt, and symptoms range from trivial to severe. The clinical course of disease generally extends for decades, but a rare few cases are fatal within a few months of onset. The clinical manifestations of MS depend on the areas of the CNS involved, and frequently affected areas include the optic chiasm, brainstem, cerebellum, and spinal cord.[52,58] The sudden onset of optic neuritis (diminished visual acuity, dimness, or decreased color perception), without any other CNS signs or symptoms, is often considered the first symptom of MS.[67] Other common visual signs in patients with MS include diplopia, blurring, nystagmus, gaze disturbances, and visual field defects.[58]

Limb weakness is characteristic of MS and can manifest as loss of strength or dexterity, fatigue, or gait disturbances. Spasticity associated with painful muscle spasms is often observed in the legs of patients with MS and may interfere with a patient's ability to ambulate. Ataxia may affect the head and neck of MS patients and may result in cerebellar dysarthria (scanning speech). Bladder dysfunction and bowel dysfunction frequently coexist and are present in >90% of MS patients. The most common complaints are urinary urgency and constipation. Sensory symptoms are the most common feature of MS, present in almost 100% of patients, and include numbness, paresthesia, and hyperesthesia in the limbs and thorax.[68] Impairments of vibratory and position sense can also exist. Paroxysmal attacks of pain and muscle spasm can occur, often triggered by specific sensory stimuli. The classic Lhermitte sign is described as sensory shock that runs up and down the spine, which is typically brought on by neck flexion. Fatigue, sleep disorders, depression, cognitive dysfunction, sexual dysfunction, vertigo, and chronic pain are frequently observed in patients with MS.[52,69] Patients with MS often experience exacerbation of neurologic symptoms in response to an elevation of the body's core temperature. This is referred to as Uhthoff's symptom and is generally seen in response to increased physical activity.[52]

Diagnosis

There is no definitive diagnostic test for detection of MS and the disease remains a clinical diagnosis, although MRI demonstrates characteristic abnormalities of MS in >95% of patients.[52] MS plaques are visible as hyperintense focal

areas on T_2-weighted images that are characteristic of chronic lesions. T_1-weighted images reveal hypointense areas that are usually indicative of active MS lesions.[52] Evoked potentials measure CNS electrical potentials, and abnormalities are detected in up to 90% of patients with MS. CSF is often analyzed in patients suspected of having MS and CSF-specific oligoclonal bands are found in 95% of patients, which indicates evidence of chronic autoimmune dysfunction.[70] Recent formulations of the diagnostic criteria for MS begin with an initial clinical presentation typical for an MS attack known as the McDonald criteria.[71] These are relatively complex criteria, but essentially rely on the presence of at least one distinct monophasic clinical episode lasting greater than 24 hours, which is then supported by confirmation of at least two distinct objective correlating findings, either on MRI imaging, evoked potentials, optical imaging, or the presence of CSF-specific oligoclonal bands.[71] These criteria require evidence of more than one distinct lesion occurring at different times (time and space), as the differential diagnosis of a single monophasic attack is broad and includes CNS vascular events, neoplasm, and infections.[71]

Treatment

Therapy for MS can be divided into three categories: (1) treatment of acute attacks; (2) disease-modifying therapies; and (3) symptomatic therapy.[51,52] Corticosteroids are used to manage both initial attacks and acute exacerbations of MS. High-dose corticosteroids have been shown to hasten recovery.[72] Intravenous methylprednisolone is typically administered at a dose of between 500 and 1000 mg/d for 3–5 days to reduce the severity and length of an attack.[58] Over the last two decades, a large number of disease-modifying agents have been approved for the treatment of MS that have shown various benefits to patients by decreasing relapse rate, clinical disease progression, and imaging-based progression.[73–75] The choice of drugs is made based on the progression of disease, side effects, risk of complications, type of administration, patient preference, and response rate.[73–75] Disease-modifying agents include subcutaneously injectable interferon (IFN)-β1a, IFN-β1b (cytokines that modulate immune responsiveness), and glatiramer acetate (mimics MBP).[76] Fingolimod (inhibits T-cell migration), teriflunomide (inhibitor of pyrimidine synthesis), dimethyl fumarate (activates nuclear factor erythroid 2-related factor), cladribine (purine antimetabolite agent), and siponiod (sphingosine 1-phosphate receptor modulator) are oral agents approved for the treatment of MS. Mitoxantrone (Novantrone) is a chemotherapeutic agent administered intravenously that is effective in reducing neurologic disability and frequency of clinical relapses in patients with MS.[77] Natalizumab (binds α-4 integrin), ocrelizumab (anti-CD 20), and alemtuzumab (binds CD52 surface proteins) are monoclonal antibodies that are given intravenously. Common agents employed for the management of specific MS symptoms include anticonvulsants, benzodiazepines, tricyclic antidepressants, smooth muscle relaxants, anticholinergic agents, and various pain medications.[51,78]

The prognosis for MS is variable. It is difficult to predict the course of MS in an individual patient; however, earlier age of onset, female sex, fewer number of baseline brain MRI lesions at time of clinical diagnosis, and less disability 5 years after onset are generally considered favorable prognostic signs.[52] Most patients with MS experience progressive neurologic disability and gait disturbances and/or difficulty with ambulation, as these are common clinical sequelae for patients with this disease.[79] Mortality as a direct consequence of MS is uncommon, and death usually results from a complication of the disease, such as pneumonia.[80]

Oral Health Considerations

Individuals may present to the oral healthcare provider with signs and symptoms of MS. Trigeminal neuralgia (TGN), which is characterized by electric shock–like pain, may be an initial manifestation of MS in up to 5% of cases.[51,81–84] MS-related TGN is similar to idiopathic TGN, and the reader is referred to Chapter 11 in this textbook that describes idiopathic TGN more thoroughly. Features of MS-related TGN include **the** possible absence of trigger zones and continuous pain with lower intensity.[82] Glossopharyngeal neuralgia (GN) affects the sensory distribution of the glossopharyngeal or vagus nerve and clinically presents as a severe, stabbing pain in the region of the ear, base of the tongue, angle of the mandible, and/or tonsillar fossa. Prevalence of GN has been reported in 0.5% of patients with MS.[85] Several medications can be used to manage TGN and GN and the reader is referred to Chapter 11 that describes these medications and alternative therapies.

Patients with MS may also demonstrate neuropathy of the maxillary (V2) and mandibular branches (V3) of the trigeminal nerve, which may include burning, tingling, and/or reduced sensation.[85] Neuropathy of the mental nerve can cause numbness of the lower lip and chin.[83,84] Myokymia may be seen in patients with MS and consists of rapid, flickering contractions of the facial musculature secondary to MS lesions affecting the facial nerve.[86] Facial weakness and paralysis may also be evident in MS patients. Dysarthria that results in a scanning speech pattern is often seen in patients with MS. Other orofacial pain conditions that may be present at higher frequency in patients with MS compared to

the general population include temporomandibular disorder and headache.[87,88] If MS is suspected, oral healthcare professionals should carefully evaluate cranial nerve function. If cranial nerve abnormalities are detected upon examination, the individual should be referred to a neurologist for further evaluation. In addition, MS patients may experience increased frequency and severity of oral disease, such as xerostomia and gingival bleeding, compared to healthy individuals.[89]

It is recommended to avoid elective dental treatment in MS patients during acute exacerbations of the disease, due to limited mobility and possible airway compromise.[90,91] Emergency dental treatment may be considered in patients experiencing an acute flare of MS in consultation with the patient's physician to ensure medical stability.[37] MS patients with significant dysfunction and/or who are medically unstable may require dental treatment in an operating room under general anesthesia due to the inability to undergo treatment in an outpatient setting. In addition, electric toothbrushes and oral hygiene products with larger handles may be necessary for completing oral hygiene in patients with significant motor impairment. It is critical for oral healthcare providers to maintain accurate medication inventories for patients with MS and to be aware of possible interactions of these medications with those commonly used and prescribed in dentistry, as well as oral and systemic side effects of these agents. MS patients managed with immunosuppressants may place those individuals at increased risk for opportunistic and community-acquired infections, emphasizing the need for optimal oral hygiene (see Table 23-2).[90]

Table 23-2 Orofacial findings associated with multiple sclerosis.

Extraoral	Intraoral
• Ocular symptoms – Diminished visual acuity – Diplopia – Nystagmus • Neuropathic pain – Trigeminal neuralgia – Glossopharyngeal neuralgia – Peripheral neuropathy • Myokymia • Facial weakness/paralysis • Ataxia • Dysarthria • Headache • Temporomandibular disorder • Vertigo	• Xerostomia – Increased risk of periodontal disease – Increased risk of dental caries – Increased risk of oral candidiasis • Increased risk of opportunistic infections (bacterial/viral/fungal) due to immunosuppressants

ALZHEIMER'S DISEASE

Epidemiology and Etiology

Dementia is defined as an acquired deterioration in cognitive abilities that impairs the successful performance of activities of daily living.[92] Memory is the most common cognitive ability lost with dementia; other mental faculties affected include problem-solving skills, judgment, visuospatial ability, and language. The global prevalence of dementia is estimated at 24 million and has been predicted to quadruple by the year 2050.[93,94] Alzheimer's disease (AD) is a disease of older age and is rare except for those with inherited forms prior to age 65. The disease doubles in prevalence every 5 years past the age of 65. The clinical features of AD were first described in 1906 by Alois Alzheimer;[95] more than a century later, the molecular basis of AD has been greatly elucidated, and enhanced diagnostic modalities have enabled clinicians to visualize neurologic changes secondary to AD.

The neuropathology of AD is characterized by neuritic plaques (extracellular beta-amyloid deposition) and neurofibrillary tangles (intracellular hypophosphorylated tau protein), coupled with a degeneration of neurons and synapses. In addition, cerebral amyloid angiopathy, inclusion of alpha synuclein (Lewy bodies and vascular brain injury), and loss of hippocampal pyramidal cells are commonly seen.[96–98] The most severe pathology associated with AD is atrophy, usually found in the medial temporal lobe structures and cortical areas of the brain.[99] While the exact pathogenesis of AD is unclear, an imbalance between the production and clearance of Aβ in the brain, termed the amyloid cascade hypothesis, is thought to be the disease-initiating event that ultimately leads to neuronal degeneration and dementia.[99] Studies have suggested a more complex pathophysiology regarding Aβ processing than previously thought.[93,100] Amyloid deposited around meningeal and cerebral vessels, termed amyloid angiopathy, may lead to cerebral lobar hemorrhages. The pathogenesis also involves tau, a microtubule-associated protein. Neurofibrillary tangles are twisted neurofilaments in neuronal cytoplasm that represent abnormally phosphorylated tau protein and appear as paired helical filaments by electron microscopy.[92] Tau protein is thought to aid in assembly and stabilization of the microtubules that convey cell organelles and glycoproteins through the neuron. In AD, tau becomes hyperphosphorylated and leads to sequestration of normal tau and other microtubule-associated proteins, thus impairing axonal transport and normal neuronal function. In addition, tau becomes prone to aggregation into insoluble fibrils that develop into tangles, further compromising neuronal function.[99]

The genetic basis of AD has been studied extensively, and specific genetic mutations have been implicated in both the familial and sporadic forms of the disease. Familial AD is an autosomal dominant disorder with onset typically prior to age 65 years. Mutations in the *APP* gene on chromosome 21 were the first to be identified as the cause of familial AD; subsequent investigations have demonstrated mutations in the presenilin 1 and 2 genes (*PSEN1* and *PSEN2*, respectively) that account for the majority of familial AD cases.[101,102] The most commonly reported gene associated with sporadic AD is apo-lipoprotein E (*APOE*) on chromosome 19, which is involved in cholesterol transport.[92,99,101] The e4 allele accounts for most of the genetic risk in sporadic AD.[99] Mutations of the sortilin-related receptor (*SORL1*) have been associated with both late-onset AD and sporadic AD.[93,103]

Clinical Manifestations

AD is a slowly progressive disorder represented by a continuum of clinical characteristics. It is a disease of the elderly; it is unusual to present prior to age of 60 unless a familial form is present. Updated clinical criteria recognize three stages of AD: (1) preclinical AD; (2) mild cognitive impairment due to AD; and (3) dementia due to AD.[104] Preclinical AD occurs before changes in cognition and everyday activities are observed and is primarily used for research purposes.[105] Cognitive impairment due to AD is characterized by mild changes in memory and other cognitive abilities that are noticeable to patients and families, but are not sufficient to interfere with day-to-day activities. Dementia due to AD is characterized by changes in two or more aspects of cognition and behavior that interfere with the ability to function in everyday life.[104] The initial signs of AD involve retrograde amnesia from progressive declines in episodic memory.[106] This may initially go unrecognized or be viewed as forgetfulness; however, as the disease progresses, memory loss begins to affect the performance of daily activities, including following instructions, driving, and normal decision-making. As AD progresses, the individual is often unable to work, gets confused and lost easily, and may require daily supervision. Language impairment, loss of abstract reasoning skills, and visuospatial deficits begin to interfere with simple, routine tasks. Advanced AD is characterized by loss of cognitive abilities, agitation, delusions, and psychotic behavior.[92] Patients may develop muscle rigidity associated with gait disturbances and tend to wander aimlessly. In end-stage AD, patients frequently become rigid, mute, incontinent, and bedridden.[99] Help is needed for basic functions, such as eating and dressing, and patients may experience generalized seizure activity. Death typically results from malnutrition, heart disease, pulmonary emboli, or secondary infections.[92]

Diagnosis

The formal diagnosis of AD requires histologic confirmation, which typical occurs post mortem, although clinical criteria exist. The clinical diagnosis should be entertained in any adult with onset of insidious and progressive memory decline and impairment of at least one other cognitive function in the absence of another confounding medical or neurologic disorder. Probable AD is defined by the decline or loss of the ability to function at work or at one's usual activities, onset of delirium or major psychiatric disorder, and cognitive impairment on objective bedside memory tests (includes the following domains: reasoning, judgment, ability to acquire and remember new information, language function, behavior, visuo-spatial abilities).[107] These bedside scales include the Mini-Mental Status Exam, Montreal Cognitive Assessment, and the standardized neurologic exam of the American Academy of Neurology. Possible AD refers to those who meet the criteria for dementia, but have another illness that may contribute to the neurologic status, such as hypothyroidism or cerebrovascular disease.[107]

Diagnostic analysis of CSF may show a slight increase in tau protein and a lower concentration of Aβ peptide compared with healthy individuals or those with other dementias. Electroencephalographic (EEG) studies typically demonstrate generalized slowing without focal features. Neuroimaging is important in evaluating suspected AD to exclude alternative causes of dementia, such as cerebrovascular disease, subdural hematoma, or brain tumor. MRI and CT typically reveal dilatation of the lateral ventricles and widening of the cortical sulci, particularly in the temporal regions.[101] Volumetric MRI uniformly demonstrates shrinkage in vulnerable brain regions, especially the entorhinal cortex and hippocampus.[101] Positron emission tomography (PET) can identify areas of hypometabolism in the temporal, parietal, and posterior cingulated cortices and has a high ability to differentiate AD from other dementias.[99] Slowly progressive decline in memory and orientation, normal results on laboratory tests, and neuroimaging showing only diffuse or posteriorly predominant cortical and hippocampal atrophy are highly suggestive of AD.[92]

Treatment

There is no cure for AD, and therapy is aimed at slowing the progression of the disease. Cholinesterase inhibitors are approved by the US Food and Drug Administration (FDA) to treat mild to moderate cases of AD and are considered the standard of care.[108,109] They provide a proven, modest symptomatic benefit for patients with AD. The three types of cholinesterase inhibitors currently available are donepezil, rivastigmine, and galantamine; these medications decrease

the hydrolysis of acetylcholine released from the presynaptic neuron into the synaptic cleft by inhibiting acetylcholinesterase, resulting in stimulation of the cholinergic receptor.[101] Common side effects of these medications include nausea, vomiting, diarrhea, weight loss, bradycardia, and syncope.[108] Memantine, a noncompetitive N-methyl-D-aspartate (NMDA) receptor antagonist believed to protect neurons from glutamate-mediated excitotoxicity, is used for treatment of moderate to severe AD.[108] Studies have demonstrated greater cognitive and functional improvement when memantine is used in conjunction with cholinesterase inhibitors compared to monotherapy.[110] Antidepressants, such as selective serotonin reuptake inhibitors (SSRIs), are commonly used to treat depression, which is often seen in the mild to moderate stages of AD.[99,111] Antipsychotic agents are used for those patients who display aggressive behavior and psychosis, especially in the later stages of the disease. Other agents that have been reported to be of clinical value in the treatment of AD include antioxidants, such as selegiline and α-tocopherol (vitamin E).[99,108,110] Currently, disease-modifying agents aimed at reducing Aβ production, preventing Aβ aggregation, promoting Aβ clearance, and targeting tau phosphorylation and assembly are being investigated for future clinical use in the treatment of AD.[110,112,113] Caregivers of patients with AD must be involved in the overall treatment, since they are responsible for maintaining the patient's general health and ensuring a meaningful quality of life; it is often necessary to provide educational, emotional, and psychological support to these individuals, as the task for caring for patients with AD can be extremely challenging.

Oral Health Considerations

Oral and dental health is a major issue in patients with AD, because significant deterioration in oral health status is commonly observed with advancing disease.[114,115] Patients with AD appear to be at higher risk for developing coronal and root caries, periodontal infections, temporomandibular joint abnormalities, and orofacial pain compared to healthy subjects.[116,117] Oral healthcare providers should be able to recognize symptoms of AD and refer patients for further medical evaluation, if necessary. Patients with AD can become frustrated, irritable, and possibly combative when confronted with unfamiliar circumstances or with questions, instructions, or information that they do not understand.[114] The presence of a caregiver may be beneficial, as they can verify patient information, interpret patient behavior, and alleviate anxiety.[116] The oral healthcare provider must approach AD patients with empathy and explain all procedures and instructions clearly, since communication is essential in the management of dental patients with AD.[118,119]

Patients with AD should be placed on an aggressive preventive dentistry program, including a 3-month recall, oral hygiene education, and prosthesis adjustment, as poor oral health status can have a negative impact on the systemic health and wellbeing of patients with AD.[120,121] Specially adapted products, such as modified toothbrushes and foam mouth props, may be useful for oral hygiene and provision of dental care in patients with AD.[116] It is recommended to complete restoration of oral healthcare function in the earliest stages of AD, because the patient's ability to cooperate diminishes as cognitive function declines.[114] Time-consuming and complex dental treatment should be avoided in persons with severe AD.[122]

Medications used to treat AD can cause a variety of orofacial reactions and potentially interact with drugs commonly used in dentistry. Cholinesterase inhibitors may cause sialorrhea, whereas antidepressants and antipsychotics are often associated with xerostomia. In addition, dysgeusia and stomatitis have been reported with use of antipsychotic agents.[114] Antipsychotic medications also increase the risk of involuntary jaw movements, which can lead to oral hard and/or soft tissue injuries (see Table 23-3).[37] Antimicrobials, such as clarithromycin, erythromycin, and ketoconazole, may significantly impair the metabolism of galantamine, resulting in central or peripheral cholinergic effects.[114] Anticholinesterases may increase the possibility of gastrointestinal irritation and bleeding when used concomitantly with NSAIDs.[114] Local anesthetics with adrenergic vasoconstrictors should be used with caution in AD patients taking tricyclic antidepressants, due to the potential risk of cardiovascular effects, such as hypertensive events or dysrhythmias.[110]

Table 23-3 Orofacial findings associated with alzheimer's disease.

Extraoral	Intraoral

• Orofacial pain
• Temporomandibular disorder
• Muscle rigidity
• Medication-induced reactions
  • Involuntary jaw movements—antipsychotics
	• Deterioration of oral health in advancing disease
	  – Increased risk of periodontal disease
	  – Increased risk of dental caries
	• Medication-induced reactions/side effects
	  – Sialorrhea—cholinesterase inhibitors
	  – Xerostomia—antidepressants, antipsychotics
	  ○ Increased risk of oral candidiasis
	  • Dysgeusia—antipsychotics
	  • Stomatitis—antipsychotics
	  • Hard/soft tissue injuries—antipsychotics

SEIZURE DISORDERS

Epidemiology and Etiology

An epileptic seizure is a "transient occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain."[123] The term *epilepsy* is a neurologic disease characterized by either an individual who has a known epileptic syndrome, or evidence that the patient's brain demonstrates a pathologic tendency to have recurrent seizures following the occurrence of at least one unprovoked seizure.[124] Epilepsy is considered resolved if a patient has been seizure free for more than 10 years while not using antiepileptic drugs (AED) for the last 5 years of this period.[125] The incidence of epilepsy in developed countries is approximately 50 per 100,000 people per year (approximately 1% of the US population), affecting over 75 million people.[126] Of these patients, 75% are untreated.[126]

The International League Against Epilepsy (ILAE) originally developed a classification system of epilepsies and epileptic syndromes based on the clinical features of seizure activity and associated EEG changes.[127] Subsequent revisions of the classification scheme have taken into consideration several other factors in classifying epileptic syndromes, such as focal or generalized onset, genetics, age at onset, and pathophysiologic mechanisms of disease.[128] Focal, generalized, and unknown seizures are currently the three major categories of seizure activity used in clinical practice.[128]

Onset of seizure activity may occur at any point throughout an individual's life, and etiology usually varies according to patient age. The most common seizures arising in late infancy and early childhood are febrile seizures without evidence of associated CNS infection; these generally occur between 3 months and 5 years of age and have a peak incidence between 18 and 24 months.[129,130] Isolated, nonrecurrent, generalized seizures among adults are caused by multiple etiologies, including metabolic disturbances, toxins, drug effects, hypotension, hypoglycemia, hyponatremia, uremia, hepatic encephalopathy, drug overdoses, and drug withdrawal.[131,132] Cerebrovascular disease may account for approximately 50% of new cases of epilepsy in patients older than 65.[133] Other etiologies for epilepsy include degenerative CNS disease, developmental disabilities, and familial/genetic factors.[131,133] Epilepsy occurs more frequently in individuals who have neurologic-based disabilities, such as cerebral palsy and autism.[134,135]

Six etiologic categories now exist for seizures: (1) structural, (2) genetic, (3) infectious, (4) metabolic, (5) immune, and (6) unknown; prior terms, such as symptomatic and cryptogenic, are no longer used.[124] Structural implies a structural lesion on neuroimaging in combination with EEG data, suggesting that the lesion is the cause of the seizure. Causes include stroke, trauma, or tumor. Genetic implies the existence of known or presumed genetic mutation(s) where seizures are a known complication of the genetic disorder that is the result of the mutation(s). This etiology includes some of the well-known genetic epilepsy syndromes, such as juvenile myoclonic epilepsy, or may include an unknown mutation but obvious familial inheritance pattern.[124] Infectious etiologies include neurocysticercosis, human immunodeficiency virus (HIV), cytomegalovirus (CMV), cerebral toxoplasmosis, and prior meningitis or encephalitis.[124] Metabolic etiologies are due to a metabolic disorder, with the core tenet being that a change in diet or supplementation may affect the disease course.[124] An immune cause of seizures is defined either by a causal autoimmune disorder such as paraneoplastic syndrome or by an immune therapy used to treat the immunologic disease.[124]

Clinical Manifestations

Classification begins with whether the seizure is focal (occurs in one hemisphere) or generalized (arises at some point in the brain and rapidly engages the entire brain network).[124] If the seizure onset is unclear, the seizure is defined as unknown.[124] The terms "partial" and "partial tonic–clonic" are no longer used.

Focal Seizures

Focal seizures, by definition, originate from the neural network in one hemisphere, and are further divided by whether the patient has a change in awareness. Awareness is defined by whether the patient knows what is going on around them during the seizure. The focal seizure is then further classified by the first, most prominent motor or nonmotor feature, which aids in the localization of the seizure onset in the neural network. Motor features include automatisms, atonic, clonic, spasms, myoclonus, tonic movements, and nonmotor features, including autonomic, behavioral arrest, emotional, cognitive, and sensory symptoms.[124] Motor automatisms are unconscious movements of the body and include licking of lips, rubbing of hands, picking at objects, walking, or undressing. Atonic motor events are a loss of motor tone and strength in a limb or other body part. Clonus indicates rhythmic movement of a body part, whereas myoclonus is irregular jerking of a limb or face on one side of the body. Spasm is a sudden flexion or bending of the trunk or extension of a limb for a few seconds. The final finding used in the classification of a focal seizure is whether the seizure evolves into a bilateral tonic–clonic seizure.

Generalized Seizures

Generalized seizures, by definition, arise at some point in the brain and rapidly involve the entire brain network. A change in consciousness is involved in all seizures, so they are first defined by the presence of motor or nonmotor

symptoms. Motor findings are subdivided similarly to those found in the focal seizures subtype, with the addition of a tonic–clonic subtype.[124] The typical tonic–clonic generalized seizure lasts less than 3 minutes. It characteristically begins with loss of consciousness, followed by the entire musculature contracting forcibly (tonic phase).[136] Contraction of the muscles of the larynx and forced expiration can produce a loud moan, often termed an "epileptic cry." Patients often become cyanotic during the tonic phase secondary to forceful closing of the mouth accompanied by forced continued expiration. The clonic phase follows the tonic phase, with the entire body rhythmically jerking for a period that usually lasts no longer than 1 minute. In the postictal phase, the patient may be unresponsive for minutes to hours, awakening gradually, often with no memory of the event.[136] Physical injury from falling or muscular convulsions and evidence of bladder emptying, tongue biting, or aspiration pneumonia are frequently experienced during the postictal phase.[129] Patients gradually regain consciousness and typically complain of fatigue and headache after a tonic–clonic seizure. Generalized tonic–clonic seizures may not abate spontaneously or may recur without the patient regaining consciousness. This condition is referred to as generalized convulsive status epilepticus and is considered a medical emergency due to the number of serious sequelae of this condition, including bodily injury, cardiorespiratory dysfunction, metabolic derangements, and irreversible neurologic damage.[137]

Generalized nonmotor seizures or absence seizures include typical, atypical, myoclonic, or eyelid myoclonic.[124] Absence seizures are characterized by seconds of unconsciousness with no loss of body tone, sometimes with eye fluttering, head nodding, or automatisms.[136] Patients suffering from absence seizures appear to be "daydreaming," although they often have the ability to continue performing a previously started motor or intellectual activity after cessation of the seizure activity. There is generally no postictal confusion in patients experiencing absence seizures. Absence seizures generally begin in childhood and up to 90% of patients with these seizures have a spontaneous remission before adulthood.[138]

Unknown Seizures

The unknown seizure type exists for seizures where the onset, either focal or generalized, is not known. They are further classified by the presence of motor or nonmotor features. If this information is not known, they remain unknown and are considered unclassified.[124]

Diagnosis

The primary goals of evaluating a patient with new onset of seizure activity are to (1) establish whether the reported episode was a true seizure; (2) determine the cause of the seizure by identifying possible risk factors and precipitating events; and (3) determine the need for AED therapy in addition to treatment of any underlying illness.[129] An in-depth history and physical examination are critical, as the diagnosis of a seizure may be based on clinical findings only. A complete neurologic examination is required for all patients with suspected seizure activity, including testing of cranial nerve function, assessment of mental status, and testing of motor function. Blood studies, such as a complete blood count, electrolytes, glucose, magnesium, calcium, paraneoplastic titers, and genetic testing, are performed routinely to identify metabolic, genetic, and immune-mediated causes of seizure activity.[139] Other useful screening tests include toxin screens to identify seizure activity due to drugs, and lumbar puncture to rule out any infectious immune (paraneoplastic) etiologies.

All patients with a possible seizure disorder are referred for brain imaging to determine underlying CNS structural abnormality and/or pathology. MRI is the diagnostic modality of choice for the detection of hippocampal sclerosis, malformations of cortical development, vascular malformations, tumors, and acquired cortical damage, all of which are common etiologies for structural seizure disorders.[140,141] Functional imaging, including nuclear medicine studies and functional MRI (fMRI), may help to localize focal structural abnormalities and aid in surgical planning.[141] CT is valuable for investigating intracranial calcification, skull fractures, and suspected CNS infection, which may not be as readily apparent on an MRI.[140]

An EEG is an important diagnostic tool for patients with suspected seizures and is helpful for classifying seizures, identifying the etiology of the seizure, and potentially aiding in the choice of AED treatment.[132,138] The EEG measures the electrical activity of the brain, interictal epileptiform discharges, and the presence of abnormal, repetitive, rhythmic electrical activity, having an abrupt onset and termination during the clinical event, defined as electrographic seizures, which confirm the diagnosis (see Figure 23-4).[129]

Treatment

Pharmacologic therapy is considered the mainstay of epilepsy treatment and the goal is to choose an AED that is most appropriate for the specific type of seizure activity, and to administer it in the proper dose to achieve control of seizure activity with minimal side effects.[130,142]

Multiple AEDs are currently available for the treatment of epilepsy and selection of a particular agent is often influenced by several factors, including medical comorbidities, side effects, drug availability, and cost.[138,142] Topiramate, phenobarbital, carbamazepine, and phenytoin are indicated for the treatment of focal seizures and generalized motor seizures.[131] Topiramate may cause bone marrow suppression

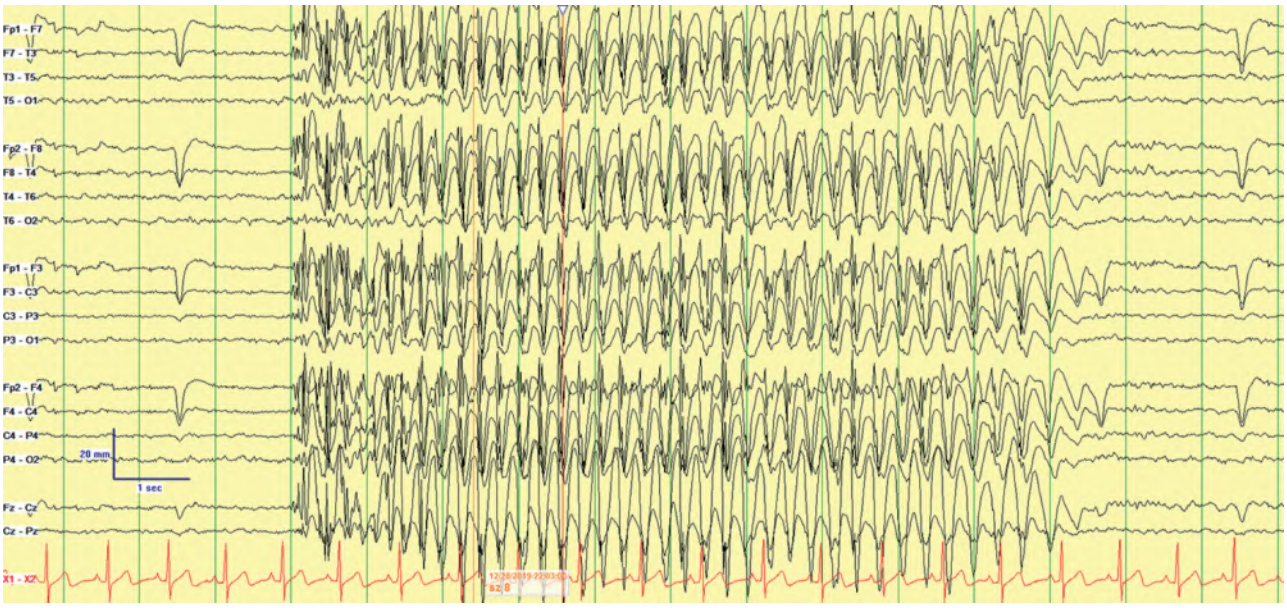

Figure 23-4 Electroencephalogram (EEG). EEG recording in the standard 10-20 system (double banana montage) of generalized 3 Hz spike-and-wave generalized myoclonic 10 second seizure. The patient had brief loss of consciousness and myoclonus of the extremities during the electrographic event.

and hepatotoxicity, which requires laboratory monitoring. Topiramate has significant cognitive effects at higher doses, but is used frequently in treatment of headache in addition to its use in treatment of seizures. Phenobarbital is a widely used drug world-wide because of its cost and long duration of action. Its main adverse side effect is sedation and effect on cognition. Phenytoin has a long half-life and is dosed less frequently than carbamazepine and lamotrigine, leading to increased patient compliance. Phenytoin is associated with gingival overgrowth, hirsutism, and coarsening of facial features. Carbamazepine can cause hepatotoxicity, leukopenia, and aplastic anemia. Next-generation carbamazepine-like drugs (eslicarbazepine and oxcarbazepine) have similar indications and side effects to carbamazepine, but have improved hepatic metabolism and drug interactions.[143]

Lamotrigine and valproic acid (VA) are indicated for treatment of focal and generalized seizures, including generalized absence seizures. Lamotrigine's major associated side effect is rash, with the potential of Stevens–Johnson syndrome. VA should be avoided in patients with preexisting bone marrow or liver disease. Levetiracetam, although not approved by the FDA for monotherapy for focal and generalized seizures, is nonetheless used clinically as a first-line drug for the treatment of these disorders in the United States due to its efficacy and safety profile.[144]

Ethosuximide has been shown to be particularly effective for the treatment of absence seizures. Perampanel, a novel AED influencing glutamatergic postsynaptic transmission, has been introduced as an adjunctive treatment for refractory focal seizures.[145] Clobazam and clonazepam are benzodiazepines that have long durations of action allowing once-a-day dosing, are indicated in the treatment of generalized seizures, and are used as adjunctive therapy. Sedation is the most significant side effect associated with their use.[144] Pregabalin and gabapentin are narrow-spectrum agents for the treatment of focal seizures, but the drug is used for the treatment of multiple other neurologic and pain disorders. It is typically well tolerated, with its major side effects being fatigue and sedation. Tiagabine is a relatively well-tolerated AED for adjunctive therapy for focal seizures. Zonisamide is a long-acting AED approved for the treatment of generalized seizures and as an adjunct for focal seizures. Zonisamide's major side effects are weight loss and sedation. Lacosamide has limited indication against focal seizure, with the major side effect being a dose-dependent PR interval prolongation.[144]

Discontinuation of pharmacologic therapy is considered when seizure control has been achieved. The following patient characteristics yield the greatest chance of remaining seizure free after discontinuation of drug therapy: (1) complete medical control of seizures for 1–5 years; (2) single seizure type; (3) normal neurologic examination, including intelligence; and (4) a normal EEG.[129] Many patients are often withdrawn successfully from medication after an interval of 2–4 years without seizures who meet the above criteria and who clearly understand the risks and benefits.[142]

In patients with refractory epilepsy, it often becomes necessary to use a combination of AEDs to attempt seizure control. Patients may use three or more drugs to successfully

treat refractory epilepsy; however, up to 30% of patients are resistant to all medical therapies.[145] Surgical procedures may be indicated for these patients, including limited removal of the hippocampus and amygdala, temporal lobectomy, or hemispherectomy.[129] Those patients who are not candidates for resective brain surgery may benefit from vagus nerve stimulation (VNS), which involves placement of an electrode on the left vagus nerve that receives intermittent electrical pulses from an implanted generator. Stimulation of vagal nuclei has been shown to lead to widespread activation of cortical and subcortical pathways and an associated increased seizure threshold.[146] Deep brain stimulation (DBS) and responsive neurostimulation systems (RNS) are also used for treatment of refractory epilepsy.[147] Gene therapy is currently being investigated as an alternative treatment modality for epilepsy refractory to standard therapies.[148,149]

Oral Health Considerations

Patients with seizure disorders are routinely evaluated and managed in the dental setting. This patient population has a higher rate of physical injuries, including dental and facial trauma, compared to healthy subjects.[150–152] In addition, patients with epilepsy demonstrate poor oral health and dental status compared to age-matched healthy subjects in long-term studies (see Figures 23-5 and 23-6).[153,154] A complete evaluation of a patient's seizure disorder is necessary prior to initiation of any dental treatment to determine the stability of the condition and an appropriate venue for treatment. Important features for the clinician to assess include the type of seizures, etiology of seizures, frequency of seizures, known triggers of seizure activity, presence of aura prior to seizure activity, and history of injuries related to seizure activity. If a patient demonstrates signs of poorly or uncontrolled seizure disorder, consultation with the patient's physician and/or neurologist is recommended.[155] Patients with poorly or uncontrolled seizure disorder may not be suited for outpatient dental care and should be referred to a hospital setting for routine dental care.[156] Patients with implanted VNSs do not require antibiotic prophylaxis prior to invasive dental procedures.[157] It is recommended not to use dental devices utilizing diathermy for these patients as it may interfere with VNS function.[158]

While providing dental care, it is prudent to avoid any known triggers of the patient's seizure activity. Patients with poorly controlled seizures often present with signs of intraoral trauma, such as fractured teeth and/or soft tissue lacerations.[157] Patients with poorly controlled disease or stress-induced seizures may require sedative medications prior to treatment; this should be determined in consulta-

Figure 23-5 Poor dentition in a patient with tonic–clonic generalized seizures.

Figure 23-6 Panoramic radiograph demonstrating poor dentition in a patient with tonic–clonic generalized seizures. Note fractured molar in left posterior maxilla and grossly decayed molar in left posterior mandible.

tion with the patient's physician.[157] To minimize risk of injury and aspiration during dental treatment, use of dental floss–secured mouth props (which are easily retrievable) and a rubber dam is recommended.[37,49] Placement of metal fixed prostheses is recommended rather than removable prostheses to decrease the risk of displacement and aspiration during seizure activity.[159]

AEDs can induce significant blood dyscrasias that can affect the provision of dental care. Several AEDs, including phenytoin, carbamazepine, and VA, can cause bone marrow suppression, leukopenia, thrombocytopenia, and secondary platelet dysfunction, possibly resulting in an increased incidence of microbial infection, delayed healing, and both gingival and postoperative bleeding.[142] Patients taking these medications may require laboratory evaluation prior to dental treatment, including a complete blood count with differential, to assess white blood cell and platelet counts, and coagulation studies to assess clotting ability. Patients on long-term carbamazepine should have serum blood levels evaluated prior to initiating dental treatment, as insufficient doses may result in inadequate seizure control and excessive doses have been associated with hepatotoxicity.[142] Aspirin and NSAIDs should be avoided for postoperative pain control in patients taking VA as they can enhance the possibility of increased bleeding.[160] There are no contraindications to local anesthetics, when used in appropriate amounts, in patients with seizure disorders.[90]

Gingival overgrowth is a significant oral complication among seizure disorder patients taking AEDs, most notably phenytoin.[161] The prevalence rate of gingival overgrowth varies and has been reported in up to 50% of individuals taking phenytoin.[161] The anterior labial surfaces of the maxillary and mandibular gingivae are most commonly affected and may be seen within 2–18 months after starting the medication (see Figure 23-7). Historically, this condition has been attributed to an increased number of fibroblasts in gingival connective tissue.[161] Studies have shown that phenytoin alters molecular signaling pathways that control collagen degradation by gingival fibroblasts, and that accumulation of collagen leads to clinically evident gingival overgrowth.[162] Inflammation can exacerbate this condition; therefore, frequent professional cleanings and use of an electric toothbrush are recommended to maintain optimal oral hygiene. Some clinicians advocate the use of chlorhexidine and/or folic acid rinses to minimize gingival inflammation among seizure disorder patients with gingival overgrowth.[163] Surgical reduction of gingival tissue may be necessary if significant overgrowth exists. In addition to gingival overgrowth, other oral side effects of phenytoin include development of intraoral lesions that clinically resemble lupus lesions and lip enlargement.[157,164]

Reduced salivary flow may result from the use of AEDs, and oral healthcare providers may observe increased frequency and/or severity of dental caries and oral candidiasis in patients using these agents. Topical fluoride should be considered for patients with seizure disorders who are at increased risk of developing dental caries, and antifungal agents should be prescribed if oral candidiasis develops. Additional oral findings in patients taking AEDs may include stomatitis, glossitis, and ulcerations (see Figures 23-8 and 23-9 and Table 23-4).[37,49]

AEDs, antiepileptic drugs.

PARKINSON'S DISEASE

Epidemiology and Etiology

Parkinson's disease (PD) is a chronic, progressive, neurodegenerative disorder characterized historically by its cardinal motor symptoms of resting tremor, rigidity, gait disturbance, and bradykinesia. A more contemporary view recognizes PD as a complex neurologic disorder with familiar motor symptoms as well as a broader spectrum of clinical features, including cognitive deficits, neuropsychiatric changes, and dysautonomia.[165–169] The disease is now divided into preclinical, prodromal, and clinical phases that impact management and diagnosis. The American Academy of Neurology has developed diagnostic, assessment, and treatment guidelines to distinguish idiopathic PD from "parkinsonian syndromes" such as corticobasal degeneration, progressive nuclear palsy, dementia with Lewy bodies, and Parkinson's disease dementia, which share similar symptoms but have different risk factors, pathologic processes, and clinical courses.[170,171]

PD is second only to AD among neurodegenerative diseases, as PD has a prevalence of approximately 1% and an annual incidence of approximately 446 cases per 100,000 population, with 50% fewer cases among African Americans and Asian Americans than among Caucasians.[172,173] Prevalence increases with advancing age, to a mean of 1.6% among individuals aged 65 years and older.[172,173] A population-based study of US Medicare beneficiaries reported significant differences in regional prevalence, with rates as high as 13.8%.[173] Areas with the highest rates included the northeastern coast and the Midwest/Great Lakes regions, where the highest prevalence was attributed to elevated agricultural and industrial exposure.[173] Mortality among elderly PD patients is 2–5 times that of age-matched controls.[173] The public health and economic burden for PD is significant and growing as the population ages, with annual costs in the United States exceeding $14 billion and prevalence projected to more than double by 2040.[174–176]

The pathology of PD is defined by the loss of dopaminergic cells in the pars compacta of the substantia nigra and presence of Lewy bodies in the brainstem.[177] The loss of dopaminergic cells leads to depletion of the neurotransmitter dopamine in the basal ganglia (caudate nucleus and putamen). Motor symptoms begin when cell loss reaches 60%–80%.[178] Lewy bodies, inclusion structures comprised of packed proteins (α-synuclein and ubiquitin) resulting from failed protein degradation, accumulate and displace essential neuronal organelles and are pathognomonic features of PD.[179,180] PD is a very heterogeneous disease in its clinical variations of motor and nonmotor symptoms, age of onset, progression, and response to therapy. The majority of PD is

likely caused by multiple factors resulting from an elaborate interplay of several genes, modifying effects by susceptibility alleles, environmental exposures, and gene–environment interactions, and their direct impact on the developing and aging brain.[181] Isolated genetic etiologies are likely only responsible for 5% of sporadic cases, with a handful of clearly identified mutations that conclusively cause monogenic PD.[181] Environmental factors and toxins appear to play an important role in the risk for PD: the protoxin n-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), used to develop animal models for testing new therapies in the human disease, has been shown to cause parkinsonism in both humans and nonhumans,[182–184] and pesticides, heavy metals, well water, woodworking, and head injury have also been linked.[177] Significant protective effects have been demonstrated for tobacco use and caffeine consumption.[183,185]

Clinical Manifestations

PD usually affects people over the age of 50, although it can occur at any age, and earlier cases occur more commonly in the familial forms of PD. PD is a progressive neurodegenerative disease and can be divided into three stages: (1) preclinical phase, where neurodegeneration has begun but the patient is asymptomatic; (2) prodromal phase, where symptoms are present but are insufficient to make the diagnosis; and (3) clinical phase, where parkinsonian symptoms are recognizable and meet the criteria for PD.[177] Premotor signs can be subtle, but typically occur to some degree in all cases of PD, including constipation, anosmia, REM sleep disorder, and depression.[177] The four cardinal motor signs of PD are resting tremor (in hands, arms, legs, jaw, and face), rigidity or stiffness (limbs and trunk), bradykinesia (slowness of movement), and postural instability or impaired balance and coordination.[177] These primary motor symptoms are often asymmetric, affecting one half of the body more than the other. Secondary motor symptoms include masked face, hypophonia, decreased blink, and arm swing. Between 30% and 50% of individuals with PD develop dementia and the majority also exhibit behavioral/psychiatric symptoms, including depression, anxiety, apathy, and irritability.[167,172] Autonomic dysfunction is common and can develop early, including orthostatic hypotension, constipation, urinary frequency and urgency, and abnormal sweating.[169] Sleep disorders are common and include insomnia, somnolence, restless leg syndrome, and REM sleep disorder.[186] As symptoms become more pronounced, patients become increasingly impaired. Though the rate of decline varies widely, PD is inevitably progressive and destructive. Age of onset is the strongest independent predictor of motor decline, with motor impairment occurring to the highest degree in late-onset PD.[170]

Diagnosis

There are currently no laboratory tests specific for idiopathic (classic) PD.[165] Clinical genetic markers are available for risk assessment where hereditary patterns of PD exist. Therefore, the diagnosis is based on the health history, neurologic examination, and response to levodopa therapy.[170] The presence of asymmetric primary motor signs and a good response to dopaminergic agents are a strong indication of the diagnosis. When symptoms are subtle and the presentation is incomplete, the diagnosis can be difficult. Differentiating classic PD from a variety of parkinsonian syndromes characterized by motor decline and/or dementia can be challenging.[170] Anatomic and functional brain imaging, CSF evaluation, and laboratory testing are often necessary to exclude other diagnoses.

Treatment

At present there is no cure for PD, but a variety of medications and procedures provide dramatic relief from the symptoms.[165,170,185,187] Therapies are based on symptoms, side effects, cost, and disease severity, along with the patient's age, functionality, values, and personal preferences.[188]

Dopamine replacement therapy using levodopa (used by neurons to synthesize dopamine), combined with carbidopa (delays the conversion of levodopa into dopamine until it reaches the brain), remains the initial gold standard.[177] Levodopa initially helps about 75% of patients, but not all symptoms respond equally to the drug; bradykinesia and rigidity respond best, whereas tremor may be only marginally reduced and impaired balance and other symptoms may not be alleviated at all. It is the best initial therapy in symptomatic patients over the age of 65.[188] Additionally, levodopa often has the unwanted side effect of increasing dyskinesias, which may occur more frequently as levodopa levels fall between dosings, so-called off periods. Levodopa/carbidopa has a half-life of about 1.5 hours, while longer-acting formulations of levodopa that are available may alleviate some of these off periods. The use of levodopa does not result in disease progression.[189]

Dopamine agonists such as bromocriptine, rotigotine, pramipexole, and ropinirole, alone or in combination with levodopa, may control PD symptoms and improve daily functioning better than treatment with levodopa alone. Dopamine agonists directly stimulate dopamine receptors and have longer half-lives. They unfortunately have a higher incidence of psychiatric side effects, including hallucinations and impulse control, as well as sleep disturbances, particularly in the elderly. Medical management can become challenging, as it commonly occurs that a medication that improves one symptom may worsen another.

Monoamine oxidase inhibitors (selegiline, rasagiline, and safinamide) have a modest effect on motor function, but are well tolerated and may be considered as an initial therapeutic option in those with mild disease.[190]

Amantadine is another well-tolerated medication that can be considered as an initial treatment with moderate efficacy for the motor symptoms of PD, particularly tremor. It can also be used for the treatment of "off-time" dyskinesias seen with levodopa therapy.[191]

Treatment of dementia, depression, and other psychiatric symptoms in PD can be challenging.[166] Rivastigmine, a cholinesterase inhibitor, is effective in treating PD dementia.[192] Clozapine, quetiapine, and primavanserin are effective for treating PD psychosis, but may worsen motor function.[193] Tricyclic antidepressants are typically avoided for treating depression due to their anticholinergic effects, but serotonin-norepinephrine reuptake inhibitors (SNRIs) or SSRIs are preferred for this common comorbidity.[193,194] Similarly, benzodiazepine medications often used to treat anxiety may worsen motor performance and confusion, while buspirone, SSRIs, and SNRIs are again preferred.[193,194] Alternative therapy, particularly exercise, has demonstrated significant benefit in physical conditioning, gait, balance, leg strength, and walking speed, with fewer falls.[195,196]

Surgical management of PD by DBS has shown excellent efficacy in patients who fail levodopa treatment or have refractory tremor, and has largely replaced lesioning procedures.[197] DBS is more often selected in younger patients with advanced PD or intolerable medication side effects. Embryonic stem cell research to provide transplantation, implantation, and gene therapy is an area of active investigation.[198]

Oral Health Considerations

Patients with PD present several challenges to the dental healthcare team and to the patient related to both the illness and its treatment, but the importance of maintaining optimal oral hygiene must be emphasized.[37,90] Patients with PD must often be treated in a relatively upright position, making complex dental procedures in the maxillary arch or posterior oral cavity a challenge. Resting tremors and drug-related dyskinesia can complicate procedures, and behavioral techniques to reduce anxiety as well as gentle cradling techniques can help. Dysphagia and impaired gag reflex increase the risk for aspiration of oral and irrigation fluids, and high-speed evacuation of fluids is important in reducing the risk for aspiration pneumonia. Some patients experience sialorrhea, making maintenance of a dry field difficult for some operative and surgical procedures.

Pharmacologic treatment for PD has implications of importance to dentistry. Levodopa and dopamine agonists can lead to both orthostatic hypertension and, rarely, severe hypertension; other side effects of particular importance to the dental team include mandibular and facial dyskinesia, xerostomia, arrhythmia, and blood dyscrasias.[90] Recent evidence suggests that PD patients managed with levodopa may experience impaired masticatory function.[115,199] Limiting use of local anesthetic with 1:100,000 epinephrine to two carpules in PD patients using catechol-O-methyltransferase (COMT) inhibitors for disease management is recommended, due to the potential for an exaggerated and prolonged pressor response to epinephrine.[37] Careful consideration and management include (1) monitoring of blood pressure; (2) correct positioning and repositioning during and after treatment; (3) xerostomia and caries risk reduction through hygiene; (4) sealants and fluorides when indicated; (5) impact of oro-mandibular dyskinesia on the design of dental prostheses, with strong consideration given to implant-supported fixed or removable prostheses to improve chewing and quality of life;[200] and (6) periodic evaluation of the complete blood count to detect drug-related hematologic adverse effects (see Table 23-5).

Table 23-5 Orofacial findings associated with parkinson's disease.

Extraoral	Intraoral
• Tremors • Involuntary mandibular and/or lip movement (dyskinesia) • Muscle stiffness/rigidity – Facial muscles – Masticatory muscles • Impaired masticatory function	• Gag reflex impairment • Dysphagia • Sialorrhea • Involuntary lip and/or tongue movement (dyskinesia) • Medication-induced reactions/side effects – Involuntary lip and/or tongue movement (dyskinesia)—levodopa and dopamine agonists – Xerostomia—levodopa and dopamine agonists ○ Increased risk of periodontal disease ○ Increased risk of dental caries ○ Increased risk of oral candidiasis

MYASTHENIA GRAVIS

Epidemiology and Etiology

Myasthenia gravis (MG) is an autoimmune neuromuscular disease that causes fatiguing weakness in ocular, bulbar, and skeletal muscles that increases during periods of activity and improves after periods of rest.[201] It can progress to involve the function of respiratory muscles in some patients during

severe exacerbations, resulting in respiratory failure requiring intubation and respiratory support. These severe episodes are termed myasthenic crises. The disease results from antibody-mediated, T cell–dependent attack of the postsynaptic neuromuscular membrane, resulting in loss and downregulation of acetylcholine receptor (AChR) along with damage and morphologic changes of the postsynaptic membrane.[202] This process results in impaired neurotransmission and fatiguing muscle weakness. Prior to effective therapy, death commonly resulted from respiratory failure and pneumonia.[203] Ocular weakness, presenting as fluctuating ptosis and/or diplopia, is the most common initial presentation of MG. Muscles of facial expression, as well as masticatory and swallowing muscles, are also affected early, resulting in facial asymmetry, dysarthria, and dysphagia.[203]

Several clinical MG subtypes are defined by clinical presentation, age at onset, autoantibody profile, and presence or absence of thymus pathology.[204] Discrimination among subtypes is important: clinical presentation and disease progression vary significantly, and recent evidence suggests differential treatment effectiveness.[204] Antibodies against the postsynaptic alpha-subunit of AChR are the most common mechanism of injury and result in AChR endplate destruction through complement activation.[205,206] In approximately one-third of MG patients without AChR antibodies, muscle-specific receptor tyrosine kinase (MuSK) antibodies are present.[207] The pathophysiology of MuSK, an autoantigen, is unclear in MG, but it has a role in the clustering of postsynaptic AChRs and their maintenance in the postsynaptic endplate is likely involved.[208] A seronegative MG subtype has also been recognized, but recent findings suggest this may represent a distinct subset with low-affinity IgG antibodies to AChR.[209] The AChR-related autoantibodies in MG are a T cell–dependent process and the thymus is felt to have a role in the pathogenesis of MG, although the exact mechanism remains unclear.[205,206] Thymic hyperplasia is common and approximately 10%–15% of MG patients have a thymic tumor (thymoma), which occurs equally in men and women, typically over age 50, tends to have a more severe clinical presentation, and exhibits high anti-AChR titers.[201]

The biologic and clinical heterogeneity of MG is reflected in a widely accepted classification system: generalized with early (under age 40) and late-onset disease or ocular disease only.[204] Generalized early onset tends to be female, with anti-AChR antibodies and thymic hyperplasia. Late onset tends to be male, with normal thymus glands. As the name implies, ocular MG is limited to the ocular muscles and tends not to generalize if weakness remains limited to ocular muscles for more than 2 years, regardless of anti-AChR titer.[204]

The estimated prevalence rate for MG is 15–20 cases per 100,000 population, with an estimated 60,000 affected patients in the United States.[203] However, the rate of MG diagnoses has increased every year for the past 50 years and probably remains underdiagnosed and underreported.[210–213] The most common age at onset is the second and third decades in women and the seventh and eighth decades in men, and as the population ages, males are more often affected than females, and the onset of symptoms is usually after age 50.[207,214] Pediatric MG is very rare.

Clinical Manifestations

The core clinical feature of MG is muscle weakness that worsens with exercise and improves with rest. Neck flexion weakness is more pronounced than extension and proximal musculature is often significantly affected. Severity of weakness typically fluctuates on a daily basis, but tends to worsen as the day progresses. A majority of MG patients present with ocular symptoms characterized by diplopia and/or ptosis.[201] Oropharyngeal, facial, and masticatory muscle weakness is common and results in dysphagia, asymmetry, and dysarthria, which are the initial symptoms in one-sixth of patients.[203] The clinical course of disease is variable, but usually progressive.[212] By 1 year after onset, 86% of ocular MG patients have gone on to generalized weakness.[215] Weakness limited to the ocular muscles for more than 1 year was unlikely to generalize in the future.[203] In general, MG patients experience an initial period of 1–2 years during which the disease reaches a maximum level of severity, followed by improvement for the majority.[215] Clinical exacerbations or crises may be triggered by several factors, including medications (antibiotics, magnesium, botulinum toxin, interferon alfa, penicillamine, quinine, beta-blockers, calcium-channel blockers, anesthetics, neuromuscular blocking agents), surgery, pregnancy, stress, heat, and viral infections.[216]

Diagnosis

The clinical examination and history are highly suggestive of MG. The most commonly used immunologic test to establish a diagnosis of MG quantifies serum anti-AChR, with a reported sensitivity of 80% for generalized MG and 50% for ocular MG.[206] The presence of other muscle cytoplasmic antibodies may raise the suspicion for thymoma[217] and CT/MRI imaging of the chest is highly accurate in detecting thymoma.

Diagnosis is confirmed by a variety of bedside, electrophysiologic, and immunologic tests. Administration of a Tensilon (edrophonium) challenge (rapid, resulting in immediate elevation of available Ach) is highly reliable in patients with ocular weakness and results in a brief increase in clinical function for a few minutes.[218] Electrodiagnostic testing is very helpful, particularly in antibody-negative cases. Abnormal decrementing compound muscle action potential following repetitive

nerve stimulation is present in 83% of generalized and 54% of ocular MG patients.[219] A special neurophysiologic test called single-fiber electromyography (EMG) can identify jitter (a neurophysiologic finding) in almost 100% of MG patients if performed on a weak muscle; its sensitivity is less given jitter presence in other neuromuscular disorders.[220]

Treatment

The goal of treatment in MG is to achieve remission or minimal symptoms with medications that result in minimal side effects. As with many autoimmune illnesses, treatment is directed at several levels, including reduction of pathologic antibody production or presence, and/or replacement/preservation of the pathologic antibody target (AChR). Anticholinesterase drugs, such as neostigmine and pyridostigmine bromide, increase acetylcholine availability and receptor binding and provide symptomatic benefit without influencing the course of the disease.[207] Anti-AChR-positive MG patients with thymus tumors may have dramatic improvement following thymectomy. MG patients have been shown to benefit clinically from thymectomy and it is recommended that all patients who develop MG are offered the procedure.[221] Plasma exchange and high-dose IV immunoglobulin can rapidly and temporarily reduce circulating antibodies and are very effective in crisis management.[222,223]

Patients with more severe symptoms or poor response to treatment have treatment using corticosteroids and nonsteroid immune suppressants to reduce antibody production and/or B-cell/T-cell lymphocyte activation/proliferation.[224] Corticosteroids, because of their rapid onset of action, are almost always used initially, particularly in patients who are resistant. Prednisone (60 mg/d) is typically started, paying special attention to the acute bulbar weakness associated with the medicine. Prednisone is slowly tapered over time to avoid long-term side effects, as other slower-acting but better-tolerated immunosuppressants such mycophenolate or azathioprine are added. Rituximab, a monoclonal antibody directed against the B-cell surface marker CD20, as in several other autoimmune disorders, has been shown to reduce B-cell counts, disease activity, and even result in remission.[225] Several reports have described its benefit for treatment of anti-MuSK MG.[203] Eculizumab, a complement inhibitor, has received FDA approval for AChR-positive MG that is refractory to other treatments.[226]

Oral Health Considerations

Orofacial signs and symptoms are prominent presenting features of MG, and dental clinicians are frequently in a position to recognize them and refer for diagnosis. Difficulty with prolonged opening and swallowing presents challenges in dental treatment delivery and the ability to tolerate treatment, and difficulty in chewing can affect diet and the design of prostheses. Implant-retained removable or fixed prosthesis may be preferable to tissue-supported prosthesis for improved chewing efficacy. Appropriate oral hygiene measures should be discussed and demonstrated to patients with MG to optimize oral health (see Table 23-6).[227]

Table 23-6 Orofacial findings associated with myasthenia gravis.

Extraoral	Intraoral
• Ocular symptoms – Diplopia – Ptosis • Muscle weakness – Ocular muscles – Facial muscles – Masticatory muscles – Neck muscles • Facial asymmetry • Dysarthria	• Muscle weakness – Oropharyngeal muscles • Dysphagia • Increased risk of opportunistic infections (bacterial/viral/fungal) due to immunosuppressants

Aspiration risks can be high and are often reduced by adequate suction, the use of a rubber dam, and avoiding bilateral mandibular anesthetic block. The MG patient may also be at risk for a respiratory crisis from the disease itself or from overmedication; if this is a substantial risk and dental treatment is necessary, dental treatment in a hospital should be considered where endotracheal intubation can be performed.[228] Emotional stress can precipitate myasthenic crisis, so dental professionals should make every attempt to minimize stress associated with dental visits.[227] Avoid prescribing drugs that may affect the neuromuscular junction, such as narcotics, tranquilizers, and barbiturates. Certain antibiotics, including tetracycline, aminoglycosides, and erythromycin, can affect neuromuscular activity and should be avoided.[227,228] Myasthenic crisis has been documented with use of fluoroquinolones in patients with MG and must be avoided.[227,228] Esther anesthetics that are metabolized by plasma cholinesterase should be avoided in MG patients on anticholinesterase therapy.

OROFACIAL DYSKINESIA/ DYSTONIA

Dyskinesia consists of involuntary movements with wide-ranging clinical features, including myoclonic jerks and tics, which can affect any part of the body.[229] Orofacial dyskinesia (ODk) is characterized by abnormal, involuntary, stereotypical movements of the tongue, lips, and jaw. ODk may be a factor contributing to muscle stiffness, TMJ degenerative changes, orofacial pain, mucosal lesions, damage to

teeth, and dental prostheses. Three types of ODk are recognized clinically: (1) tardive dyskinesia, (2) edentulous dyskinesia, and (3) spontaneous dyskinesia.[230]

Tardive Dyskinesia

The term tardive dyskinesia (TD) was introduced in 1964 to describe dyskinesia associated with antipsychotic medication.[231] The prevalence of TD in patients treated chronically with conventional antipsychotic medication is estimated to be approximately 20%.[232] Other classes of medications associated with TD include atypical antipsychotics, antiemetics, tricyclic antidepressants, and SSRIs.[230,233] Diagnosis of TD requires a minimum of 3 months of cumulative exposure to the offending drug and must persist for 3 months after withdrawal of the medication.[233] Striatal dopamine D2 receptor supersensitivity has been associated with the development of TD.[233] Clinically, patients with TD may present with tongue protrusion and twisting, lip puckering, and smacking and/or chewing movements.[233]

Edentulous Dyskinesia

Complete loss of teeth is associated with the development of edentulous dyskinesia (ED). Partial or complete loss of sensory receptors associated with dental and/or perioral structures, contributing to disruption of central proprioceptive function, is thought to be the cause of ED.[234] The general prevalence of ED is difficult to estimate due to lack of reported data.[230] Evidence suggests that patients with ED exhibit mild masticatory and labial movements compared to patients with TD.[230] Lack of denture replacements may also initiate this condition.[235] Intensity of movement and overall clinical improvement of disease may be observed in ED patients who wear properly fitted dentures.[230,234]

Spontaneous Dyskinesia

Spontaneous dyskinesia (SD) typically affects approximately 3% of the healthy elderly, with a higher prevalence in the elderly living in retirement homes.[233] A higher prevalence of SD has been reported in women and clinical presentation is typically mild, with combinations of tongue, lip, and jaw movements.[233] SD is associated with ill-fitting removable prostheses and also occurs in association with several CNS conditions, including AD, chronic schizophrenia, and autism.[233]

The emphasis in the management of ODk is on prevention, because no one treatment is predictably effective and safe. A dentist observing ODk in a patient taking drugs associated with this condition should inform the physician managing the medication. Palliative treatment using tetrabenazine, a central monoamine depleter, clonazepam, and baclofen has been tried.[235] Fabrication of dentures or replacement of ill-fitting dentures may be of benefit to patients with ODk.[230]

Oromandibular Dystonia

Dystonia is characterized by muscle contraction that may present in acute (transient contracture) or tardive (persistent contracture) forms.[229] Oromandibular dystonia (OMD) is a focal disorder characterized by involuntary and excessive contractions of tongue, lip, and jaw muscles. Primary (idiopathic) OMD is more common than the secondary form, which may be associated with medications, illicit drugs, CNS injury and/or neurodegenerative conditions.[233,236] The incidence of OMD is estimated at 7 per 100,000 persons in the United States, is more common among women, and the mean age of symptom onset is between 31 and 58 years.[233,236] Etiopathogenesis is thought to be related to dysfunction in the basal ganglia, abnormalities with signaling pathways, aberrant dopamine signaling, and/or modified brainstem and spinal cord inhibition.[236] Compared to ODk, OMDs are intermittent and observed as short, sustained muscular contractions resulting in abnormal movements.[233] In addition to typical clinical features, OMD may also be associated with dysarthria, dysphagia, and temporomandibular disorders.[236] Conservative treatment of OMD consists of physical and speech therapy, acupuncture, and biofeedback. Evidence suggests benefit with botulinum toxin A injections to affected musculature for the management of OMD, while central pharmacologic therapy appears to have a more limited role.[236] Limited evidence supports peripheral and/or central surgical interventions in the management of OMD.[236] Dental professionals should be able to identify patients with signs and symptoms suggestive of OMD and refer those individuals to appropriate healthcare providers for further evaluation and management. Occlusal appliance therapy for OMD patients with severe bruxism may be considered to mitigate tooth wear in appropriate cases.

Psychological and Psychiatric Aspects of Oral Health

J. Tim Newton, PhD
Beth J. Guildford, DClinPsy, PGDip

Patients seen in oral medicine departments commonly have conditions with features that can be challenging to live with and can be associated with distress. Examples of such features include pain or other unpleasant sensations, fatigue, chronicity, and altered facial appearance. Healthcare professionals working in this specialty have a vital role to play in taking a holistic approach to assessment and treatment. This chapter has five sections. In the first, the psychological management of patients with chronic orofacial pain is discussed in detail. Patients in pain (such as those with chronic orofacial pain and with burning mouth syndrome [BMS]) are among the most common presentations in dentistry and oral medicine. An understanding of the psychological processes involved in patients' interpretation of their pain, as well as the impact of chronic pain on mood and behavior, is critical to the care of these patients. The second section will outline psychological approaches applicable to people with orofacial pain, as well as to other long-term orofacial conditions commonly seen in oral medicine. The next section describes the psychological impact of changes in appearance, such as can occur in conditions including orofacial granulomatosis (OFG). The penultimate section deals with communicating difficult news to the patient (such as a diagnosis of oral cancer). The final section will provide an overview of those psychiatric conditions likely to present among the population of patients with orofacial conditions and the implications of each diagnosis for patient management.

PSYCHOLOGICAL ASSESSMENT AND MANAGEMENT OF INDIVIDUALS WITH OROFACIAL PAIN

The Biopsychosocial Model and Relationship to the Gate Control Theory of Pain

The biopsychosocial model is the most useful in clinical dentistry. The model suggests that the development and experience of illness are the result of the interplay of three broad groups of factors: biologic, psychological, and social (Table 24-1).[1] The biologic grouping includes genetic predispositions, evolutionary vulnerabilities, infective agents, and other biologic processes. The psychological factors include both behaviors and thoughts (cognitions) that

Burket's Oral Medicine, Thirteenth Edition. Edited by Michael Glick, Martin S. Greenberg, Peter B. Lockhart, and Stephen J. Challacombe.

Table 24-1 The biological, psychological and social factors that need to be taken into account in assessing a patient's clinical response to pain (the biopsychosocial model).

Biologic	Psychological	Social
Genetic predispositions	Behaviors	Living circumstances
Evolutionary vulnerabilities	Thoughts (cognitions)	Economic factors
Infective agents	Experience of psychosocial stress	Interpersonal factors
Other biologic processes	Beliefs about disease	Social support
	Symptom interpretation	

influence the onset of disease (for example health-related behaviors, the experience of psychosocial stress, beliefs about disease, and symptom interpretation) and the course of the disease.

Examples of thoughts that would have an impact on disease perceptions include beliefs about the ability to control symptoms, the extent to which symptoms are perceived as "normal" or "abnormal," coping strategies, and so on. Social factors cover living circumstances, economic factors, but also interpersonal factors that operate at the level of the person's immediate social group, including social support and engagement with the "sick role." Most illness is socially distributed—that is, related to the social gradient in society—with the experience of illness being more common in those who are most economically deprived, who may also have the fewest resources to address their illness. Furthermore, social support may ameliorate the impact of biologic disease processes.

The *gate control theory of pain* was proposed over 50 years ago by Melzack and Wall,[2] but has stood the test of time. The theory incorporates the biopsychosocial approach just detailed, with the assumption that the experience of pain is the result of a combination of physical, emotional, and cognitive components. The gate control theory is underpinned by an essentially physiological model of pain experience through the interaction of the peripheral and central nervous systems.

Melzack and Wall proposed that the dorsal horn on the spinal cord acts as a "gate" between the peripheral fibers and communication with the pain centers of the brain via the spinal cord. When the gate is open, the nerve fibers can transmit messages to the brain and thus pain is experienced. When the gate is closed, these pain messages are blocked. The gate can be opened and closed both locally and centrally; small fibers at the location of injury may inhibit or excite the gate, which can also be modulated by descending signals from the brainstem. As the brainstem is affected by cortical activity, then cortical activity can indirectly open and close the gate.[3]

Concordant with the biopsychosocial model, the gate control theory identifies three components of the pain experience. First, there is the sensory–discriminative component that gives information about the location, type, and intensity of the pain stimuli. The second is that the affective–motivational component characterizes the emotional responses to pain (such as anxiety, fear, or distress). Finally there is the cognitive–evaluative component, which refers to the interpretation or meaning that the individual ascribes to the sensory experience, and which is related to their characteristic pattern of thinking about their pain, their beliefs, expectations, and other cognitions concerning the pain, as well as the presence of psychological comorbidities such as depression. Together these interact to determine the individual experience of pain. Figure 24-1 summarizes the interaction of the sensory–discriminative component, the affective–motivational component, and the cognitive–evaluative component to form the experience of pain.

Assessments of the different dimensions have found that pain of different origins can be distinguished according to these dimensions. Melzack et al.[2] report that the pattern of reporting of the pain experience using the McGill Pain Questionnaire (MPQ; see later) was different for patients presenting with atypical facial pain compared with those with trigeminal neuralgia. Similarly, while the sensory component of toothache and the pain of BMS were reported to be similar, the affective–motivational and cognitive–evaluative components were different according to the two sources of pain.[4]

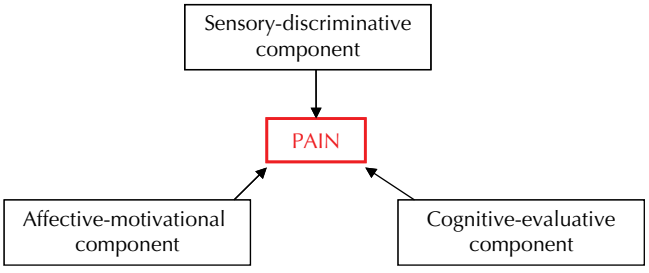

Figure 24-1 The components of pain as identified by gate control theory.

Psychological Assessment of Individuals with Chronic Orofacial Pain

The initial assessment of an individual with chronic pain should encompass the following areas:

- The pain experience.
- Psychological wellbeing (including the most common manifestations of psychological disturbance: depression and anxiety, as well as significant risks such as suicidal ideation).
- The impact of pain on functioning and wellbeing.

The Experience of Pain

The three broad components of pain as identified in gate control theory have implications for the comprehensive assessment and management of chronic pain. The McGill Pain Questionnaire was designed to assess all three components of the pain experience.[5] Patients are asked to select from a list of 78 pain-related adjectives (arranged in 20 groups) those that most accurately reflect their pain experience. Sections 1–10 explore the sensory component of the pain, sections 11–15 the affective component, and the evaluative dimensions are covered in section 16. There is also a miscellaneous set of sections (16–20). A single Pain Intensity item asks the patient to rate their pain on a six-point Likert scale (Present Pain Index, PPI), and finally there is a picture of a human figure facing forward and backward, and the patient is asked to shade those areas where they experience pain. The full MPQ takes approximately 15 minutes to complete. A short form is available that takes approximately 5 minutes to complete. The short form comprises 15 descriptive words taken from the MPQ, each of which is scored on a four point Likert scale, as well as the PPI and a Visual Analogue Scale to assess pain intensity. The short form correlates highly with the full McGill Pain Scale.

Psychological Wellbeing

The identification of coexisting negative impacts on psychological wellbeing, such as low mood or anxiety, is important in the assessment of an individual with chronic orofacial pain, since such issues may have an impact on adherence to medical advice, as well as exacerbating the negative impact of pain on everyday functioning and pursuit of valued goals by the patient. An impact on psychological wellbeing, although not inevitable, has been found to be increased above general population rates in orofacial pain, including temporomandibular dysfunction (TMD)[6] and BMS.[7]

Depression and Suicidal Ideation

Depression and depressive disorders are characterized by a disturbance in mood that is marked and of prolonged duration. It differs from the regular changes in mood that are experienced every day by duration and intensity. The disturbance in mood may take the form of sadness, flat mood, or an unusual degree of irritability. Depression is often accompanied by the experience of changes in the way in which the body is experienced: those affected may report increased aches and pains or a feeling of slowness, excessive sleep, and poor quality of sleep. Depression is accompanied by distinctive changes in the way the person thinks (cognitions), which are often characterized as being negative thoughts about themselves or their situation, and are perceived to be personal (the result of their own actions or character, rather than the situation in which they find themselves) and fixed (not susceptible to change).

The lifetime prevalence of depression and depressive symptoms is about 25% for women and 12% for men, though at any one time it is estimated that approximately 7% of the population will be experiencing marked symptoms of depression.[8] There are many questionnaire measures of depression available, and in considering which measure to adopt a key factor should be consideration of the extent to which the measure includes items relating to the somatic aspects of depression (aches, pains, difficulty sleeping, etc.). Such items may overlap with the individual's experience of pain and as such give an elevated score for the "depression" construct.

The most useful is the Patient Health Questionnaire (PHQ-9),[9] which is a brief measure that assesses nine diagnostic features of depression as identified in the Diagnostic and Statistical Manual of Diseases (DSM-5). The nine items also include a single item relating to suicidal ideation, which is an important risk to assess as part of the identification and management of depression. The scale can be administered over the phone and takes only a few minutes for the patient to self-complete. Scores range from 0 to 27, with higher scores indicating a greater severity of depressive symptoms. Where mild or moderate depressive illness is identified, the patient should be referred to psychological and/or psychiatric services for management. If suicidal ideation is identified during the risk assessment (i.e., the score for the single item on suicidal ideation is "more than half the time"), then an urgent referral should be made for assessment by a psychiatric team.

Anxiety

A patient faced with the uncertainty of the diagnosis of a chronic condition will inevitably be concerned for their future wellbeing and the impact socially in terms of family, friends, and work. Where the degree of anxiety becomes debilitating, this may have an impact on the individual's wellbeing and functioning. Anxiety disorders are manifest when the anxiety experienced is such as to have an impact on the individual's wellbeing; they are associated with high levels of autonomic arousal, hypervigilance, and avoidance behaviors, such as withdrawal from activities that might increase

the person's anxiety level. *Panic attacks* are a particular manifestation of anxiety whereby the physiologic and cognitive response to the fear becomes overwhelming.

A range of questionnaire measures of anxiety exist. The authors recommend the use of the Generalized Anxiety Disorder Assessment (GAD-7[10]). Developed by the same team as the PHQ-9, the GAD-7 is easy and quick to complete and gives a score in the range of 0–21, with higher scores indicating higher levels of anxiety. The scale has high levels of sensitivity and specificity in detecting anxiety disorders presenting in nonpsychiatric populations.[11] Where a moderate or marked level of anxiety is identified, the patient should be referred for psychological and/or psychiatric assessment.

Impact of Pain on Functioning and Wellbeing

An assessment of the impact of pain and any associated psychological changes on the individual's functioning is an essential part of the evaluation of chronic pain. People experiencing chronic pain conditions will often make adjustments to their lifestyle in order to incorporate their perceived limitations as a result of the pain experience. Some patients may benefit from a referral to a multidisciplinary pain rehabilitation program. A primary goal of any pain rehabilitation program is the recovery of physical and social functioning and psychological wellbeing, even in the absence of change in the sensory experience of pain. Measures of quality of life, health-related quality of life, and specific assessments of oral health-related quality of life are all available. The West Haven-Yale Multidimensional Pain Inventory (WHYMPI[12]) is a 52-item, 12-scale measure of three dimensions of the experience of chronic pain. Part I assesses the perceived interference of pain in vocational, social/recreational, and family/marital functioning; support or concern from spouse or significant other; pain severity; perceived life control; and affective distress. Part II assesses patients' perceptions of the degree to which spouses or significant others display solicitous, distracting, or negative responses to their pain behavior. Part III explores patients' report of the frequency of common everyday activities: household chores; outdoor work; activities away from home; and social activities. The WHYMPI provides a comprehensive assessment of the social and psychological impact of the individual's chronic pain, together with an identification of the thoughts, behaviors, and contingencies that may be maintaining the pain behavior.

As part of the overall clinical evaluation, it is important to explore any valued activities that the patient may have decreased or ceased as a result of their pain, since these can form the target of psychological interventions in the pain rehabilitation program.

PSYCHOLOGICAL INTERVENTIONS IN CHRONIC OROFACIAL PAIN AND OTHER LONG-TERM CONDITIONS

Psychological approaches are widely recommended for long-term health conditions, including chronic pain, in order to help people live with their condition more effectively. These approaches combine techniques to address the cognitive and behavioral manifestations associated with long-term health conditions. Appreciation of psychological techniques will help oral medicine clinicians to better manage these patients. Examples of common presentations in which it is helpful to have an appreciation of psychological techniques include those in which there is:

- Anxiety about the condition and/or its progression.
- Avoidance of activity, leading to reduced quality of life.
- Continued requests for further investigations or a cure, despite the condition being chronic and/or further investigations not being indicated.

Some patients may additionally benefit from referral to a psychologist for further assessment and a course of psychological therapy to address these issues in more depth.

Cognitive behavioral therapy (CBT) is an example of a brief psychological therapy with proven effectiveness. It uses both behavior modification techniques and cognitive restructuring procedures to change maladaptive beliefs and behaviors. Behavioral aspects of CBT include learning relaxation skills, conducting mini-experiments, pacing (building an awareness of cycles of energy and fatigue and arranging activity around those cycles), and behavioral activation (encouraging patients to engage in activities that they have previously avoided).

Cognitive aspects of the approach are based primarily in the analysis of people's cognitions (e.g., thoughts, beliefs, interpretations). The central concept is that the way people think about events plays a central role in their emotions (e.g., anxiety) and physiological responses and paves the way to establishing and maintaining unhelpful behaviors such as avoidance. Cognitive therapy therefore aims to facilitate a new understanding (cognitive restructuring) by the patient.

An important principle underlying CBT is its focus on the "here and now," as the origin of any behavior may differ from the factors that maintain it. For example, while pain may have originally arisen in response to a physical trauma, pain-related behavior such as avoiding housework or social isolation may be maintained by a fear of increased pain or by the secondary gain of avoiding an unpleasant activity. In contrast to other psychotherapies, CBT is a short-term therapy, with treatment typically lasting 6–10 sessions. Other

characteristics of CBT that set it apart from other therapies include the collaborative nature and structured approach of therapeutic sessions, and asking clients to spend time each day working on specific tasks in order to practice and establish the skills they have learned in their CBT sessions. The cognitive components of a CBT approach may include psychoeducation: learning more about the nature of their health condition and ways to manage it, challenging beliefs about their health condition (such as that the chronic pain they experience is not an indication of ongoing damage), and small-scale experiments to test beliefs, for example the patient testing for themselves in a small and systematic way whether increased activity would result in increased pain.

Acceptance and commitment therapy (ACT) is an advanced form of CBT that has been used successfully with patients with various long-term health conditions. Central to this form of therapy is the notion of "psychological flexibility," which is a concept that explores how flexible our thoughts and actions are in relation to the demands of the current situation. For many people everyday behavior is habitual and unreflective. This allows many of the day-to-day decisions about what to do to be made easily, without too much thought. However, when faced with an unusual situation or challenge (such as the experience of a long-term health condition), habitual and established patterns of thoughts and behavior may not be helpful. ACT uses notions of acceptance and mindfulness strategies, together with commitment and behavior change strategies, to increase psychological flexibility. Rather than concentrate on trying to change their situation, patients are encouraged to accept the current state of things and seek flexible strategies to move toward their valued goals. The great benefit of ACT for patients with long-term health conditions is acceptance of the current situation and an emphasis on return to activities that may have been suspended or avoided.

APPEARANCE-RELATED ISSUES

Psychosocial Issues Experienced by People with a Visible Difference

Some conditions such as oral cancer and OFG can be associated with changes in appearance, also commonly termed visible difference. Rumsey and Harcourt[13,14] give a detailed account of the psychosocial issues related to visible difference. In summary, visible difference can be associated with:

- Anxiety and depression.
- Negative self-perceptions and self-esteem.
- Challenging encounters with other people (e.g., staring), which can contribute to distress.
- Behaviors such as avoiding social situations. In the longer term, avoidance can compound distress.

Importantly, the level of psychosocial distress experienced by an individual is *not* related to the severity of the visible difference.[15] Factors that are associated with more positive psychosocial outcomes in people with visible difference include having good social support and effective communication skills.[13]

It should also be noted that the treatments for some of the conditions in which visible difference occurs can be demanding. Furthermore, physical functioning can be affected and the patient may be in pain. These factors can present additional challenges and sources of distress, alongside a visible difference.

Identification and Management of Psychosocial Issues

It is important for oral medicine clinicians to include assessment of psychosocial concerns as part of their consultation. Since clinicians' judgment of the severity of the visible difference is not an accurate predictor of psychosocial adjustment, it is important that clinicians do not make assumptions based on this; for example, referring somebody for psychological support simply because they have an objectively large visible difference. Example questions that can be used to identify patients' psychosocial needs are included in Box 24-1. Including questions about how patients feel about their appearance is an important part of normalizing their concerns, as well as recognizing when further support may be required. Organizations such as the UK charity Changing Faces can provide training and resources for health professionals in this regard.

As part of the consultation, questionnaires such as the PHQ-9 and GAD-7 can be used to screen for psychological distress. More specifically, the Derriford Appearance Scale-24 (DAS24[16]) is a widely used measure that assesses distress and

Box 24-1 Useful Questions to Aid in Identification of Psychosocial Needs

- Do you think your medical condition has affected your appearance?
- Have you stopped doing anything because of how you feel about your appearance?
- Are there any situations you avoid because of how you feel about your appearance?
- Has how you feel about your appearance affected your relationships with others? In what ways?
- What helps you cope? Have you got a supportive network of family and/or friends?
- What do you say or do if somebody asks you about your appearance?

dysfunction related to visible difference (such as distress at one's reflection and avoidance of social situations). The information from the questionnaires, in conjunction with discussion with the patient, can inform recommendations about psychosocial interventions (Bessell and Moss offer a review of psychosocial interventions for visible difference[17]). Self-help resources and support groups are among the interventions to which the clinician may direct patients. A smaller proportion of patients may require referral for psychological therapy, including CBT, and/or social interaction skills training. Social interaction skills training involves helping patients to feel more confident when interacting with others. For example, patients with facial alterations due to surgery or OFG learn ways to prepare for challenging social situations, such as when a stranger asks "What's wrong with your face?"

It is helpful if there is ready access to psychology professionals in Oral Medicine departments, both to provide consultation to the team and to see those patients who may need more support (such as CBT or social interaction skills training). Including a psychologist in multidisciplinary clinics is an effective and nonstigmatizing way to achieve this.

COMMUNICATING WITH PATIENTS

Effective Communication in Medical/Dental Settings

The way healthcare professionals communicate with patients can have a significant influence on patients' adjustment to their condition, their satisfaction with their care, health outcomes, and adherence to treatment. Riedl and Schüßler provide a systematic review of the influence of doctor–patient communication on health outcomes[18] and Newton reviews dentist–patient communication.[19] Useful models to aid communication in dental and medical settings have been developed and include the Calgary-Cambridge communication guide[20,21] and Scambler and Asimakopoulou's model of patient-centered care.[22]

Some principles of effective communication in dental/medical settings include the following:

- Avoid jargon, or make sure to explain it when its use is necessary.
- Include open-ended questions such as "What problem brought you to the hospital today?" to allow the patient to tell their story.
- Elicit and explore the patient's perspective. For example, ask about the patient's understanding of their health condition and about their perspective on the costs and benefits of the proposed treatment.
- Collaborate with the patient when discussing treatment choices.
- Demonstrate empathy. For example, let the patient know that it is understandable that they might be nervous about a potential treatment.
- Give opportunities for the patient and their family to ask questions.
- Summarize key information at regular interviews.
- Check that the patient has understood key messages by asking them to recap what has been said.

Breaking Difficult News

The oral medicine clinician will at times have to inform patients of difficult news, including diagnoses of chronic conditions (such as HIV) or of conditions with poor or uncertain prognoses (such as in some cases of oral cancer). The SPIKES protocol is a helpful framework to consider when breaking difficult news and has been shown to increase clinicians' confidence in doing so (Table 24-2).[23]

PSYCHIATRIC CONDITIONS IN ORAL MEDICINE

Individuals living with psychiatric disorders in general experience poorer oral health than those who do not have psychiatric disorders.[24] Those with three particular disorders (somatic symptom disorder, body dysmorphic disorder, and the eating disorders anorexia nervosa and bulimia nervosa) are especially prone to present with oral and dental symptoms and are discussed in detail here.

Somatic Symptom Disorders

The somatic symptom disorders are a group of psychiatric disorders where the patient presents with a physical symptom that cannot be explained or explained adequately by the individual's medical condition or the use of a substance, or another psychiatric disorder. The term "somatic symptom disorder" replaces the earlier term "somatoform disorder." Three broad criteria must be met for the diagnosis: there should be no medical or physical explanation for the severity of the symptom(s); the patient's concern in relation to the symptom(s) is out of proportion to the severity of the symptom; and the condition must have lasted in excess of 6 months (Box 24-2).[25] The group includes body dysmorphic disorder (BDD), which is discussed separately later.

Patients may present in oral healthcare settings with unexplained symptoms of this sort, including pain of unidentifiable origin. Diagnosis of somatic symptom disorder is achieved through the gradual and systematic refutation of alternative diagnoses. Management approaches typically include CBT, occasionally with the adjunctive use of pain-relieving medication.[26,27]

Table 24-2 The SPIKES framework.

Step	Details and Example Phrases
1 SETTING up the interview	• What? Make sure you have checked all the available information and have test results. Decide general terminology to be used • Where? Arrange for some privacy • Who? Who should break the news, should other staff be there or significant others? • Starting off. Introductions and appropriate opening
2 Assessing the patient's PERCEPTION	• Determine the patient's current perception of the situation, particularly of the seriousness of the condition • "What have you made of the illness so far?" • "What did your doctor/doctor X tell you when s/he sent you here?" • Note the language the patient uses and aim to use the same language in your responses
3 Obtaining the patient's INVITATION	• Ascertain how much information the patient would like at this time • "How much information would you like me to give you about your diagnosis and treatment today?" • "Are you someone who prefers to know *all* the details about what is happening?"
4 Giving KNOWLEDGE and information to the patient	• Give the patient some warning that difficult news is coming: "Unfortunately, I've got some difficult news to share with you" • Use the same language the patient uses • Give information in small chunks and check regularly that it has been understood: "Is this making sense so far?" • Modify the rate at which you provide the information
5 Addressing the patient's EMOTIONS with empathic responses	• Allow expression of emotion: "How does hearing this make you feel?" • Show empathy: "I understand that this news is distressing for you" • Allow silence • Do not argue
6 STRATEGY and summary	• Summarize the main points of the discussion • Make a plan or strategy and explain it • Identify the patient's coping strategies and reinforce them • Identify other sources of support for the patient and incorporate them • Invite questions • Tell the patient what happens next. Plan follow-up

Box 24-2 Criteria for Diagnosis of Somatic Symptom Disorder

- There should be no medical or physical explanation for the severity of the symptom(s).
- The patient's concern in relation to the symptom(s) is out of proportion to the severity of the symptom.
- The condition must have lasted in excess of six months.

Body Dysmorphic Disorder

BDD is a condition that falls within the scope of somatoform disorders in the DSM-5. It is manifest as a disproportionate concern about the appearance of a particular body part, or appearance in general. People with BDD are likely to present for cosmetic treatments. Among sufferers, the body part causing the most distress varies from person to person. However, there are certain areas that are more frequently cited as troublesome than others. These include nose, eyes, ears, balding, genitals, and breasts, and it is not uncommon for a patient to have an issue with more than one of these body parts at any one time.[28] Veale and colleagues report that 86% of patients diagnosed with BDD perceived themselves to have a facial defect, with 12% reporting specific dental defects,[29] while Phillips reports that 20% of sufferers had concerns about their teeth.[28]

The high levels of distress experienced by sufferers of BDD can sometimes lead to patients attempting to take their own life. In a study conducted by Phillips, it was found that about 80% of 185 subjects had experienced suicidal

ideation and 28% had a history of a suicide attempt, which was 45 times higher than levels experienced by the general population.[30] These extremely high rates indicate the necessity for dental professionals to screen for potential instances of BDD and to refer those experiencing such issues for psychiatric help immediately, rather than carrying out further medical or surgical treatment.

Guidelines on the treatment of BDD identify that any attempt to address the concerns about appearance through surgical care is contraindicated. Treatment options include the use of selective serotonin uptake inhibitors and CBT.[31] The clinician suspecting that a patient has presented with issues related to BDD should make a referral for psychiatric assessment.

Anorexia Nervosa and Bulimia Nervosa

Anorexia nervosa and bulimia nervosa are two psychiatric diagnoses that fall within the grouping of feeding and eating disorders within the DSM-5 classification. This group includes a variety of problems around food and eating, as well as some disorders with a marked similarity to anorexia nervosa or bulimia nervosa where the individual does not fulfill all the criteria for one of those diagnoses (Box 24-3).

All the criteria must be met for a diagnosis. The persistent behaviors referred to may include self-induced vomiting, laxative abuse, excessive exercise, and a variety of other behaviors alone or in combination.

For a diagnosis of bulimia nervosa, the criteria are:

- Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
  - Eating in a discrete period of time (e.g., within any two-hour period) an amount of food that is definitely larger than what most individuals would eat in a similar period of time under similar circumstances.
  - A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).
- Recurrent inappropriate compensatory behaviors in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, or other medications; fasting; or excessive exercise.

Box 24-3 Criteria for Diagnosis of Anorexia Nervosa

- Restriction of energy intake relative to requirements leading to a low body weight.
- Intense fear of gaining weight or persistent behaviors that interfere with gaining weight.
- Disturbance in the way a person's weight or body shape is experienced or a lack of recognition about the risks of the low body weight.
- Binge eating and inappropriate compensatory behaviors both occur, on average, at least once a week for three months.
- Self-evaluation is unduly influenced by body shape and weight.
- The disturbance does not occur exclusively during episodes of anorexia nervosa.

Note that self-induced vomiting in the presence of low weight is given a diagnosis of anorexia nervosa.

Among individuals who regularly induce vomiting, the most common oral manifestations are dental erosion, dental caries, and reduced salivary secretions leading to xerostomia.

Dental erosion is a frequent oral finding among bulimics. It is accepted that patients who self-induce vomiting are 5.5 times more likely to experience dental erosion than healthy controls.[32] Clinicians noting erosions in their clinical examination therefore need to have bulimia in mind as a possible diagnosis. While the primary factor leading to dental erosion is frequent vomiting, food choices may also have an impact on dental erosion. Bulimics are more likely to consume herb tea, soft drinks, and apple vinegar than healthy controls. Carbonated drinks are also frequently consumed, often to decrease the reflex stimulus for hunger.[33]

Self-induced vomiting may result in enlarged salivary glands, particularly the parotid glands. Prevalence estimates ranged between 0 and 80% of bulimia sufferers, but is very rare in age-matched control subjects.[34] Although they are commonly associated with vomiting, the precise causes of enlarged parotid glands among bulimics are unclear, though it is apparent that when present, their effect is to cause a reduced salivary flow rate, not an enhanced rate.

Data concerning the relationship between bulimia nervosa and caries experience are equivocal. Vomiting may have an effect on the risk of caries, both directly and as a result of reduced salivary flow rate. In addition, the food choices made by bulimics during a binge, which are largely carbohydrate based, will increase caries risk. In a young adult with reduced saliva flow and parotid enlargement, the presence of self-induced vomiting as a causative factor should be considered. Referral for a psychiatric opinion should be made if anorexia nervosa or bulimia nervosa is suspected.

CONCLUSIONS

Patients living with chronic orofacial conditions may experience elevated levels of psychological distress. The assessment of such distress together with the impact of chronic pain and other orofacial conditions on the patient's health and wellbeing is central to a holistic

biopsychosocial model of care. Psychological approaches can have great value in helping the patient return to valued activities. Certain psychological conditions may manifest as orofacial conditions—an awareness of these will help the clinician to direct the patient to appropriate sources of care and support.

Pediatric Oral Medicine

Catherine Hong, BDS, MS, FDS RCSEd
Christel M. Haberland, DDS, MS, FAAPD

A wide spectrum of soft tissue lesions of the oral maxillofacial region may occur in children and adolescents. Fortunately, the majority of pediatric pathologies are benign and the management of these conditions is relatively straightforward. As many of these conditions also occur in adults, the aim of this chapter is to focus on those that are more prevalent in children and to highlight the considerations specific to this population.

CONSIDERATIONS IN CHILDREN

According to the American Academy of Pediatrics (AAP), the upper age limit of "pediatric care" is 21 years, though exceptions may be made, particularly in an individual with special healthcare needs. Childhood development is grouped into early childhood (0–8 years), middle childhood (8–12 years), and adolescence (12–18 years).[1] The early and middle childhood stages may be further categorized into newborn (0–1 month), infant (1 month–1 year), toddler (1–3 years), preschool (3–5 years), and school-age (6–12 years) children. Stratifying childhood into stages is clinically relevant because the needs of patients in this group are constantly changing due to their rapid physical and cognitive development within a relatively short period. As such, certain unique considerations with regard to eliciting history, patient examination, and treatment may arise in this age group that are not relevant in adults.

Burket's Oral Medicine, Thirteenth Edition. Edited by Michael Glick, Martin S. Greenberg, Peter B. Lockhart, and Stephen J. Challacombe.

Eliciting History

There is pertinent content in a pediatric medical history that is not required for an adult. In addition, the value of certain aspects of the history changes in significance as the child transitions through the various developmental stages. For instance, prenatal history is an essential component of the history in an infant, but diminishes in importance in older children and adolescents.

History-taking is another aspect that is different in children and adolescents. For an infant and toddler, the history is obtained exclusively from the parent/caregiver; while for older children, the history is usually elicited from both the parent and the patient. The history-taker should be cognizant that parents and caregivers may be influenced by their frame of mind, emotional state, presumptions, and expectations, which may compromise the reliability of the history. Children above the age of 4 years are often able to supplement their parent's description with their own account. School-age children and adolescents can assume a larger role in being the main historian and the reliance on parents is further reduced. This is potentially a delicate situation and the history-taker needs to negotiate the process tactfully to avoid offending the parents or embarrassing older children/adolescents when sensitive topics are being discussed. Involving the child/adolescent in the interview process builds rapport and is the foundation for a successful and long-term patient–doctor relationship.

Patient Examination

It is recommended to gather as much information as possible from the parent, and through observation and interaction with the child prior to the examination. The factors that influence the child's compliance include past experiences, temperament, approachability, adaptability to the environment, and stage of cognitive development. There are several theories on how children evolve as they mature; the best known is Piaget's theory of cognitive development. The four stages of Piaget's theory correspond with age: sensorimotor (0–2 years), preoperational (2–7 years), concrete operational (7–11 years), and formal operational stage (11 years to adulthood). Behavioral management strategies are generally based on these theories. To maximize compliance for an examination, the practitioner should utilize the most appropriate behavioral management technique (Table 25-1) based on the child's developmental age, temperament, and past experiences.

Generally, children under the age of 3 years are pre-cooperative and behavioral management strategies have limited benefit. The goal then is to perform an examination in a gentle and time-efficient manner. For newborns and infants, clinical examination may be done on a flat surface or in the parent's arms. For older infants and toddlers, a "knee to knee" examination is commonly performed. The infant/toddler lays flat on both the examiner's and parent's laps, with the head on the examiner's lap and the lower half of the body on the parent. The child's legs hang loose or looped around the parent's waist. Children between the ages of 3 and 7 years are potentially cooperative and behavioral management strategies should always be employed. Children of these ages may be able to sit on the dental operatory chair independently for an examination. If the child is apprehensive, the parent may be invited to sit with the child on the dental chair.

Table 25-1 Behavioral management techniques and appropriateness by age.

Behavioral Management Techniques	Neonate/ Infant	Toddler/ Preschool	School-age
Nonverbal communication, e.g., appropriate contact, posture, facial expression, and body language	√	√	√
Voice control: controlled alteration of voice volume, tone, and/or pace	–	√	√
Tell–show–do: verbal explanations, demonstrations, and completion of the procedure	–	√	√
Modeling: direct observation of a video or another cooperative child undergoing the procedure	–	√	√
Positive reinforcement: praising desired behaviors	√	√	√
Distraction	√	√	√

Diagnostic Investigations

Ordering of diagnostic investigations is less straightforward in younger children for numerous reasons. In general, any investigation that rely on subjective response (e.g., pain on palpation or percussion) is less reliable in children. The ability to comply with an investigation is another consideration unique to this population. If a young child is unable to remain still for a radiographic imaging or will not allow blood to be drawn for a hematologic test, the practitioner then needs to decide whether the investigation is sufficiently critical to justify sedating the child (and exposing the child to the risk of sedation or general anesthesia) to complete the investigation. Another frequent parental concern is the risk of radiation exposure. The radiation exposure from dental radiographs is small and dental radiographs should be taken if the image finding will impact treatment. Although the radiation doses are higher with medical-grade imaging, the same principle will apply.

Treatment

As with adults, symptomatic, aggressive, potentially malignant, or malignant conditions in children should be managed immediately. The decision to treat asymptomatic, slow-growing, and likely benign lesions is less clear in a young child, especially when sedation or general anesthesia is needed. With a recent flurry of reports of potentially negative impact of repeated general anesthetics on the brain development of children under the age of 3 years,[2] the practitioner needs to weigh the pros and cons of performing the procedure under sedation, versus monitoring and delaying intervention until the child is able to comply for the procedure under local anesthesia.

Medications for oral medicine conditions are often prescribed "off-label" due to a lack of clinical trials.[3] Of the limited studies available, most are in the adult population. The effectiveness, safety, and adverse reactions of a particular drug in an adult may differ in a child, especially in those under the age of 2 years. As such, practitioners must exercise caution when prescribing a medication for a child, even if the same medication may have been found beneficial in an adult. Other considerations include the impact of the medication on growth and development, the need for dose adjustments in overweight and obese children as well as in newborns and infants due to immature metabolic processes, the potential for miscalculated doses, as well as the ability and the compliance of the child to adhere to the route and frequency of the prescribed regimen. A general guide to ascertain whether an off-label medication should be used in a child may be guided by these principles: (1) moderate- or high-quality evidence supporting the off-label use; and (2) obtaining informed consent whereby the rationale of using the medication, side effects, and alternative treatments are explained to the parent and the patient.

Consent

The consent process varies between countries. Practitioners should be familiar with and must abide by the local laws and regulations where they practice. In the United States, both the 1976 and 1995 AAP policies on informed consent stipulate that permission must be obtained from the parent or legal guardian prior to medical interventions for patients under 18 years of age.[4] The 1995 policy also states that older children and adolescents should participate in the medical decision-making process and provide assent to their care whenever reasonable.[5] Although assent is only mandatory for enrollment in research studies, the value of involving young patients in their own medical decision-making is increasingly being acknowledged. Assent may be obtained from children as young as 6–7 years of age. Assent involves explaining to the child in a language that they can understand as to what to expect with investigations and treatment, and encouraging questions to ensure that the child understands the situation. This process will help them become more involved in their medical care. While involving children and adolescents in medical decision-making is desired, they are vulnerable decision-makers. This is attributed to their neuropsychologic immaturity (e.g., adolescent behaviors such as sensation-seeking and risk-taking), influences from peers, and inexperience with decision-making, especially in complex and stressful situations. Thus, it is imperative that the parent/legal guardian remains the final decision-maker. When a treatment or intervention is deemed essential, assent should not be sought. Instead, the pediatric patient should be informed of the decision. Dissent by the pediatric patient will carry more weight for elective interventions or interventions that can be deferred without substantial risks or complications.

DEVELOPMENTAL CONDITIONS

Developmental Oral Cysts of the Newborn

Developmental oral cysts are common in newborns, with no gender predisposition. It is difficult to provide an estimate of the prevalence because of reporting bias as well as differences in study design, diagnostic criteria, and sample population between studies. Fromm classified developmental oral cysts based on their etiology and location.[6] Epstein pearls are located on the mid-palatal raphe, Bohn's nodules may be found at the junction of the hard and soft

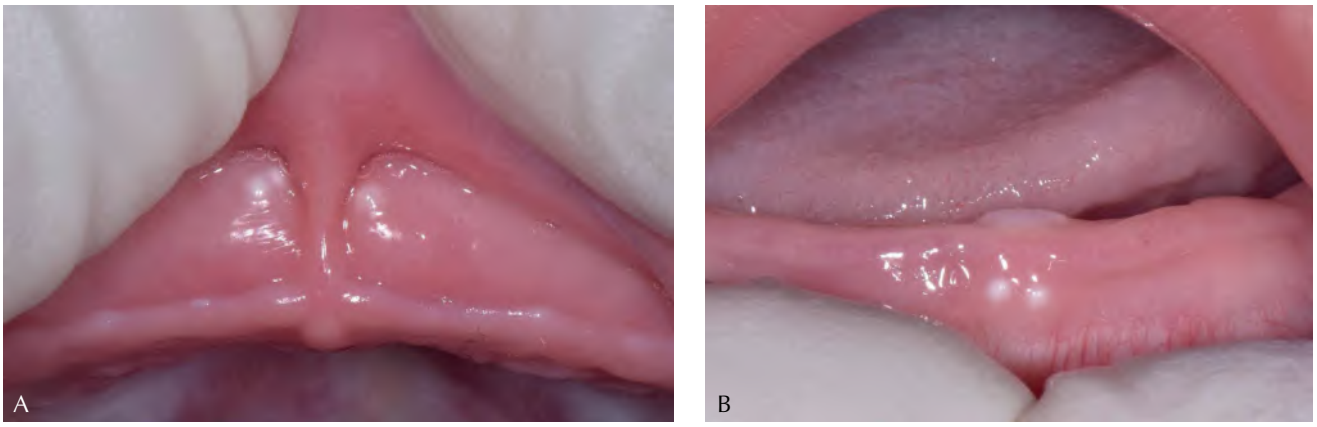

Figure 25-1 A, B. Developmental cysts of the newborn.

palate or at the vestibular region (rare), and dental lamina (gingival) cysts are found on the alveolar ridge crest. An Epstein pearl is thought to be a result of epithelium entrapment between the palatal shelves when they fuse in the midline in utero to form the secondary palate. Bohn's nodule is thought to be derived from the epithelial remnants of minor salivary glands.[7] Unlike Epstein pearl and Bohn's nodule, dental lamina (gingival) cyst (Figure 25-1) is odontogenic in origin and arises from the cell rests of Serres (remnants of dental lamina epithelium).[8] Of note is that these three terms are often used interchangeably, although the term "developmental oral cyst of the newborn" is preferable. Regardless of the origin and location, developmental oral cysts typically present as a single or multiple painless, small nodules filled with keratin, which imparts a white/yellowish appearance. The diagnosis is made clinically based on the presentation, location, and age. Developmental oral cysts of the newborn are benign and resolve spontaneously within the first few months of life, thus no treatment is needed.

Lymphangioma of the Alveolar Ridge

Lymphangiomas of the alveolar ridges (Figure 25-2) in infants were first described in 1976 and present as a single or multiple, fluid-filled, sessile, dome-shaped, bluish lesions on the maxillary or mandibular posterior dentoalveolar ridges.[9] The condition usually occurs bilaterally.[10] Lymphangiomas of the alveolar ridges have only been reported in infants of African descent, with a male predilection. The histologic examination reveals a proliferation of endothelial-lined lymphatic spaces. The diagnosis is often made clinically based on the presentation and ethnic predilection. No treatment is needed, as the lesions are benign and all cases have been reported to resolve spontaneously.[11]

Figure 25-2 Lymphangioma of the alveolar ridge.

Eruption Cyst

An eruption cyst is a benign odontogenic cyst that is considered to be a soft tissue variant of the dentigerous cyst. It is recognized as a separate clinical entity from a dentigerous cyst and is proposed to develop from the separation of the reduced enamel epithelium from the crown of the tooth.[12] The eruption cyst usually presents in the first decade of life and is commonly associated with the eruption of the permanent first molars and maxillary incisors. Clinically, the cyst appears as a soft, fluctuant, sessile, dome-shaped, translucent swelling overlying the crown of an erupting tooth. Occasionally, the swelling may appear blue or blue-black when it is filled with blood (eruption hematoma), likely attributed to trauma during function. The diagnosis is made clinically based on the presentation and temporal relationship with the eruption of a tooth. Radiographs are generally not necessary, as there are no characteristic findings. Furthermore, the cystic space cannot be visualized, as the cyst is entirely in soft tissue. The majority of eruption cysts are asymptomatic and rarely

require intervention. The cyst naturally marsupializes as the tooth erupts into the cystic space and through the gingiva. In individuals who complain of discomfort during mastication and in situations whereby the cyst continues to enlarge to cause discomfort, simple surgical removal of the roof of the cyst to expose the crown of the tooth under local anesthesia may be performed.

Congenital Epulis of the Newborn (Congenital Granular Cell Tumor)

The congenital epulis (CE) is a rare, soft tissue benign tumor (0.0006%) that occurs almost exclusively in newborns (Figure 25-3). The tumor occurs 8–10 times more often in females than in males.[13] The etiology is unknown, but there are several hypotheses regarding the origin of CE. The most popular ones are those that favor gingival and odontogenic epithelial origins.[14] Clinically, CE appears as a single, firm, smooth-surfaced, sessile or pedunculated, round, pink or reddish mass commonly occurring on the anterior maxillary alveolar ridge. Multiple tumors have been reported in a minority of cases.[15] CE does not appear to grow after birth and the majority are less than 2 cm, though tumors as large as 10 cm have been reported.[16] Large CE may interfere with feeding and cause airway obstruction. The granular cells in CE resemble the cells in granular cell tumor histologically (i.e., large round cells with abundant granular, eosinophilic cytoplasm, and round basophilic nuclei) and thus it is also known as congenital granular cell tumor. However, unlike granular cell tumor, CE does not display a strong reactivity to S100 protein.[17,18] A clinical diagnosis of CE is not difficult to make because of its presence at birth, appearance, and location. Nevertheless, histology is needed to confirm diagnosis. Spontaneous regression is rare.[17] Surgical excision is the treatment of choice and recurrence is unlikely even when the removal is incomplete.

Figure 25-3 Congenital epulis of the newborn.

Lingual Thyroid

Lingual thyroid is an ectopic thyroid gland found at the base of the tongue. This occurs as a result of the thyroid gland failing to descend to its normal anatomic site in utero. The incidence is approximately 1 in 100,000 to 1 in 300,000 live births and is 4–7 times more common in females.[19] Lingual thyroid may present as small asymptomatic nodules or a single large mass. The diagnosis is made by radionuclide imaging, ultrasonography, computed tomography, and magnetic resonance imaging. Most affected individuals do not require treatment.[19] Some individuals may be hypothyroid and require thyroid hormone replacement.[20] Over 70% of cases have no other functional thyroid tissue, thus surgical removal is contraindicated unless the structure is causing airway obstruction, bleeding, or shows cystic degeneration. The potential for malignant change appears to be similar to that of orthotropic thyroid tissues.[21]

Melanotic Neuroectodermal Tumor of Infancy

Melanotic neuroectodermal tumor of infancy (MNTI) is rare and only about 350 cases have been reported in the literature.[22] The tumor commonly occurs in children under 1 year of age. The majority of MNTI are benign, but a few malignant cases have been reported.[23,24] The high urinary levels of vanillylmandelic acid in individuals with MNTI support the neural crest origin of MNTI. Clinically, the tumor typically presents as a painless, nonulcerative, firm, smooth-surfaced, sessile swelling on the anterior maxillary alveolar ridge. The color varies greatly, ranging from mucosal colored with a bluish hue to a reddish-brown lesion. Although benign, MNTI grows rapidly and can infiltrate and destroy the adjacent bone and soft tissue. The histologic examination reveals two distinct cell types that form sheets, nests, or cords within a dense collagenous stroma.[25] The first cell type is a larger, cuboidal epithelioid cell containing melanin granules, generally found at the periphery of the tumor. The other cell type is smaller and round, with a hyperchromatic nuclei and scant cytoplasm. These cells tend to grow in nests and are surrounded by the larger cuboidal cells. The diagnosis is made based on the clinical presentation, high urinary vanillylmandelic acid, and histology. Surgical intervention is the treatment of choice. Recurrence ranges greatly, between 10% to 60%.[22,26] Younger age and surgical curettage were associated with the highest recurrence, while segmental resection was associated with the lowest recurrence.[26]

Vascular Anomalies

Vascular anomalies are common in newborns and the majority are benign and self-limiting. They are broadly categorized into vascular tumors and malformations. Vascular tumors are true neoplasms of endothelial cells, while vascular malformations are abnormalities of the vessel structure. Historically, the term "hemangioma" was used to describe any vascular tumor-like lesion; however, this definition should not be used when referring to vascular malformations.

Vascular Tumors

Infantile hemangioma (IH) is the most common benign vascular tumor in infancy. IH occurs in approximately 5%–10% of the population and is more common in low-birthweight (less than 1 kg) premature infants, females, and Caucasians.[27,28] The majority are on the skin and 60% occur in the head and neck region. Intraoral IHs are uncommon, but have been reported to occur on the tongue, buccal, and palatal mucosa as well as the gingiva.[29] The exact pathogenesis is unclear; the proposed origin of IH is thought to arise from the proliferation of endothelial cells or angioblasts, which is influenced by internal (e.g., dysregulation of vasculogenesis and angiogenesis) and external factors (e.g., tissue hypoxia). The behavior of IH is distinctive and is characterized by a proliferative phase followed by an involution phase. At birth, the majority of IHs are not evident, but they become apparent within the first few days or months of life. The proliferation is rapid for the first few months and slows down between the 6th and 12th months of life. Spontaneous involution typically begins after 1 year of age and approximately 90% of IHs completely involute by 9 years of age.[30] The rate and extent of involution vary greatly between cases. Complete involution does not always result in normal-appearing skin. About 50% will experience permanent changes such as scarring, atrophy, wrinkling, discoloration, and telangiectasia.

IH usually presents as a solitary lesion and the size ranges from a few millimeters to several centimeters. The clinical appearance varies based on the depth of involvement.[28] Superficial IH involves only the skin and is the most common. The lesion presents as a firm, rubbery, bright red papule, nodule, or plaque surrounded by normal skin that does not blanch on pressure. Superficial IH has been called "strawberry" hemangioma, but this term is discouraged as not all superficial IHs have the "strawberry" appearance. Deep IH involves only the subcutaneous tissue and appears as a raised, skin-colored nodule with a bluish hue. Combined IH typically displays features of both superficial and deep IH, as the lesion involves both the skin and the underlying subcutaneous tissue. The initial clinical sign of involution for a superficial IH is a color change from bright red to dark or violaceous red to gray, often beginning at the center of the lesion. For deep IH, the lesion becomes less blue and feels less warm. These descriptions are for skin lesions. To date, intraoral IHs are poorly described due to their rare occurrences and the inconsistency of how they are defined in the literature. Based on the available reports, intraoral IH appears as a soft, fluctuant, sessile, dome-shaped, erythematous mass that blanches slightly with pressure.[29,31] As with cutaneous IH, intraoral IH appears to involute; however, the changes during involution for intraoral IH are not well described.[29] The diagnosis of IH is often made clinically based on history and presentation. Imaging studies may be needed for deeper lesions. The majority of cutaneous IHs do not require treatment unless they are deemed to be unlikely to involute or are located in areas associated with significant morbidity (e.g., visual impairment in periorbital IHs). Intraoral IH may require intervention, especially if the lesion is on the tongue, which may interfere with mastication and speech.[29] In cases where intervention is indicated, the treatment modalities include topical (for superficial lesions) or systemic (for large lesions) propranolol, corticosteroids (intralesional or systemic depending on extent of lesion), laser treatment, and surgical removal.[28,32,33] PHACE syndrome (**p**osterior fossa anomalies, **h**emangioma, **a**rterial anomalies, **c**ardiac anomalies, and **e**ye anomalies) is an uncommon sporadic disorder that should be considered in an infant presenting with a large (>5 cm) segmental hemangioma, especially on the face, scalp, or posterior neck. The management of PHACE syndrome is based on the severity of the clinical manifestations and the risks associated with the arterial abnormalities.

Congenital hemangioma (CH), tufted angioma (TA), and Kaposiform hemangioendothelioma (KH) are other rare vascular tumors that occur in infancy and early childhood. Although these tumors look similar to IH, they behave differently clinically and are histologically and immunophenotypically distinct. Unlike IH, CH is fully developed at birth.[34] There are two variants of CH: rapidly involuting congenital hemangioma (RICH) and noninvoluting congenital hemangioma (NICH). RICH involutes within a few days to a few weeks after birth and usually completely disappears by 14 months of age. NICH does not regress and grows in proportion with general physical growth. A thorough history as to whether the lesion presented as a palpable mass (suggesting CH) or a flat/subtle area of discoloration at birth with a history of rapid postnatal growth will help to differentiate IH from CH. If a definitive diagnosis is needed, a histologic examination demonstrating a positive (IH) or negative (CH) immunohistochemical stain for glucose transporter protein-1 will differentiate the two entities. TA and KH are discussed together as they are believed to be part of the same spectrum. Unlike IH, they tend to be located on the extremities

or on the trunk. Both TA and KH typically appear as an indurated, reddish or purplish lesion with ill-defined borders. TA is absent or barely evident at birth, but will manifest over time. KH may be present at birth or develop during early childhood. KH is more locally aggressive than TA. Kasabach-Merritt phenomenon (KMP) is associated with 70% of KHs and 10% of TAs. KMP is a life-threatening condition characterized by severe thrombocytopenia and the consumption of fibrinogen and other coagulation factors.[35] There are case reports of TAs occurring in the oral cavity (e.g., tongue, floor of mouth), with the majority being located on the lip.[36–38] The diagnoses of KH and TA are made based on clinical, radiographic (magnetic resonance imaging), histologic, and laboratory findings (to rule out KMP). The management of TA and KH vary based on the size, location, symptoms, and whether the conditions are associated with KMP. The current treatment modalities are largely based on limited evidence and include observation for asymptomatic tumors, pulsed dye laser, surgical excision, and use of single- or multiple-agent chemotherapeutics (e.g., vincristine, sirolimus).

Vascular Malformations

Vascular malformations (VMs) are categorized by the International Society for the Study of Vascular Anomalies into (1) simple malformation consisting of only one type of vessel; (2) combined malformation defined as ≥2 VMs in a single lesion; (3) anomalies of major named vessels; and (4) VM associated with other anomalies (Table 25-2).[39] VMs are further divided based on the type of involved vessels and flow characteristics: low flow (capillary, venous, lymphatic, or combination) and high flow (arterial, arteriovenous). The diagnosis for small localized or superficial lesions is often based on history and clinical presentation. The use of imaging such as Doppler ultrasonography and magnetic resonance imaging may be needed to confirm the diagnosis of extensive and deeper lesions.

Approximately 50% of VMs occur in the head and neck region, with a slight female predisposition.[40] All VMs are present at birth, but may be clinically subtle. They become more apparent over time and grow proportionately with the infant's overall growth. VMs generally do not involute (with the exception of nevus simplex), and their growth may be influenced by trauma, infection, and hormonal changes.

Lymphatic Malformations

Lymphatic malformations (traditionally known as "lymphangiomas") are benign, low-flow lesions consisting of malformed, dilated lymphatic channels or cysts of varying sizes. These abnormal structures do not communicate with the rest of the lymphatic or venous systems, resulting in lymphedema, lymphangiectasia, and proliferation in the affected area. The majority of the lymphatic malformations are congenital and are due to the abnormal development of lymphatic jugular sacs. Acquired lesions are thought to arise as a result of trauma or respiratory infection. The reported incidence ranges from 1 in 500 to 1 in 4000 live births.[41] Lymphatic malformations are usually diagnosed at birth or before 2 years of age.[42] Two-thirds of the cases occur in the head and neck region.[43,44]

Table 25-2 Classifications of vascular malformations.

Vascular Malformations			
Simple	**Combined**	**Anomalies of Major Named Vessels**	**Associated with Other Anomalies (Not Exhaustive)**
1) Low flow • Lymphatic malformation • Capillary malformation • Venous malformation 2) High flow • Arteriovenous malformation (development)* • Arteriovenous fistula (acquired)*	Any combination of the four types of vessels (lymphatic, capillary, venous, or arteriovenous) or ≥2 vascular malformations in a single lesion, e.g., capillary–venous malformation, capillary–arteriovenous malformations	Affecting veins, arteries, or lymphatics of large caliber	1) Sturge–Weber syndrome 2) Klippel–Trenaunay syndrome 3) Capillary malformation–arteriovenous malformation syndrome 4) Cutis marmorata telangiectatica congenita 5) Macrocephaly–capillary malformation syndrome 6) Maffucci syndrome 7) Phakomatosis pigmentovascularis 8) Proteus syndrome 9) CLOVES (**c**ongenital **l**ipomatous **o**vergrowth, **v**ascular malformations, **e**pidermal nevi and **s**coliosis/skeletal/spinal anomalies) syndrome

*Although arteriovenous malformations/fistulas contain arteries, veins, and capillaries, they are not considered a combined venous malformation with an arterial malformation, but an entity involving several types of vessels.

Lymphatic malformations are classified into three types: microcystic, macrocystic (cysts >2 cm, formerly known as cystic hygroma), and mixed type. Microcystic lesions are commonly found above the level of the mylohyoid muscle, while macrocystic lesions are typically located below the level of the mylohyoid muscle and involve the anterior and posterior cervical triangles.[43,44] An intraoral lymphatic malformation is usually of the microcystic type and commonly presents on the anterior portion of the tongue. The condition presents as a cluster of multiple, small, firm, clear vesicles ("pebbly" or "frog's eggs" appearance) that may infiltrate the underlying subcutaneous tissues and muscles (Figure 25-4A). The vesicles sometimes appear red or purplish due to secondary bleeding from trauma. A macrocystic lymphatic malformation appears as a smooth, compressible swelling under normal or bluish skin (Figure 25-4B). The symptoms and the severity of complications vary based on the type, size, depth, and location(s) of the malformation. Fortunately, medically significant lymphatic malformations are rare. The main treatment objectives are restoration and preservation of function and esthetics. The treatment modalities range from observation, drug therapy (e.g., sirolimus), sclerotherapy, laser therapy, and radiofrequency ablation to surgical excision.[45,46] Small lesions that do not affect function and do not cause cosmetic disfigurement are managed conservatively. Large head and neck lymphatic malformations often require intervention, as they may obstruct the airway. Such lesions are extremely difficult to manage (e.g., high risk of complications, incomplete resection) due to their close proximity with adjacent vital structures.

Capillary Malformations

Capillary malformations are low-flow malformations of the dermal capillaries and postcapillary venules. There are two types of capillary malformations: nevus simplex (macular stain) and nevus flammeus (port-wine stain).[47]

Nevus simplex is a common condition affecting 40%–60% of newborns and presents as single or multiple, blanchable, pale pink to red patches with indistinct borders. The patch becomes more visible when the infant is crying. Nevus simplex typically occurs on the midline, commonly affecting the eyelid, glabella, and midline of the nape of the neck. Nevus simplex generally fades without treatment within 1–2 years.

Nevus flammeus affects 0.1%–0.3% of newborns and presents as a flat, pink or purple macule with variable blanchability that is most common on the face. The affected area typically has a unilateral distribution that does not cross the midline and frequently follows the distribution of the trigeminal nerve. Nevus flammeus does not regress and grows in proportion to the infant's growth, becoming darker and nodular ("cobblestone" appearance) with age. Nevus flammeus is usually an isolated condition, but may be associated with other abnormalities (e.g., glaucoma, central nervous system [CNS] involvement) or be part of a syndrome such as in Sturge–Weber syndrome. There are several reports of accompanying oral findings in individuals with facial port-wine stains and Sturge–Weber syndrome.[48,49] These manifest as unilateral hemangiomatous lesions occurring on the gingiva, lips, tongue, and palate. In a case series of 30 individuals with facial port-wine stains and corresponding oral lesions, hemorrhage after dental procedures appeared to be low.[50] The treatment objectives are esthetic improvement and prevention of complications. Pulsed dye laser is considered to be the standard of care for the treatment of nevus flammeus.

Venous Malformations

Venous malformations are the most common low-flow VMs. The malformation can affect any tissue, but primarily develops in cutaneous, subcutaneous, or mucosal tissues. Approximately 40% occur in the head and neck region.

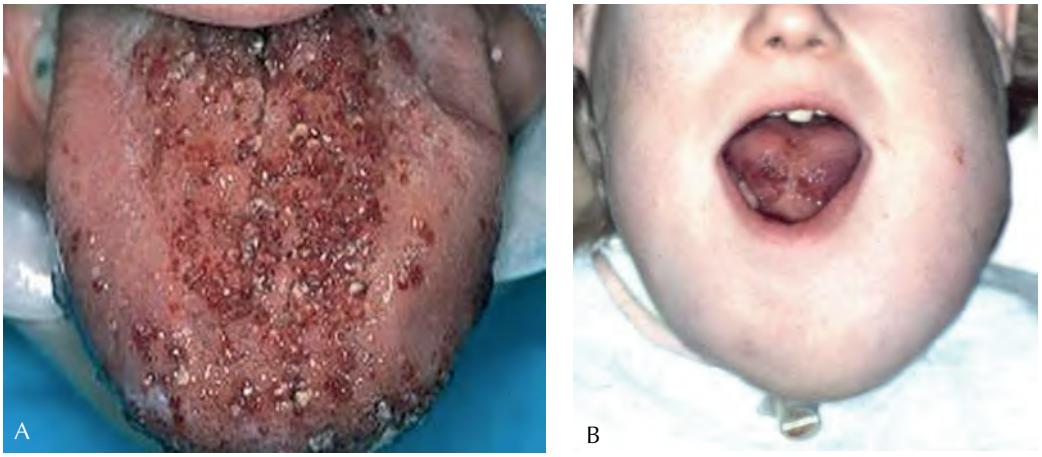

Figure 25-4 Lymphatic malformations. (A) Microcystic type. (B) Macrocystic type.

Figure 25-5 Venous malformation.

Intraoral venous malformation appears as a slow-growing, soft, compressible, bluish lesion that may swell with the Valsalva maneuver (Figure 25-5). Occasionally, phlebolith formation within a venous malformation may occur, thought to be due to trauma or venous stasis.[51,52] Intraoral venous malformations may cause speech and masticatory difficulties if they are on the tongue. Some may be life-threatening if they are close to vital structures. Venous malformation is frequently misdiagnosed as IH; a detailed history of the presentation at birth and the behavior in the first few months of life will help distinguish the two entities. The treatment modalities include sclerotherapy, laser therapy, compression therapy, and surgical resection.[53] The choice of treatment is based on the location and extent of the malformation as well as the individual's preference.

Arteriovenous Malformations

Arteriovenous malformations (AVMs) are high-flow VMs that occur due to the abnormal connections of arteries, veins, and capillaries, resulting in a direct arterial and venous communication. AVMs commonly occur in the head and neck region, but overall they are rare.[54] They are the most dangerous among all the vascular anomalies because they are associated with life-threatening complications. In the oral cavity, AVMs have been reported to occur on the tongue (most common), floor of the mouth, and palate, as well as the gingival and buccal mucosa.[55,56] An intraoral AVM appears as a soft, blanchable, red to bluish swelling, usually with a palpable thrill or audible bruit. Other oral findings include warmth, tissue expansion and destruction, ulceration, disfigurement, bleeding and pain. Clinically, AVM may be differentiated from IH by the continuous expansile growth after birth and from capillary malformation by the high-flow rate. The treatment objectives are to control the shunting effect and minimize clinical manifestations and complications. The treatment modalities include embolization and surgical management.[57]

Intraosseous Vascular Malformations

Intraosseous VMs are extremely rare. Fortunately, the majority of intraosseous VMs are predominantly venous malformations and AVMs are uncommon.[58–60] Intraosseous AVM is the more serious condition because of the risk for catastrophic hemorrhage after a dental extraction or a routine biopsy.[61–63] Affected individuals frequently present with pain, facial swelling and asymmetry, skin discoloration, loose teeth, bleeding from the gingival sulcus or associated with erupting teeth, and audible or palpable pulsations. Intraosseous venous malformation is a slow-growing, indolent mass with variable intraoral presentations depending on the location and extent. The condition may be totally asymptomatic or present with signs and symptoms similar but milder than that observed in an intraosseous AVM. Radiographically, intraosseous VM commonly appears as a unilocular or multilocular radiolucency, with each locule having a "soap bubble" or "honeycomb" appearance. A "sunburst" radiographic pattern may be observed with larger malformations. Teeth in the affected area may show root resorption. In addition to the treatment modalities for mucosal VMs, partial or total jaw resections may be indicated.[63,64]

Lip Anomalies

Cleft Lip and Palate

The incidence of cleft lip (CL) with or without cleft palate (CP) is approximately 1 in 700 live births.[65] About a quarter of cases are isolated CL (25%), 45% are CL with CP, and 30% are isolated CP. CL arises due to the failure of the medial nasal process to fuse with the maxillary process, while CP arises due to the failure of the palatal shelves to fuse. About 70% of CL with CP and 50% of CP cases occur as isolated entities, while the rest occur as part of a syndrome.[66] Hundreds of syndromes have been associated with CL with or without CP; the notable ones are van der Woude syndrome, Stickler syndrome, chromosome 22q11 deletion, oral–facial–digital syndrome type 1, and Treacher Collins syndrome. Nonsyndromic CL with or without CP is most frequent in males, while isolated CP is most typical in females. The risk of nonsyndromic CL with or without CP is associated with several maternal risk factors

such as tobacco and alcohol use, folate deficiency, obesity, stress, viral infections, and medications.[66] The clinical phenotype varies widely and is dependent on the number of structures affected, complete or incomplete presentation, and unilateral or bilateral involvement. The teeth near or within the cleft are often missing or malformed (typically the maxillary incisors). Early management include feeding and airway management, as well as surgical repair of lip and palate at 3 and 6 months of age, respectively. Additional surgery, speech therapy, and orthodontic treatment are often needed in later years.

Lip Pits

Commissural lip pits are small, unilateral or bilateral invaginations at the corners of the mouth on the vermillion border. They may extend up to a depth of 1–4 mm. Although considered developmental, they are often incidentally discovered in adulthood during a routine examination. No treatment is needed.

Paramedian lip pits (Figure 25-6) are rare congenital, bilateral symmetric depressions in the vermillion border of the lower lip. The most significant finding of paramedian lip pits is their autosomal dominant inheritance and their association with syndromes, most commonly van der Woude syndrome (characterized by lower lip pits, CL with or without CP, and congenitally missing premolars).[67] The treatment is directed toward problems associated with the congenital defects (e.g., CL, CP) or for esthetic reasons.

Tongue Anomalies

Ankyloglossia

Ankyloglossia or tongue tie is a developmental abnormality characterized by a short lingual frenum or a frenum attachment at or near the tongue tip, resulting in restricted tongue movement. Posterior ankyloglossia is a widely used term to specifically refer to a frenulum attachment at the middle to posterior aspect of the undersurface of the tongue. The use of the term "posterior ankyloglossia" is discouraged, because the frenulum attachment may be normal in these cases and the associated feeding difficulties are likely caused by other factors. The term "symptomatic ankyloglossia" is thus more appropriate. The reported prevalence of ankyloglossia ranges widely from <1% to 12%, with a male predilection.[68,69] The diagnosis has increased significantly in the past two decades due to the increased advocacy of breastfeeding coupled with the awareness of the impact of ankyloglossia on breastfeeding.[70]

There are generally two classification systems used to grade ankyloglossia severity: those that utilize anatomic criteria such as point of tongue attachment and length of frenulum (e.g., Coryllos system, Kotlow system) and those that incorporate function in addition to anatomic criteria (e.g., Hazelbaker Assessment Tool for Lingual Frenulum Function, Bristol Tongue Assessment Tool).[68] Classification systems that incorporate function are generally preferred, but so far none is universally accepted. The clinical examination often reveals the presence of a heart-shaped tongue on protrusion or the inability of the tongue to touch or protrude beyond the vermillion border. Infants with ankyloglossia are reported to experience more difficulty with breastfeeding. In such cases, frenotomy, which involves elevating the tongue, isolating the frenulum with a retractor/gloved fingers, and cutting of the frenulum with scissors, may be performed. Hemostasis is easily achieved with the application of pressure with gauze. Frenotomy may also be carried out with a laser or electrocautery. A randomized clinical trial concluded that topical anesthesia is not beneficial for pain relief. Instead, 24% sucrose solution given orally before the procedure accompanied by postprocedure nonnutritive sucking can help reduce discomfort.[71] Complications are rare, but may include bleeding (most common), pain, injury to the Wharton ducts, infection, and recurrence. The association between ankyloglossia and articulation problems, malocclusion, gingival recession, and mandibular growth is not clearly defined. A recent systematic review concluded that there was insufficient evidence to support frenotomy for these conditions.[72,73]

Figure 25-6 Paramedian lip pits and bilateral cleft lip and palate in a patient with van der Woude syndrome. *Source*: Courtesy of Dr. Chng CK.

Tongue Size Anomalies

Macroglossia is characterized by an abnormally large tongue. Pseudomacroglossia is a condition in which the tongue size is normal, but appears large in relation to adjacent structures. Microglossia is a rare condition characterized by an abnormally small tongue with an unknown etiology. There are only approximately 50 cases reported in the literature. Microglossia is often associated with a small

Table 25-3 Congenital causes of abnormal tongue size.

Macroglossia	Microglossia
Beckwith Widerman syndrome	Oromandibular limb hypogenesis syndromes
Congenital hypothyroidism	• Charlie M syndrome
Congenital idiopathic macroglossia	• Hypoglossia–hypodactylia syndrome
Trisomy 21* (Down syndrome)	• Mobius syndrome
Glycogen storage disease type 2	
Mucopolysaccharidosis	
Multiple endocrine neoplasia type 2B	
Neurofibromatosis	
Vascular malformations	

*There is debate with regard to whether a protruding tongue in children with Trisomy 21 is caused by true macroglossia or poor muscular tone.
Refer to Online Mendelian Inheritance in Man for complete lists: https://www.ncbi.nlm.nih.gov/omim/?term=macroglossia; https://www.ncbi.nlm.nih.gov/omim/?term=microglossia.

mandible, atrophic mandibular ridge, and missing incisors. The common developmental causes for both conditions are listed in Table 25-3. The need for intervention depends on the etiology and severity of the condition.[74] Treatment is warranted for a grossly enlarged tongue if there is ulceration and necrosis of the tip of tongue, airway obstruction, and swallowing difficulties. The treatment modalities include orthodontics and/or surgery (i.e., glossectomy).

Fissured Tongue

Fissured tongue is characterized by shallow or deep grooves or fissures on the dorsum of the tongue. The prevalence ranges greatly between 0.6% to as high as 30% in some parts of the world.[75,76] Although considered a developmental condition, it is observed more frequently in adults. The condition is generally asymptomatic and does not require treatment. Deep fissures can trap food debris and individuals may complain of slight discomfort due to inflammation or secondary fungal infections. Affected individuals are encouraged to gently brush their tongue daily to prevent the recurrence of symptoms. Antifungals may be prescribed if needed. Fissured tongue has been associated with benign migratory glossitis (geographic tongue), Trisomy 21 (Down syndrome), and Melkersson–Rosenthal syndrome.[77–79]

Retrocuspid Papillae

The retrocuspid papilla is a small (2–3 mm), moderately firm, smooth-surfaced, sessile, round, pink (normal gingival color) to red papule located on the attached lingual gingiva of the mandibular canine. They often occur bilaterally and are observed more frequently in children and females. The reported prevalence ranges from 25% to 80%. The histologic examination reveals large, stellate-shaped, multinucleated fibroblasts that are similar to those observed in giant cell fibroma.[80] The diagnosis is made clinically based on the bilateral presentation and location. Retrocuspid papillae are asymptomatic and spontaneously resolve with age. No treatment is needed.

Café-au-Lait Pigmentation

Café-au-lait pigmentation appears as well-circumscribed, uniformly light to dark brown skin macules that are typically two to three shades darker than the normal skin color. They vary from a few millimeters to ≥10 cm and can occur anywhere on the body. Café-au-lait pigmentation is often present at birth or appears in the first months of life. Isolated macules are common and usually have no clinical significance. However, multiple café-au-lait spots or macules should prompt evaluation for underlying genetic disorders such as Peutz–Jeghers syndrome, McCune–Albright syndrome, or neurofibromatosis type 1.[81,82] The outline of the café-au-lait spots may provide a clue as to the underlying genetic disorder. Café-au-lait spots in McCune–Albright syndrome have characteristic irregular borders analogous to the coast of Maine, unlike the smooth borders of the hyperpigmentation in neurofibromatosis, which is analogous to the coast of California. Multiple mucosal pigmentations on the lips and buccal mucosa have also been observed in these genetic disorders.[83] Of these disorders, perioral pigmentation is a prominent feature in Peutz–Jeghers syndrome. The intraoral pigmentation associated with genetic conditions, especially those on the buccal mucosa, do not fade and tend to persist with age.[81] Another case report suggested that intraoral pigmentations associated with genetic disorders appeared to develop later in life compared to the cutaneous café-au-lait pigmentation.[84]

Congenital Lingual Melanotic Macule

Congenital lingual melanotic macule (CLMM) is a rare benign condition that was first described in 2003.[85] The prevalence is unknown. CLMM (Figure 25-7) is present at birth and appears as a homogeneous or heterogeneous, 2–5 mm brown or black macule on the midline or the lateral border of the tongue. The size appears to increase with the infant's

Figure 25-7 Congenital lingual melanotic macule.

growth. The histologic examination reveals increased melanin deposition in the basal cell layer and varying degrees of hyperkeratosis.[86] The diagnosis is often made clinically based on the characteristic appearance and the presence at birth. No treatment is required other than routine reviews to ensure that the macule has not rapidly increased in size or demonstrated any signs of induration or ulceration. A biopsy is indicated if the macule displays these signs and symptoms.

Physiologic Pigmentation

Physiologic pigmentation is common among darker-skinned individuals and results from an increase in melanin production. The attached gingiva is the most common location, where it appears as a homogeneous, ribbon-like band of light brown to almost black pigmentation. Physiologic pigmentation may be observed elsewhere in the oral cavity, including the tips of the fungiform papillae. The color appears to darken with age. The diagnosis is made clinically and no treatment is required.

Genetic Disorders with Significant Oral Mucosal Findings

Hereditary Gingival Fibromatosis

Hereditary gingival fibromatosis (HGF) is a rare condition characterized by a slow, progressive gingival enlargement due to the collagenous overgrowth of connective tissue. The incidence ranges greatly between 1 in 175,000 to 1 in 750,000 live births. HGF may be an isolated disorder with an autosomal dominant or recessive mode of inheritance (less common), or may occur as part of a syndrome (Table 25-4).[87] The gingival enlargement is asymptomatic and the enlarged gingival tissue is firm, fibrotic, and pink in color (normal mucosal color). There is minimal inflammation. The location of the gingival enlargement may be generalized or localized to either a quadrant or the interdental papillary area. The condition is rarely present at birth and the onset appears to correlate with the eruption of the permanent dentition, though there have been reports of earlier onset coinciding with the eruption of the deciduous dentition. The gingival enlargement worsens during adolescence, suggesting a hormonal influence. The complications include mastication and speech difficulties as well as teeth displacement. The diagnosis is usually made clinically based on presentation, family history, and exclusion of drug-induced causes of gingival enlargement. For minimal gingival enlargement, regular professional dental cleaning and a good oral hygiene home-care program are often adequate. Gingivectomy may be carried out for more extensive involvement, but repeated interventions are needed due to recurrence.

Multiple Neuroendocrine Neoplasia Type 2B

Multiple endocrine neoplasia syndromes (MENs) are a group of rare autosomal dominant disorders classified into types 1, 2A, 2B (formerly type 3), and 4 based on the genetic mutations and phenotypic features. The estimated prevalence of MEN type 2 is 1 in 30,000 and the disorder is due to a mutation in the *RET* proto-oncogene. This mutation causes a gain of function, resulting in increased cell proliferation and abnormal division in tissues where the *RET* proto-oncogene is expressed (i.e., thyroid, parathyroid, adrenal glands). Oral findings are prominent features in MEN type 2B, typically occurring in the first decade of life, and are often the first signs of the syndrome. The oral findings present as multiple asymptomatic, pink or mucosal-colored nodules or papules ("oral neuromas").[92] They are frequently located on the labial mucosa or anterior tongue,[93,94] but may also be observed on the buccal mucosa, gingiva, or palate. The presence of bilateral neuromas on the commissures of the lips is characteristic for MEN type 2B.[95] The histologic examination of the neuroma reveals an encapsulated mass of myelinated and unmyelinated nerves in a connective tissue background.[96] Other clinical features include full lips, thickened eyelids, high-arched palate, and a marfanoid body habitus. A serious complication in all individuals with MEN type 2B is the early development of aggressive medullary thyroid carcinoma (MTC).[97] Approximately 50% will also develop pheochromocytoma. A preliminary diagnosis of MEN type 2B is made based on the clinical presentation and confirmed with genetic testing. The treatment objectives are early diagnosis and prophylactic thyroidectomy at an early age (usually during the first year of life). Those who do not undergo thyroidectomy are likely to develop metastatic MTC. No treatment is necessitated for the oral neuromas as they are benign. They may be surgically excised if they interfere with function or for esthetic reasons.

Table 25-4 Syndromes associated with hereditary gingival fibromatosis.

Syndrome[87]	Inheritance	Features Apart from Gingival Enlargement
Costello syndrome[88]	Autosomal dominant	• Coarse facial features including relative macrocephaly, high forehead, bi-temporal narrowing, hypertelorism, short nose with depressed nasal bridge, large mouth with thick upper lip vermillion, low-set ears • Nasal and perioral papillomas • Redundant skin on neck, hands, and feet • Short stature
Cross syndrome	Autosomal recessive	• Athetosis • Hypopigmentation • Intellectual disability
Amelogenesis imperfecta, type Ig (Enamel–renal–gingival syndrome)[89]	Autosomal recessive	• Amelogenesis imperfecta • Nephrocalcinosis
Gingival fibromatosis with hypertrichosis	Autosomal dominant	• Hypertrichosis • Intellectual disability
Hyaline fibromatosis syndrome[90] (Figure 25-8)	Autosomal recessive	• Joint stiffness and contractures • Osteopenia • Pink papules on chin, nasolabial folds, forehead, ears, and back of neck • Subcutaneous nodules • Systemic manifestations, e.g., failure to thrive, persistent diarrhea, recurrent infections
Jones syndrome	Autosomal dominant	• Progressive sensorineural hearing loss
Ramon syndrome	Autosomal recessive	• Cherubism • Epilepsy • Hypertrichosis • Intellectual disability • Juvenile rheumatoid arthritis • Ocular abnormalities • Stunted growth
Rutherford syndrome	Autosomal dominant	• Corneal dystrophy • Delayed tooth eruption
Zimmermann–Laband syndrome[91]	Autosomal dominant	• Dysplastic or absent nails • Ear and nose defects • Hepatosplenomegaly • Hirsutism • Hypoplasia of distal phalanges • Joint hyperextensibility • Scoliosis

Genodermatoses

Genodermatoses are a large group of inherited skin disorders. Many of these disorders have accompanying oral findings, which are discussed in this section.

Cowden Syndrome (Multiple Hamartoma Syndrome)

Cowden syndrome is an autosomal dominant disorder characterized by the distinctive mucocutaneous findings of trichilemmomas, acral keratosis, as well as facial and oral papillomatous papules. The estimated prevalence is 1 in 200,000 to 1 in 250,000. The majority of cases are due to a mutation in the *PTEN* gene. The *PTEN* gene is considered to be a tumor suppressor gene and the loss of function results in uncontrolled cell proliferation. The age of onset of the skin and oral findings ranges from 4 to 75 years of age, but is most commonly noticed in the second decade of life. The oral findings present as multiple asymptomatic papules on the gingiva, buccal mucosa, and tongue in up to 80% of affected individuals and impart a "cobblestone" appearance to the affected surfaces. This oral presentation has been termed "oral papillomatosis" or "fibropapillomatosis."[83,98] A recent study suggested that the etiology of the oral papillomatous papules may be related to the human papilloma virus.[99] Other dental findings include high-arched palate, increased risk of periodontal disease, and dental caries.[100] The systemic presentations include hamartomas in multiple organ systems, gastric and intestinal polyps, increased risk for breast (most common), thyroid, endometrial, and renal carcinomas, macrocephaly, and cognitive delay. The National Comprehensive Cancer Network clinical criteria are often used to obtain a preliminary diagnosis of Cowden syndrome.[101,102] Follow-up genetic testing should be performed to confirm diagnosis if the individual fulfills the criteria. The treatment objectives include close cancer surveillance and genetic counseling. No treatment is usually needed for the mucocutaneous lesions as they are benign. Surgical excision may be carried out for esthetic reasons or if the lesions interfere with function.

Dyskeratosis Congenita (Zinsser–Engman–Cole Syndrome)

Dyskeratosis congenita (DC) is a rare inherited disorder characterized by the classic triad of mucocutaneous features: dystrophic nails, oral leukoplakias, and reticular skin hyperpigmentation. Three modes of inheritance are recognized: X-linked recessive, autosomal dominant, and autosomal recessive. The estimated incidence is 1 in 1,000,000 live births. DC is caused by a defect in the telomere complex resulting in genomic instability and premature cell death. Several genetic mutations have been reported, including *ACD*, *CTC1*, *DKC1*, *NHP2*, *NOP10*, *PARN*, *RTEL1*, *TERC*, *TERT*, *TINF2*, and *WRAP53*.[103] The oral lesions in DC present as bullae on the tongue or buccal mucosa that rupture to form erosions or ulcers (Figure 25-9). The chronic cycle of mucosal breakdown and healing eventually results in the development of generalized intraoral white plaques (oral leukoplakia).[83,104] The tongue is the most frequently affected site. Oral leukoplakias are present in 65%–80% of individuals with DC, including those younger than 15 years of age. One-third of the oral leukoplakias will become malignant within a 10–30-year period.[83] In addition to the increased risk for head and neck squamous cell carcinoma, individuals with DC are at an increased risk for hematologic (e.g., leukemia, myelodysplastic syndrome)[105] and solid organ malignancies (e.g., lung, stomach). Other reported oral/dental findings include complete loss of papillae on the tongue, spontaneous oral bleeding, intraoral pigmentation, oral lichenoid changes, aggressive periodontitis, decreased crown-to-root ratio, increased risk of dental caries, hypodontia, and taurodontism.[106–108] DC is usually diagnosed between the ages of 5 and 12 years and is made based on the classic mucocutaneous

Figure 25-9 Dyskeratosis congenita with widespread ulceration and microstomia.

features. Reticulate hypopigmentation involving the chest and neck, and small thin nails with longitudinal ridges that fade with age, are the typical initial findings. The management of DC is based on the involved organ systems. Early diagnosis and referral to a hematologist are essential because of the risk of bone marrow failure. Hematopoietic cell transplantation is the definitive treatment for bone marrow failure associated with DC, but this does not resolve the oral lesions. The use of topical corticosteroids and thalidomide for oral ulcers in both children and adults has been reported with variable effectiveness.[105] As the oral leukoplakias in individuals with DC have a 1000-fold increased risk of malignant transformation compared to the general population, a comprehensive oral mucosal examination should be performed every 6 months.[109] Biopsy is indicated if the oral leukoplakic areas demonstrate clinical features suspicious for malignant changes (i.e., thickening surface, granular or verruciform surface, erythroplakia).

Epidermolysis Bullosa

Epidermolysis bullosa (EB) is a genetically diverse group of disorders characterized by epithelial fragility resulting in blisters and ulcers after minor trauma. The estimated incidence is 1 in 50,000 live births. EB is classified into four main types based on the level of blister formation: EB simplex (most common; Figure 25-10), junctional EB, dystrophic EB, and Kindler syndrome.[110] Within each type, there are various subtypes that are further classified based on the inheritance pattern, the defective protein, and phenotypic features.[111] Table 25-5 summarizes the key findings of the various EB subtypes. The diagnosis of EB is confirmed by skin biopsy with immunofluorescence microscopy. Some cases may require transmission electron microscopy or mutational analysis to identify the level of cleavage and subtype. There is no cure for EB and the treatment strategies are largely supportive (e.g., pain control, wound care, prevention of secondary infections). Oral healthcare is an integral component of the multidisciplinary care needed for individuals with EB because of their increased risk for dental caries (due to difficulty in maintaining adequate oral hygiene) and oral malignancies. The general dental management includes emphasis

Figure 25-10 A–D. Epidermolysis bullosa simplex

Table 25-5 Epidermolysis bullosa types, mutations, and presentations.

Type/ Inheritance	Gene	Defect and Level of Bullae/ Blister Formation	Common Subtypes	Key Findings	Oral Findings				
					Blister/ Ulcer (Severity)	Scarring	Microstomia	Enamel Defects	Oral SCCA
EB Simplex/ mostly AD	Common • *KRT5* • *KRT14* Rare • *DSP* • *DYS* • *DST* • *EXPH5* • *ITGA6* • *JUP* • *KLHL24* • *PKP1* • *PLEC1* • *TGM5*	Mostly caused by keratin defects, which result in a cleavage at the intraepidermal level	• Localized • Generalized intermediate • Generalized severe	• Onset at birth or early infancy for generalized types, may be later for localized type • Bullae in areas of trauma (e.g., hands, elbows, and feet), which usually heal without scarring for milder types • Generalized severe type may have nail and hair abnormalities • Usually normal life span	Yes, severity depends on type (Localized: + Generalized: ++)	Localized: No Generalized severe: Yes	No	No	No
EB Junctional/ AR[116]	Common • *LAMA3* • *LAMB3* • *LAMC2* Others • *COL7A1* • *ITG6A* • *ITGB4*	Mostly caused by a lack of laminin-332, which results in a structural defect of the anchoring filament, causing a cleavage at the intralamina lucida level	• Localized • Generalized intermediate • Generalized severe	• Onset at birth or early infancy for all types, though milder for localized type • Localized type: mild with blistering localized to hands, feet, knees, and elbows that heal without scarring • Generalized types: severe widespread mucocutaneous blistering that heals with scarring • Generalized severe type is associated with mortality before 1 year of age	Yes, severity depends on type (Localized: ++ Generalized: +++)	Yes	Localized: No Generalized: Yes	Yes	No

EB Dystrophic/ AD or AR[117]	*COL7A1*	Mostly caused by collagen type VII defect (main constituent of anchoring fibrils), which results in a cleavage at the sublamina densa level	• AD generalized • AR generalized intermediate • AR generalized severe	• Onset at birth • Generalized bullae that heal with scarring • Contraction flexures at elbows and fusion of digits of hands and feet due to scarring • Nail dystrophy • AR types more severe than AD type and are associated with shortened life expectancy due to infection and severe malnutrition	Yes, severity depends on type (AD: + AR: ++/+++)	Yes, but less severe in AD	AD: No AR: Yes	No	AD: No AR: Yes
Kindler syndrome/ AR[118]	*FERMT1*	Caused by a defect in kindlin-1 that results in cleavages at multiple levels (Intraepidermal, intralamina lucida, sublamina densa)	Not applicable	• Skin bullae usually present at birth and may be severe, but appear to decrease with age • Nail dystrophy • Photosensitivity • Progressive poikiloderma • Skin atrophy • Sparse hair	Yes (++), though blisters/ ulcers appear to decrease with age	Yes	Variably present or absent	No (but periodontal disease is common)	Yes

AR, autosomal recessive; AD, autosomal dominant; SCCA, squamous cell carcinoma; +, mild if present; ++, present and moderately severe; +++, always present and severe.

on preventive care (e.g., diet counseling, placement of fissure sealants, alcohol-free fluoride rinses, fluoride varnish) and regular professional oral examinations. Special precautions are needed during dental visits to minimize injury to the oral mucosa. Copious lubrication of the oral tissues, gloves, radiographic films, and instruments as well as contact avoidance of suction tips on mucosal tissues should be routinely carried out. If blisters form during dental treatment, they may be drained with a sterile needle to limit blister growth.[112] The management of the oral ulcers is largely symptomatic (e.g., sucralfate, bland mouth rinses).[113,114] A recent pilot study evaluated the use of cord blood platelet gel with or without low-level laser therapy and found them safe and effective for the treatment of oral lesions in individuals (mean age: 19 years, range: 9 to 34 years) with EB.[115]

Hereditary Benign Intraepithelial Dyskeratosis (Witkop-von-Sallman Syndrome)

Hereditary benign intraepithelial dyskeratosis (HBID) is a rare autosomal dominant disorder of the conjunctiva and oral mucosa with a prevalence of <1 in 1,000,000.[119] This condition was first described in descendants of the Haliwa-Saponi Native American tribe in North Carolina. Sporadic cases have been reported. The genetic defect is not well characterized, though de novo duplication of 4q35 has been reported in some cases.[120] The oral findings present as asymptomatic white plaques of varying thickness on the buccal and labial mucosa.[121,122] They are occasionally observed on the floor of the mouth or lateral border of the tongue. Clinically, they appear similar to white sponge nevus. The histology examination reveals prominent parakeratin production and marked acanthosis. In addition, an unusual feature whereby an epithelial cell appears to be surrounded by another epithelial cell ("cell-within-cell" pattern) is present.[123] The ocular lesions initiate early in life and are present in almost all individuals with HBID by 1 year of age. The conjunctival plaques are usually bilateral and often associated with dilated hyperemic epibulbar blood vessels, giving rise to the appearance of eye redness. The ocular signs and symptoms vary based on the extent and severity of involvement. Preliminary diagnosis is made based on the ocular and oral presentations, and diagnosis is confirmed with histology. There is no cure for HBID and the treatment is symptomatic. The oral lesions are often asymptomatic and thus do not require treatment. Furthermore, no cases of malignant transformation have been reported.[83] For ocular lesions, surgical excision is indicated for patients with impaired vision; however, the lesions tend to recur after excision.

Neurofibromatosis Type 1 (Von Recklinghausen's Disease)

Neurofibromatosis (NF) type 1 is the most common form of neurofibromatosis and is characterized by multiple café-au-lait macules and neurofibromas. The incidence is 1 in 2500 to 1 in 3000 live births. About half of the cases are inherited (autosomal dominant inheritance), while the rest are a result of sporadic mutations. NF type 1 is caused by a mutation of the *NF1* gene, which results in the lack of production or reduced function of the tumor suppressor protein neurofibromin.[124] More than 70% of affected individuals with NF type 1 present with intraoral neurofibromas and enlargement of the fungiform papillae.[125,126] Another common oral finding is the enlargement of the attached gingiva. Dental radiographic examination may reveal enlargement of the mandibular foramen. The most serious complication of NF type 1 is the development of malignant peripheral nerve sheath tumors and other cancers such as rhabdomyosarcoma, Wilms tumor, leukemia, and tumors of the CNS.[127] The diagnosis is made clinically based on the presence of ≥2 characteristic clinical features (Table 25-6). There is no cure for NF. The management objectives are early detection through regular reviews and treatment (e.g., surgical intervention, pain control) when complications (e.g., interference with function, compression of vital structures, esthetic concerns) arise. Treatment is not routinely needed for intraoral neurofibromas as they are mostly benign, though there have been reports of malignant transformation.[128,129]

Table 25-6 Diagnostic criteria for neurofibromatosis type 1.

≥6 cafe au-lait macules of >5 mm (greatest diameter) in prepubertal individuals, and >15 mm (greatest diameter) in postpubertal individuals
≥2 neurofibromas or one plexiform neurofibroma
Axillary or inguinal freckling
Optic glioma
≥2 iris hamartomas (Lisch nodules)
Distinctive bony lesion, such as sphenoid dysplasia, or medullary narrowing and cortical thickening of the long bone cortex with or without pseudarthrosis
A first-degree relative with neurofibromatosis type 1 diagnosed based on the above criteria

Keratosis Follicularis (Darier–White Disease, Dyskeratosis Follicularis)

Keratosis follicularis is a rare autosomal dominant disorder characterized by skin, nail, as well as oral and other mucosal changes (i.e., esophageal, vaginal, anal, rectal). The condition has a prevalence of 1 in 30,000 to 1 in 100,000 and affects both males and females. Keratosis follicularis is caused by a mutation in the *ATP2A2* gene, which codes for the calcium pump of the endoplastic reticulum of the epithelial cells. The mutation results in abnormal cell adhesion. Oral findings are present in approximately 13%–50% of cases and appear as white papules of varying sizes with a central

depression. The papules may coalesce and impart a "cobblestone" appearance to the affected surfaces.[104,130] The skin lesions are characterized by red-brown keratotic papules following a seborrheic distribution. The nail changes are characterized by white and red bands along the longitudinal length of the nails with a V-shaped notch at the free nail border. The diagnosis is made based on the mucocutaneous presentations and histology of skin lesions. There is no cure for keratosis follicularis. The treatment objectives are to improve the skin appearance, prevent or treat infectious complications, and provide symptomatic relief. Treatment for the oral lesions is usually not needed as they are asymptomatic.

Pachyonychia Congenita (Jadassohn–Lewandowsky syndrome)

Pachyonychia congenita is a rare autosomal dominant disorder characterized by plantar keratoderma and hypertrophic nail dystrophy. As of June 2019, there were 907 individuals registered on the International Pachyonychia Congenita Research Registry[131] The condition is caused by mutations in five keratin genes, *KRT6A*, *KRT6B*, *KRT6C*, *KRT16*, or *KRT17*.[132] The consequence is a weakened keratin cytoskeleton, resulting in epithelial fragility. Up to 50% of affected individuals present with oral leukokeratosis, which appears as thick, whitish gray plaques on the dorsum of the tongue, gingival, buccal, and palatal mucosa.[104,132,133] The lesions may be painful. The presence of natal or neonatal teeth has been reported in some individuals.[132,133] A diagnosis is made based on the mucocutaneous presentations and confirmed with genetic testing. There is no cure for pachyonychia congenita. The treatment objectives are to reduce the nail and skin changes as well as offer pain control.

Tuberous Sclerosis Tuberous sclerosis is an autosomal dominant hamartoneoplastic disorder affecting multiple organ systems, including the brain, heart, skin, kidneys, and lungs. The reported incidence is 1 in 6000 to 1 in 10,000 live births. Tuberous sclerosis is caused by a mutation in either the *TSC1* or, more frequently, the *TSC2* gene.[134] The *TSC* genes function as tumor suppressor genes; thus, their mutations result in the abnormal production of hamartin (*TSC1*) and tuberin (*TSC2*), which regulate cell growth and size. The characteristic oral finding is the presence of fibromas, commonly occurring on the anterior gingiva.[135,136] They may also be present on the buccal and palatal mucosa, lips, tongue, and intraosseously.[104,137] A prominent dental finding is the enamel pitting on the facial surfaces of anterior teeth. Other reported dental/oral findings include diffuse gingival overgrowth not associated with drug therapy, mucosal and intraosseous vascular anomalies, CL, CP, high-arched palate, bifid uvula, and delayed dental eruption. In addition to the features in Table 25-7, other systemic findings include seizures, cognitive deficits, autism spectrum disorder, and the increased risk of renal cell carcinoma, rhabdomyosarcoma, and malignant tumors of the CNS. The disorder is usually diagnosed by 4–10 years of age and is based on the clinical criteria with or without genetic testing. The clinical diagnosis is made based on the presence of 2 major features or 1 major feature with ≥2 minor features (Table 25-7). Those who fulfill the criteria do not need to undergo genetic testing for diagnosis. The management of the oral fibromas includes regular reviews and surgical excision if they interfere with function or for esthetic reasons. However, they are likely to recur.

Table 25-7 Tuberous sclerosis diagnostic criteria.

Major Features	Minor Features
Hypomelanotic macules (≥3, >5 mm)	"Confetti" skin lesions (1–3 mm hypopigmented macules on the extremities)
Angiofibromas (≥3) or fibrous cephalic plaque	Enamel pits (≥3, up to 3 mm)
Angiomyolipomas (≥2)	Intraoral fibromas (≥2)
Cardiac rhabdomyoma	Multiple renal cysts
Cortical dysplasia (includes tubers and cerebral white matter radial migration lines)	Nonrenal hamartomas
Lymphangioleiomyomas	Retinal achromic patch
Multiple retinal hamartomas	
Shagreen patch	
Subependymal giant cell astrocytoma	
Subependymal nodules	
Ungual fibromas (≥2)	

White Sponge Nevus White sponge nevus (WSN) is a rare autosomal dominant disorder with high penetrance but variable expression. The prevalence is estimated to be <1 in 200,000. The condition is caused by a mutation in genes encoding for keratin (e.g., *KRT4*, *KRT13*).[138] WSN typically presents at birth or in early childhood and is characterized by bilateral, diffuse, corrugated or velvety, white plaques commonly affecting the buccal mucosa and tongue.[83] Other mucosal surfaces such as the nasal, esophageal, and anogenital mucosa may be involved. The skin is not involved. The histologic examination reveals prominent hyperkeratosis, marked acanthosis, and intracellular edema of the spinous cells, which is similar to HBID (differentiated by ocular involvement in HBID). The diagnosis is made based on the clinical presentation and histology. Most individuals do not report any discomfort, but some may complain of an altered mucosal texture. No treatment is needed as this is a benign condition.

Natal and Neonatal Teeth

Natal teeth are teeth present at birth, while "neonatal" teeth refer to teeth that erupt within the first month of life. Natal teeth occurs three times more frequently than neonatal teeth.[139] The majority of natal and neonatal teeth are a result of the early eruption of teeth of the deciduous dentition, most commonly the lower central incisors.[139] The precise etiology for the natal and neonatal teeth is unknown. Most are isolated occurrences, though natal teeth have been associated with several syndromes such as chondroectodermal dysplasia, pachyonychia congenita, and oculomandibulofacial syndrome with hypotrichosis.[140] Clinically, the shapes of natal and neonatal teeth often resemble normal teeth but are smaller in size. Some may appear yellowish-brown due to enamel hypoplasia or hypomineralization. Natal and neonatal teeth are frequently mobile due to incomplete or defective root development. The complications include maternal discomfort during breastfeeding, sublingual ulceration, and tooth aspiration. The diagnosis is made clinically based on the time of eruption of the tooth and appearance. The management is directed by signs and symptoms.[141] No treatment is needed if there is no maternal or infant discomfort. When there is maternal/infant discomfort, smoothening the incisal edges of the tooth may alleviate symptoms.[142] In situations where the tooth is excessively mobile (only held by soft tissue) and is at significant risk for aspiration, extraction is indicated. Socket curettage after extraction should be performed to prevent continued development of the dental papilla cells, which may result in eruption of tooth-like structures later on.

Developmental Alterations in Number, Size, Shape, and Structure of Teeth

Alterations in number, size, shape, and structure of teeth typically occur as an isolated trait, but may be part of a syndrome. The associated problems are largely related to esthetics (e.g., malocclusion, ectopic eruption), aberrant eruption pattern/sequence, and dental sensitivity/pain. Table 25-8 provides a brief summary on common developmental dental abnormalities and the associated syndromes.

ACQUIRED CONDITIONS

Infectious Conditions

Herpes Simplex Virus Infections

Primary Herpetic Gingivostomatitis

Approximately 30% of herpes simplex virus (HSV) infections are symptomatic. The most common symptomatic presentation of an initial HSV infection is primary herpetic gingivostomatitis. The infection typically afflicts children between the age of 6 months and 5 years, and transmits mainly by direct contact with infected oral secretions or lesions. In young children, the presence of clusters of pin-head vesicles together with painful, edematous, and erythematous marginal gingiva that bleed easily are characteristic initial findings. The vesicles eventually rupture and coalesce to form larger ulcers. The ulcers occur on both the keratinized (most common on the gingiva, other sites tongue, hard palate) and nonkeratinized (most common on the buccal and labial mucosa) tissues. The lesions may also be present on the pharynx and perioral skin. Fever above 100.4 °F and malaise generally precede the oral findings. Most ulcers heal without scarring in 7–10 days. In severe cases, healing may take up to 14 days. In older children and adolescents, severe pharyngitis may be the main presenting symptom. The diagnosis is generally made clinically based on the history and clinical presentation. The main treatment objectives are pain control with either acetaminophen or ibuprofen and maintenance of adequate fluid intake. The use of "magic mouthwash" and other topical anesthetics such as topical benzocaine or lidocaine is not recommended in young children due to safety concerns and lack of evidence to demonstrate efficacy.[148] Topical antiviral therapy is not recommended for immunocompetent children. In immunocompromised individuals, topical antiviral therapy may accelerate resolution of the lesions, but parenteral therapy is generally preferred. Oral acyclovir (15 mg/kg/dose, 5 doses/day, 5–7 days) may be prescribed for immunocompetent children who present within 72–96 hours of disease onset and/or are in great pain or are unable to eat or drink.[149,150] For immunocompromised children, oral (children ≥2 years: 1000 mg/day divided in 3–5 doses, 10–14 days) or intravenous (children of all ages: 30 mg/kg/day divided in 3 doses, 10–14 days) acyclovir should be given regardless of time of onset. The refusal to drink may lead to dehydration, warranting hospitalization for parenteral fluid replacement.

Table 25-8 Dental abnormalities and associated syndromes.

Dental Abnormality and Type		Commonly Associated Syndromes
Number of teeth	• Hypodontia[143] – Most are isolated occurrences where only 1 or 2 teeth are congenitally missing. Permanent second premolars and maxillary lateral incisors are most likely to be missing – Anodontia (congenitally missing all teeth) and oligodontia (congenitally missing ≥6 teeth) are rare and more likely to be associated with syndromes	• Charcot–Marie–Tooth disease type 2E • Cleft lip/palate including associated syndromes with cleft lip/palate • Coffin–Lowry syndrome • Ectodermal dysplasias* • Rubinstein–Taybi syndrome • Trisomy 21 (Down syndrome)
	• Hyperdontia[140,144] – Most are isolated occurrences, commonly occurring at the anterior midline region (i.e., mesioden) – Extra teeth are known as supernumerary teeth	• Cleft lip/palate • Cleidocranial dysplasia • Familial adenomatous polyposis • Oculo-facial-cardio-dental syndrome • Oral–facial–digital syndrome types I and III • Rubinstein–Taybi syndrome • Trisomy 21 (Down syndrome)
Tooth size	• Microdontia – Most are isolated occurrences, often affecting the maxillary lateral incisor (peg lateral)	• Hemifacial microsomia • Pituitary dwarfism • Trisomy 21 (Down syndrome)
	• Macrodontia	• Hemifacial hyperplasia • Pituitary gigantism
Tooth shape	Most are isolated occurrences • Accessory cusps (e.g., cusp of Carabelli, dens evaginatus, Talons' cusp) • Concrescence • Ectopic enamel ("enamel pearl") • Fusion • Germination • Hypercementosis • Taurodontism	• Associated with hypercementosis – Paget's disease of bone[145] • Associated with taurodontism[146] – Amelogenesis imperfecta- taurodontism type IV – Klinefelter syndrome – Oral–facial–digital syndrome type II – Tricho-dento-osseous syndrome – Trisomy 21 (Down syndrome)
Tooth structure[147]	• Amelogenesis imperfecta • Dentinogenesis imperfecta • Dentine dysplasia • Regional odontodysplasia	• Associated with dentinogenesis imperfecta type 1 – Osteogenesis imperfecta

* Ectodermal dysplasias are a large group of inherited disorders characterized by abnormal structures (i.e., skin, nails, sweat glands, and teeth) derived from the embryonic ectoderm. Many of them are associated with hypodontia.

Neonatal Herpes Simplex Virus Infection

Neonatal HSV infection is a serious and potentially fatal condition that occurs in 1 in 3000 to 1 in 10,000 live births.[151] The incidence appears to correlate with the seroprevalence of HSV-2 in the general population. Neonatal HSV infection may be transmitted in utero (5%), during intrapartum (85%), or postnatally (10%) and is grouped into three categories; localized skin, eye, and mouth (SEM) disease, CNS disease with or without involvement of SEM, and disseminated disease. SEM disease accounts for 45% of neonatal HSV infections.[152] Initially asymptomatic, the oral presentation eventually manifests as localized ulcers involving the oral mucosa, tongue, and palate. Eye involvement presents as excessive watering of the eye and conjunctival erythema. Skin lesions appear as clusters of coalescing vesicles with erythematous bases. The diagnosis is made by scraping of the

vesicles on the skin or oral mucosa and isolating the HSV virus by culture or detecting HSV DNA with polymerase chain reaction assays from these samples. Serology is not indicated, as it is only useful for determining past exposure. The treatment objectives are early intravenous antiviral therapy (at the time of suspected diagnosis) and supportive measures (e.g., fluid and electrolyte maintenance, antimicrobial therapy for secondary infections).[153] Fortunately, mortality is rare in HSV SEM disease. However, these patients should still be evaluated for CNS involvement and disseminated disease.

Varicella Zoster Virus Infection

The characteristic presentation of primary varicella zoster virus (VZV) infection is the vesicular and often pruritic skin rash on the face, trunk, and extremities. The main routes of transmission are via contact with aerosolized droplets from an infected individual or from direct contact with the vesicle fluid from the skin lesion. A prodrome of fever, malaise, pharyngitis, and loss of appetite usually presents 24 hours before the skin rash. Oral findings are common in VZV infections and may precede the skin rash. The oral lesions begin as small, white opaque vesicles, which eventually rupture to form small ulcers on the palate and buccal mucosa. They resemble the ulcers in primary herpetic gingivostomatitis, but are less painful.[154] The diagnosis is frequently made clinically from the history and typical skin presentation. Varicella zoster infections are self-limiting in immunocompetent individuals and the management is primarily symptomatic. Oral acyclovir (children ≥2 years: 20–30 mg/kg/dose, 4 doses/day, 5–10 days; longer for immunocompromised children, maximum dose 800 mg) or valacyclovir (20 mg/kg/dose, 3 doses/day, 5–10 days, longer for immunocompromised children, maximum dose 1000 mg) should be initiated for immunocompromised children and may be initiated for immunocompetent children who are at increased risk for complications (e.g., unvaccinated individuals, intermittent oral or inhaled steroid therapy, chronic salicylate therapy).[155]

Coxsackievirus Infections

The majority of herpangina and hand–foot–mouth disease (HFMD) cases occur in infants and children. The causative viruses for both conditions belong to the enterovirus family (Table 25-9) and the main route of transmission is through the fecal–oral route. The diagnosis for herpangina and HFMD is usually made clinically based on the history and oral (and skin for HFMD) presentation(s).

Herpangina

The onset of herpangina (Figure 25-11) is acute, with high fever, sore throat, and dysphagia. Prodrome is usually absent or very short (a few hours). Other associated symptoms include headache, nausea, and anorexia. The oral lesions begin as papules at the anterior pillars of the fauces, soft palate, tonsils, and uvula that eventually form vesicles, which rupture to form 3–4 mm aphthous-like ulcerations. The number of ulcers varies, but there is usually fewer than 10.

Table 25-9 Causative virus of hand–foot–mouth disease and herpangina.

Herpangina	Hand–Foot–Mouth Disease
Coxsackievirus **A1–A6**, A7, **A8**, A9, **A10**, A16, A22, B1 to B5	Coxsackievirus A2, A4–A10, **A16**, B2, B3, B5
Echovirus 6, 9, 16, 19	Echovirus 1, 4, 7, 19
Enterovirus A71	**Enterovirus A71**

Bold: common causes

Figure 25-11 Herpangina.

Hand–Foot–and–Mouth Disease

Individuals with HMFD present with oral pain, often with accompanying fever and flu-like symptoms (e.g., malaise, myalgia). As with herpangina, prodrome is usually absent. The oral ulcers resemble herpangina ulcers, but are more numerous. The location of the oral ulcers in HFMD also differs from herpangina and they are located anterior to the faucial pillars, most commonly on the tongue, labial, and buccal mucosa. The hand lesions are located on the dorsum of the fingers, interdigital spaces, and palms. The foot lesions are typically on the dorsum of the toes, sole, heel, and lateral borders of the foot. In infants, toddlers, and preschool children, lesions may occur on the buttocks. The skin lesions may be macular, maculopapular, or vesicular. The skin vesicles contain a clear or turbid fluid surrounded by a halo of erythema. HFMD caused by enterovirus A71 and a novel coxsackievirus A6 genotype are associated with more severe disease patterns (Enterovirus 71: CNS disease, heart failure; Coxsackievirus A6: wider distribution, longer duration).[156–158]

The management for both herpangina and HMFD is usually symptomatic, as the majority of the infections are mild and resolve within 1–2 weeks. Topical oral anesthetics are not routinely prescribed due to safety concerns and lack of evidence to demonstrate efficacy in children. Antiviral therapy is also not recommended, as there is no specific drug against coxsackieviruses. Hospitalization may be needed for severe forms of HFMD due to the difficulty of maintaining adequate hydration and the potential for neurologic or cardiovascular complications.

Measles

Measles is an infection caused by the morbilli (rubeola) virus belonging to the *Paramyxovirus* virus family. The infection is transmitted through direct contact and the average incubation period is 14 days. The prodrome consists of fever, malaise, conjunctivitis, and cough. In addition, over 70% of cases present with a characteristic oral finding known as Koplick spots.[159] Koplick spots are 1–3 mm white spots surrounded by erythema, usually observed on the buccal mucosa. They are thought to represent foci of epithelial necrosis. Koplick spots appear 1–2 days before the characteristic skin rash (often beginning on the face and spreading downward) and typically last for 12–72 hours before sloughing off. Enamel pitting on the permanent teeth has been reported in children who develop measles in early childhood. The approaches to diagnosis differ depending on the prevalence of measles in the region. In general, measles should be considered in an unvaccinated individual presenting with the corresponding clinical signs (e.g., skin rash) and symptoms (e.g., fever, malaise), as well as a recent travel history to an area of high measles prevalence. Definitive diagnosis is made by one of the following investigations: detection of serum measles immunoglobulin (Ig) M antibody, a substantial rise in measles IgG antibody titers between acute and convalescent states, isolation of measles virus from culture, or detection of measles RNA by polymerase chain reaction. The treatment is supportive, as there is no specific antiviral therapy for measles. Early recognition is essential for infants due to their increased risk for complications, the most serious being respiratory tract complications and encephalitis.

Human Immunodeficiency Virus–Associated Lesions

Oral lesions associated with human immunodeficiency virus (HIV) infections are common in both adults and children. However, some are more common in children, while others are seldom observed in children (Table 25-10).[160,161] Recent studies suggest that HIV-associated oral lesions have significantly reduced in the post–highly active antiretroviral therapy era, with the exception of salivary gland disease and oral papillomas.[161]

Oral Findings in Other Acute Viral Infections

Oral and dental findings do occur in other viral infections not already mentioned so far in this chapter; however, they may not be consistently observed in all individuals. Table 25-11 summarizes these other viral infections and the associated findings.

Human Papillomavirus Infections

Human papillomavirus (HPV) is a double-stranded DNA virus that is epidermotropic and affects both mucosa and skin. To date, more than 130 types have been identified. The types are classified as either low or high risk based on their role in the pathogenesis of potentially malignant and malignant conditions. HPV types 16 and 18 have been associated with cervical, anal, oropharyngeal, laryngeal, and esophageal carcinomas.[162] HPV infection is transmitted by vertical or horizontal transmission (e.g., sharing utensils and toys) and/or self-inoculation from skin, genital, or anal lesions. The common HPV oral infections in children are squamous papilloma, verruca vulgaris (common wart), condyloma acumina-

Table 25-10 Pediatric human immunodeficiency virus (HIV)-associated oral lesions.

Group 1 Lesions Commonly Associated with Pediatric HIV Infection	Group 2 Lesions Less Commonly Associated with Pediatric HIV Infection	Group 3 Lesions Strongly Associated with HIV Infection But Rare in Children
Angular cheilitis	Cytomegalovirus infections	Kaposi's sarcoma
Erythematous and pseudomembranous candidiasis	Human papilloma virus infections	Non-Hodgkin lymphoma
Herpes simplex virus infections	Necrotizing ulcerative stomatitis	Oral hairy leukoplakia
Linear gingival erythema	Molluscum contagiosum	Tuberculosis-related ulcers
Parotid enlargement	Seborrheic dermatitis	
Recurrent aphthous ulcers	Varicella zoster virus infections	
	Xerostomia	

Table 25-11 Other viruses and the associated oral and dental findings.

Virus	Oral and Dental Findings
Cytomegalovirus	1) Most cases are asymptomatic 2) If symptomatic: • Pharyngitis is common in immunocompetent individuals • Chronic oral ulceration may be present in immunocompromised individuals • Congenital and neonatal infections result in developmental tooth defects
Epstein–Barr virus	1) Most cases are asymptomatic 2) Acute infectious mononucleosis is the most common symptomatic presentation of acute infection, typically affecting young adults: • Pharyngitis, tonsillitis, secondary tonsillar abscesses, palatal petechiae 3) Delayed complications usually associated with immunocompromised states: • Oral hairy leukoplakia • Lymphoproliferative disorder 4) Association with certain malignancies: • Burkitt lymphoma • Hodgkin lymphoma • In human immunodeficiency virus patients: non-Hodgkin lymphoma and smooth muscle tumors (specific in children: leiomyomas and leiomyosarcomas) • Nasopharyngeal carcinoma • T-cell lymphoma
Mumps	• 90% of cases present with bilateral parotid swelling • Orifice of Stensen's duct may be erythematous and enlarged
Rubella	• Forchheimer spots, which present as transient nonspecific red spots on the soft palate, may be observed in some individuals

Figure 25-12 Multifocal epithelial hyperplasia (Heck's disease).

tum, and multifocal epithelial hyperplasia (Heck's disease; Figure 25-12). Table 25-12 summarizes the clinical presentations and treatments for these conditions.[163,164] Notably, HPV may be present in the oral mucosa without any observable clinical lesion.[165] The diagnosis is made based on the clinical presentation and histology. Several vaccines are available, including the bivalent vaccine targeting HPV 16 and 18, a quadrivalent vaccine for HPV 6, 11, 16, and 18, and the 9-valent vaccine for HPV 6, 11, 16, 18, 31, 33, 45, 52, and 58. Currently, only the 9-valent vaccine is available in the United States. The Centers for Disease Control and Prevention recommend HPV vaccination for children 11–12 years of age. The recommendation for girls is for the prevention of cervical, anal, vaginal, and vulvar cancers, as well as anogenital warts. In boys, the vaccine is recommended for the prevention of anal and penile cancers, as well as for anogenital warts. There is evidence that vaccination protects against oropharyngeal HPV infections, but the evidence with regard to protection against HPV-associated oropharyngeal cancer is unclear.[166]

Superficial Candida Infections

Most superficial fungal infections are caused by *Candida albicans*. Pseudomembranous or erythematous candidiasis, angular cheilitis, and central papillary atrophy (CPA) are common superficial fungal infections in children.[170] Most of the causes and clinical presentations of these conditions are similar to adults and their descriptions are covered elsewhere in this textbook. Pseudomembranous candidiasis is relatively common in newborns (5%–10%) and is likely attributed to their immature immune system. Mild cases of

Table 25-12 Human papilloma virus (HPV)-associated oral lesions.

HPV Lesion	Causative HPV Type	Location	Presentation	Management	Recurrence/ Prognosis
Verruca vulgaris	2	• Labial mucosa • Anterior dorsum of tongue • Vermillion border of lip	• <5 mm papule • Pedunculated or sessile • Papillary projections or pebbly surface • Usually white color	• Surgical excision • Laser ablation (may produce HPV plume) • Electrosurgery	• May resolve spontaneously • Recurrence is low • No malignant transformation reported
Squamous papilloma	6, 11	• Labial mucosa • Tongue • Soft palate	• 5–10 mm papule • Usually pedunculated • Exophytic surface projections • Red, white, or normal mucosal color		• Recurrence is unlikely • No malignant transformation reported
Condyloma acuminatum	6, 11, 16, 18	• Labial mucosa • Lingual frenum • Soft palate	• 10–15 mm papule • Sessile • Blunt papillary projections • Pink color		• No malignant transformation reported even when caused by HPV subtypes 16 and 18[167] • This is considered a sexually transmitted lesion. If sexual abuse is suspected, a report to the appropriate authorities is warranted
Multifocal epithelial hyperplasia (Heck's disease) (Figure 25-12)	13, 32	• Labial, buccal, and lingual mucosa • Gingiva • Palate • Floor of mouth • Tonsillar mucosa	• Primarily seen in children • Papulonodular variant: multiple smooth-surfaced pink papules of varying sizes between 1 and 10 mm • Papillomatous variant: pebbly-surfaced white or pink papules of varying sizes between 1 and 10 mm	• Surgical excision • Laser ablation (may produce HPV plume) • Electrosurgery • Topical agents,* e.g., Imiquimod 5% cream, interferon-β cream168 • Others: intramuscular interferon-α injection[169]	• May resolve spontaneously • May recur after excision • No malignant transformation reported

*Data in children limited and mostly based on case reports.

pseudomembranous candidiasis in neonates may resolve without treatment. Angular cheilitis in children is often associated with chronic lip licking and thumb sucking. Occasionally, there is involvement of the perioral skin secondary to chronic lip licking known as cheilocandidosis. CPA (previously median rhomboid glossitis) is a form of erythematous candidiasis formerly thought to be a developmental defect.[171] However, studies have demonstrated that the prevalence of CPA is not higher in children, dispelling the belief that CPA is developmental in etiology.[172] Table 25-13 summarizes the various antifungal agents commonly prescribed for children and the treatment considerations specific to them.[173]

Impetigo

Impetigo is a contagious superficial skin infection caused by either *Staphylococcus aureus* (majority of cases) or group A *Streptococcus* (e.g., *Streptococcus pyogenes*). The infection is commonly observed among children 2–5 years of age. The transmission is by direct contact with the bacteria. Predisposing factors include poor hygiene, crowded living conditions, and hot, humid climates. There are three variants of impetigo: nonbullous impetigo, bullous impetigo, and ecthyma. Although there are no intraoral lesions, the nonbullous variant, which is the most common form, presents with significant perioral skin lesions. The lesions begin as papules and progress to vesicles, which break down to

Table 25-13 Antifungal therapy in children.

Condition	Medication	Specific Considerations
General Considerations • Topical treatment with nystatin is generally the first-line therapy for immunocompetent children • Nystatin suspension contains high sucrose content, which may increase the risk of dental caries when used chronically • Antifungal treatment should be continued 48 hours after resolution of lesions to reduce recurrence of infection • Bottle nipples and pacifiers should be sterilize (e.g., by boiling) before each use		
Pseudomembranous/ erythematous candidiasis	Nystatin suspension 100,000 U/mL • Neonates up to 1 month: 1 mL, 4 times/day, duration 5–10 days • Immunocompetent infants 1 month–11 months: 2 mL, 4 times/day, duration 7–14 days • Immunocompetent children ≥12 months: 4–6 mL, 4 times/day, maximum dose 2.4 million U/day, duration 7–14 days	• Applied with gauze or cotton swab • Should be administered after feeds • Avoid feeding for 5–10 minutes after application • For neonates and infants, split each dose into two portions, one for each side of the mouth • If able to swish, rinse for several minutes and swallow or spit
	Clotrimazole 10 mg troche • Children ≥4 years: suck 5 times/day, duration 14 days	• Choking hazard for children <4 years
	Fluconazole oral suspension 10 mg/mL, 40 mg/mL • Neonates up to 1 month: 3 mg/kg/day, single dose/ day, duration 7 days • Infants 1 month–11 months: 3–6 mg/kg/day, single dose/day, maximum dose 200 mg/day, duration 7–14 days • Children ≥12 months: day 1: 6 mg/kg/day, single dose/day; day 2 onward: 3 mg/kg/day, single dose, maximum dose 200 mg/day; duration 7–14 days	• Used only for widespread infections, in immunosuppressed children, or if topical treatment fails to resolve infection • If symptoms do not improve in 7 days, fungal culture and susceptibility testing recommended • Adverse effects include nausea, vomiting, headaches, rash, abdominal pain, and diarrhea • Hepatic toxicity, including fatalities, has been reported rarely • Contraindicated use with drugs metabolized by CYP3A4 and those known to prolong QT interval
Angular cheilitis or cheilocandidosis	Nystatin ointment or cream 100,000 U/g • Infants >2 months: apply a thin layer to affected area, 3–4 times/day	
	Nystatin suspension 100,000 U/mL and triamcinolone acetonide 0.1% • Infants >2 months: apply a thin layer to affected area, 3–4 times/day	• Not Food and Drug Administration (FDA) approved for this use
	Miconazole 2% ointment or cream • Children >2 years: apply to affected area, 3–4 times/ day	• Not as first-line therapy • Off-label use, as not FDA approved for children

form thick, adherent lesions with a gold, crusty appearance. The majority of the cases are diagnosed clinically by the characteristic skin presentation. In cases when the diagnosis cannot be made from the clinical presentation, isolation of the bacteria by gram stain and culture may be performed. Acute glomerulonephritis and rheumatic fever are significant postinfectious complications of impetigo infections caused by group A *Streptococcus*. Thus, the treatment objectives are to reduce the spread of infection and risk of complications.[174] Topical treatment with mupirocin, retapamulin, or fusidic acid is preferred for limited disease. Other over-the-counter antibiotic ointments may not be as effective. For extensive disease, systemic antibiotics, typically cephalexin or dicloxacillin, for 7 days are recommended.

Scarlet Fever

Scarlet fever is a complication of group A streptococcal tonsillopharyngitis common in children. It is due to a delayed reaction to the exotoxin most often produced by *Streptococcus pyogenes*. Enanthem of the tonsils, pharynx, or soft palate

may be present, but these findings are of the tonsillopharyngitis and not specific for scarlet fever. "Strawberry tongue" is the characteristic oral finding in scarlet fever. The tongue initially appears white. The white tongue coating eventually sheds to reveal an erythematous dorsal surface of the tongue, with inflamed and hyperplastic fungiform papillae. A diffuse papular erythematous skin rash is also present. The diagnosis is made clinically based on the mucocutaneous presentations. If the diagnosis cannot be made clinically, a throat culture or a rapid streptococcal test may be performed. The main treatment objective is to treat the primary infection (i.e., streptococcal tonsillopharyngitis) so as to reduce the risk of scarlet fever and other poststreptococcal complications (e.g., acute glomerulonephritis, rheumatic fever, poststreptococcal reactive arthritis). The antimicrobial of choice is either penicillin or amoxicillin for 10 days.

Noninfectious Conditions

Benign Migratory Glossitis (Also Known as Geographic Tongue or Erythema Migrans)

Benign migratory glossitis (BMG) is a benign, chronic, recurring inflammatory condition of unclear etiology. In children, the prevalence ranges between 0.4% and 14.3%. BMG is characterized by multiple well-demarcated areas of erythema (due to the atrophy of filiform papillae) that are surrounded partially or completely by slightly elevated, yellow to white scalloped borders. The condition is frequently observed on the anterior two-thirds of the dorsum of the tongue, but may be seen less commonly in other oral mucosal locations, such as the buccal and labial mucosa, or floor of the mouth. The location, size, and shape of the erythematous areas change with time. The diagnosis is made clinically based on the history and characteristic presentation. BMG is usually asymptomatic and often noted as an incidental finding. Some individuals may report a burning sensation when inflamed. A myriad of treatment modalities, ranging from topical corticosteroids, analgesics, and diphenhydramine with or without topical anesthetics, have been reported in the literature. A recent systematic review concluded that there was insufficient evidence to support any specific treatment for symptomatic BMG.[175] Thus, the current recommended treatment is largely conservative and includes reassurance and avoidance of acidic foods when symptomatic. BMG has been associated with fissured tongue, psoriasis, and atopic dermatitis.[176,177]

Frictional Keratosis

Both linea alba and morsicatio (Figure 25-13) are variants of frictional keratosis that are common in children. Linea alba is usually bilateral and presents as an asymptomatic, nonulcerated, white hyperkeratotic line coinciding with the level of the occlusal plane. It is associated with low-grade trauma caused by friction, or sucking trauma from the buccal surfaces of the teeth. Morsicatio appears as white plaques on the oral mucosa, with surface shredding and occasionally with areas of erythema or ulceration. The condition occurs as a result of chronic nibbling or chewing of the mucosa and is most frequently observed on the buccal mucosa (morsicatio buccarum), followed by the labial mucosa and lateral borders (morsicatio linguarum) of the tongue. The diagnosis is usually made clinically based on the history and clinical presentation. No treatment is necessary for either condition and cessation of habit will result in spontaneous regression.

Figure 25-13 Morsicatio.

Recurrent Aphthous Stomatitis

Recurrent aphthous stomatitis (RAS) is also referred to as aphthous ulcers or "canker sores." RAS is a common condition that often initiates in childhood and affects up to 40% of the population. Similar presentations of recurrent aphthous-like oral ulceration may occur in association with systemic diseases such as autoimmune conditions (e.g., periodic fever-aphthous stomatitis-pharyngitis-adenitis syndrome [PFAPA], Behcet syndrome), immunodeficiency states (e.g., cyclic neutropenia), nutritional deficiency (e.g., iron/folate/vitamin B_{12} deficiencies), and gastrointestinal disorders (e.g., celiac disease). Therefore, the term RAS should be reserved for oral ulcers that are not associated with systemic diseases. The clinical presentation, subtypes, triggers, diagnosis, and management in children are similar to adults, which are described elsewhere in this textbook. The use of topical corticosteroids is the treatment of choice for RAS, which may be concerning for parents when prescribed for a child. Currently, there is no study specifically evaluating the safety of topical corticosteroid use for RAS in children. Extrapolation from pediatric dermatologic studies suggest that low- to medium-potency topical corticosteroids (Groups 4–7) for short durations are generally safe.[178,179] However, the frequent and routine use of mild corticosteroids has been reported to cause hypothalamic–pituitary axis (HPA) suppression in children. In a meta-analysis of 522 children

aged 3 months–18 years on topical corticosteroids for atopic dermatitis for 2–4 weeks, the HPA suppression rates using low-, medium-, or high-potency corticosteroids were 2%, 3.1%, and 6.6%, respectively.[180] Triamcinolone acetonide 0.1% (Kenalog orabase) is a medium-potency corticosteroid that is often used for minor RAS. Unlike in atopic dermatitis, corticosteroid use in RAS is intermittent and limited to a small area for a short period of time; thus, adverse effects are unlikely.

Riga–Fede Disease

Of the various types of traumatic ulcers, Riga–Fede disease and ulcerations arising from self-injurious behaviors (e.g., trauma from lip biting after local anesthesia) are unique to the pediatric population. These types of ulcerations are more common in individuals with cognitive impairment. Riga–Fede disease is an ulcerative condition that occurs in infants and is observed on the ventral surface of the tongue (Figure 25-14). The ulcer is caused by persistent trauma to the tongue by the lower incisors. The lesion may be extensive and/or present as a large fibrous indurated mass, whereby the possibility of malignancy is raised. The diagnosis is usually made clinically based on the temporal relationship as well as the location of the ulcer with the eruption of the lower incisors (or parafunctional/self-injurious habit). The treatment is challenging, because the infant's compliance often limits the treatment options. Smoothening of the incisor edges and good wound care are recommended. Extraction of the incisors may be needed in severe, nonhealing ulcers.

Figure 25-14 Riga–Fede disease.

Pigmented Lesions

Pigmented lesions are caused either by increased melanin deposition or a deposition of endogenous or exogenous pigments in the epithelium and underlying connective tissue.[181] The lesion color depends on the quantity, location, and depth of the pigment. Intraorally, oral melanotic macule (frequently found on the labial and buccal mucosa, gingiva, and palate) and amalgam tattoo are the most likely encountered pigmented lesions in the pediatric population. The detailed descriptions of these lesions are covered elsewhere in this textbook. As mucosal melanomas are exceedingly rare in children, a biopsy is generally not routinely performed for diagnosis. The management of these lesions is largely observational. A biopsy should be considered if the lesion is located on the maxillary alveolus, gingiva, or palate and displays worrisome characteristics suspicious of a melanoma. The ABCDE acronym (marked **a**symmetry; **b**order irregularity; **c**olor variegation, e.g., shades of black, brown, tan, red, or pink; **d**iameter >6 mm; change in surface **e**levation, e.g., nodule formation) is a common checklist used to evaluate the malignant risk of pigmented lesions.[182]

Localized Juvenile Spongiotic Gingival Hyperplasia

Localized juvenile spongiotic gingival hyperplasia (LJSGH; Figure 25-15) is a recently described lesion of unknown etiology. This condition occurs most frequently in children, with a mean age of 12 years. The lesion is commonly observed on the facial free gingiva margins (may extend to

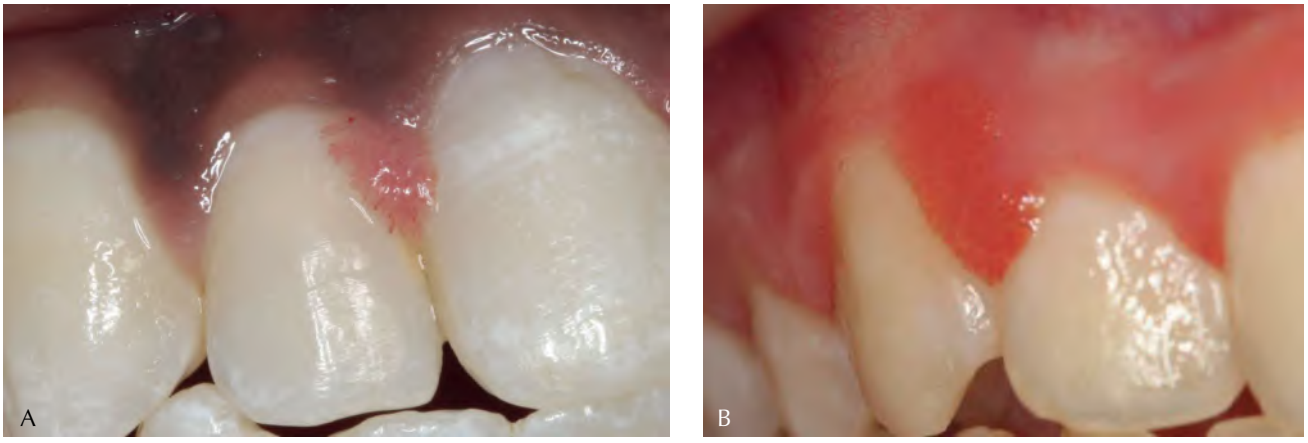

Figure 25-15 A, B. Localized juvenile spongiotic gingival hyperplasia.

the mucogingival junction) at the anterior maxillary region. LJSGH usually occurs in solitary cases, but multifocal cases have been reported. Two clinical presentations have been described: a bright red plaque with a granular or velvety surface or a nodule with a papillary surface. The lesion is painless, but tends to bleed easily.[183] The histologic examination reveals areas of nonkeratinized, acanthotic stratified squamous epithelium, exhibiting spongiosis. Rete pegs elongation, atrophy of the epithelium overlying long connective tissue papillae, and a neutrophilic infiltrate are also present. The diagnosis is frequently made clinically based on the location and distinctive clinical presentation, and thus does not always require histologic confirmation. As LJSGH is not related to local plaque accumulation, conventional plaque control measures are not effective. The most frequently reported treatment is surgical or laser excision, with recurrence rates ranging from 6% to 16%.[184] Treatment with topical corticosteroids has been found to have mixed results.[184]

Pyogenic Granuloma

Pyogenic granuloma (Figure 25-16) is a reactive oral mucosal lesion common in children and adolescents, with a female predisposition. The etiology is thought to be due to an exaggerated soft tissue response to local irritation or trauma. Notably, pyogenic granulomas have recently been classified under vascular tumors and termed lobular capillary hemangiomas by the International Society for the Study of Vascular Anomalies.[39] This was based on the difficulty in definitively ascertaining whether pyogenic granulomas were reactive or neoplastic in origin.[39,185] Clinically, pyogenic granuloma presents as a painless, rapidly growing, pedunculated, erythematous soft tissue mass, with or without an ulcerated surface. The lesion is usually located on the maxillary gingiva, but has been observed on other sites such as the labial and buccal mucosa, or the tongue. The diagnosis is made based on the

Figure 25-16 Pyogenic granuloma.

Figure 25-17 Peripheral ossifying fibroma.

clinical presentation and histology. The treatment is surgical excision, with a reported recurrence rate of 3%–5%.

Peripheral Ossifying Fibroma

Peripheral ossifying fibroma (Figure 25-17) is a reactive oral mucosal lesion common in adolescents and young adults, with a female predisposition. The exact etiology of peripheral ossifying fibroma is unclear and the lesion is unrelated to central ossifying fibroma.[186] Peripheral ossifying fibroma presents as a firm, smooth-surfaced or ulcerated, pedunculated or sessile, pink or red, gingival mass, often arising from the interdental papilla. They are usually <2 cm in size and are most commonly observed at the incisor/canine region. The histologic examination reveals a cellular fibrous proliferation associated with the presence of mineralized products such as bone, cementum-like, or dystrophic calcifications. The diagnosis is made based on the clinical presentation and histology. The treatment is surgical excision, with a recurrence rate of 8%–16%.

Peripheral Giant Cell Granuloma

Peripheral giant cell granuloma is a reactive lesion thought to occur secondary to local irritation or trauma. Approximately 20%–33% occur in the first two decades of life, with a female predisposition. Peripheral giant cell granuloma presents as a smooth-surfaced or ulcerated, pedunculated or sessile, red or reddish-purple mass on the gingiva. The most common location is at the anterior mandibular area. A periapical radiograph may occasionally show superficial resorption or "cupping" of the underlying alveolar bone caused by the lesion.[187] The radiograph also aids in determining the origin of the lesion, as some central giant cell granulomas can erode through the cortical bone and present as gingival masses. Histologically, peripheral giant cell granuloma is similar to central giant cell granuloma, and is considered to be the soft tissue counterpart. There is a proliferation of multinucleated giant cells in a stroma of spindle

cells and abundant hemorrhage. The diagnosis is made based on the clinical presentation and histology. The treatment of choice is surgical excision, with a recurrence rate of 10%–18%.

Oral Mucocele: Extravasation Type (Mucus Extravasation Phenomenon)

Mucus extravasation phenomenon (Figure 25-18) occurs due to the rupture of the minor salivary glands, often from local trauma, resulting in mucous extravasation into the surrounding soft tissues. The phenomenon is common in children and presents as a soft, fluctuant, smooth-surfaced, dome-shaped bluish swelling. The size ranges from a few millimeters to several centimeters and is most commonly observed on the lower labial mucosa.[188] Individuals typically report a history of a painless swelling, which appears and disappears periodically. The histologic examination reveals an area of spilled mucin surrounded by a granulation response without an epithelial lining. The diagnosis is made by the history, clinical presentation, and histology. In children, where compliance is an issue, small mucoceles of ≤5 mm may be monitored, as some will resolve spontaneously without treatment within a few months. Children should be advised not to use their teeth to bite or chew on the mucocele. Larger or chronic mucoceles displaying signs of fibrosis or keratinization will likely require surgical excision. Recurrences may occur, especially if the surrounding minor salivary glands are not removed during the removal of the original mucocele.

Common Malignant Conditions with Oral Mucosal Findings in Children

In the 5–14-year-old age group, cancer is the second most common cause of death. The most frequent malignancies in children are leukemias. Table 25-14 summarizes the common malignancies with oral mucosal findings in children.

Figure 25-18 Mucocele.

Systemic Diseases and Related Medical Therapy with Significant Oral Mucosal Findings

Periodic Fever, Aphthous Stomatitis, Pharyngitis, Adenitis Syndrome

Periodic **f**ever, **a**phthous stomatitis, **p**haryngitis, and **a**denitis (PFAPA) syndrome is characterized by recurrent episodes of fever, malaise, chills, aphthous-like oral ulcerations, pharyngitis, headache, and tender cervical adenopathy of unknown origin. The condition occurs at 4- to 6-week intervals over periods of years.[193] PFAPA syndrome is typically diagnosed between the ages of 1 and 4 years and usually resolves spontaneously by 10 years of age. Oral ulcerations are present in about 40%–80% of PFAPA episodes. The oral ulcers resemble recurrent aphthous ulcerations and are usually observed on the labial or buccal mucosa.[194] The diagnosis is made clinically based on the exclusion of other causes of fever and a thorough history of the temporal relationship of the periodic fevers with clinical findings. The treatment is largely supportive, as the condition is self-limiting. Observation is an acceptable option if parents prefer no treatment. Antipyretics and nonsteroidal anti-inflammatory analgesics are not effective in relieving any of the signs and symptoms except for fever. As such, the preferred treatment is early administration of a single dose of prednisone (1–2 mg/kg), which will rapidly relieve the fever in a few hours; other symptoms will take longer to resolve. However, glucocorticoid therapy has been shown to result in an increase in episode frequency. In such individuals, prophylactic therapy with cimetidine (20–40 mg/kg/day in divided doses every 12 hours) or colchicine (children 4–6 years: 0.6–1.2 mg/day, children >6 years: 1.2–1.8 mg/day) may be considered.[195] Tonsillectomy is an effective treatment for PFAPA, especially in those who do not respond to drug therapy.[196]

Kawasaki Disease

Kawasaki disease is an acute vasculitis of primarily the medium-sized arteries of unknown etiology. The condition typically affects infants and children, with 80% occurring under 5 years of age. The highest prevalence is in Japan, at approximately 250 cases per 100,000 children, compared to 20 cases per 100,000 in the United States.[197,198] The prodrome consists of nonspecific findings such as cough, rhinorrhea, vomiting, diarrhea, abdominal pain, and irritability. The inflammation of the dorsum tongue with enlargement of the fungiform papillae imparts a "strawberry tongue" appearance.[199] The diagnosis is made clinically based on a history of fever above 101.3 °F for ≥5 days and ≥4 of the following physical findings:

- Bilateral bulbar conjunctivitis.
- Cervical lymphadenopathy (single lymph node >1.5 cm).

Table 25-14 Common malignancies with oral mucosal findings in children.

Malignancy	Key Features	Oral Presentations
Acute leukemia[189]	• Most common childhood malignancy • Acute lymphocytic leukemia (ALL) 80% of cases • Acute myeloid leukemia (AML) 15% of cases • 5-year survival rates: – ALL: 90% – AML: 40%	• Easy bruising and gingival bleeding secondary to thrombocytopenia • Neutropenic ulcers • Opportunistic infections, e.g., oral candida infections, herpetic infections • Leukemic infiltrates mostly observed with AML, which manifests as diffuse gingival enlargements or discrete mass secondary to leukemic infiltrates into the soft tissue
Langerhans's cell histiocytosis (LCH)[190,191] (Figure 25-19)	• About 10–20% occurs in jaws • Mean age of occurrence 1–4 years of age • Bone most commonly involved • Single-system LCH involves only one organ system, but may be unifocal or multifocal • Multisystem LCH has ≥2 organ systems involved • Prognosis is worse for children <2 years of age • 5-year survival rate 80%; however, 30%–50% of patients will experience recurrence	• Pain and/or tenderness • Mobile teeth • Rarely, LCH lesions may involve only oral soft tissues • Nonspecific oral findings including mucosal ulcerations, gingival hyperplasia, gingival bleeding • Jaw lesions may extend beyond bone and manifest as a gingival mass Radiographic features: • Jaw radiolucency with floating teeth appearance
Rhabdomyosarcoma[192]	• Accounts for 50% of sarcomas in childhood • About 35% occur in the head and neck region • Mean age of diagnosis 7–8 years of age • 5-year survival rate 44%–95% (varies based on histopathologic type)	• Painless, locally aggressive mass with rapid growth • Palate most common intraoral site

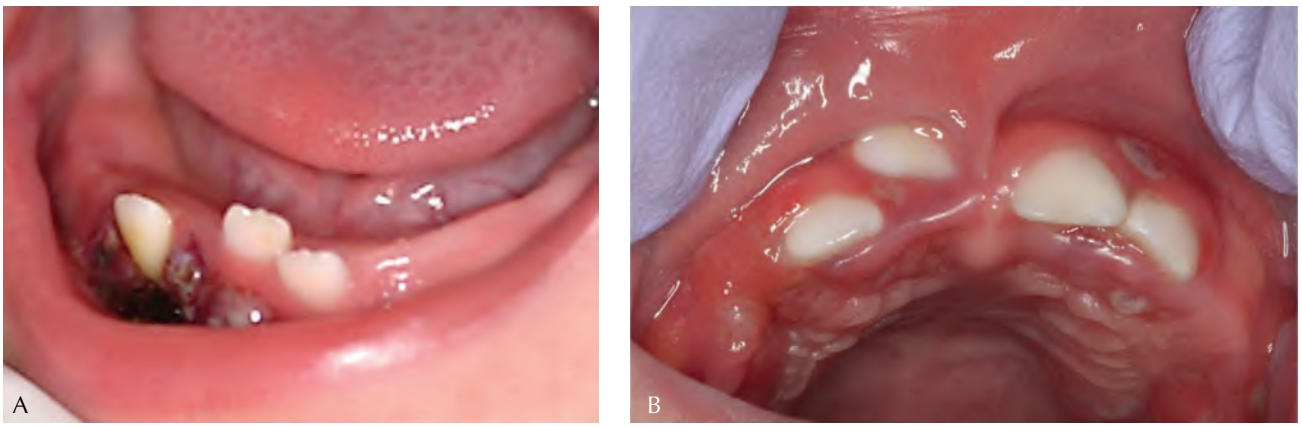

Figure 25-19 Langerhan's cell histiocytosis. (A) Bone to soft tissue. (B) Soft tissue.

- Oral mucosal changes including strawberry tongue, fissured or cracked lips, and oropharyngeal erythema.
- Extremities changes including erythema of the palms and soles, edema of the hands or feet, and periungual desquamation.
- Polymorphous diffuse maculopapular rash in the extremities and trunk.

All cases of Kawasaki disease should be treated with IV immune globulin infusion and aspirin at the time of diagnosis.[200] Some may also require glucocorticoid therapy. Delayed treatment is associated with a fivefold increase in the prevalence of coronary artery aneurysms.

Figure 25-20 Phenytoin-induced gingiva hypertrophy.

Drug-Related Gingival Enlargement

Many systemic medications (e.g., nifedipine, cyclosporine, and phenytoin) are associated with abnormal gingival overgrowth (Figure 25-20). In children, most cases are secondary to phenytoin (50%) or cyclosporine therapy (>70%).[201] The gingival enlargement is typically seen within 1–3 months of drug use and originates at the interdental papilla. The anterior facial gingiva is the most commonly affected area. Severe cases may extend to the incisal or occlusal surfaces and interfere with speech, mastication, and maintenance of adequate oral hygiene. The enlarged gingiva is fibrotic, firm, and usually pink in color. In individuals with poor oral hygiene, the gingival tissues may be edematous, erythematous, and bleed easily. The diagnosis is made clinically based on the presentation and its temporal association with a medication known to cause gingival enlargement. As the severity of the enlargement is influenced by plaque control, the main treatment is implementation of a good oral hygiene program (e.g., frequent professional cleanings, meticulous home care to minimize plaque accumulation). Systemic antimicrobial therapy with azithromycin, metronidazole, and clarithromycin has been found to be beneficial for some cases.[202] The proposed mechanisms of action include antibacterial and anti-inflammatory properties as well as suppression of fibroblast activity. In severe cases, surgical intervention is needed for functional or esthetic reasons. However, recurrence is likely if the individual is still on the causative medication. The substitution of cyclosporine with tacrolimus to reduce the risk for gingival overgrowth may be considered, but this is not always feasible due to the constraints of the underlying systemic condition.

Impact of Cancer Therapy on Growth and Development

A unique complication in childhood cancer survivors is the impact of cancer therapy on their growth and development. The dental defects range from enamel defects, microdontia, or hypodontia to root abnormalities (e.g., shortened or V-shaped roots). The craniofacial abnormalities are retardation of the mandibular growth and vertical facial growth.[203,204] Multimodality cancer therapy, high-dose head and neck radiation, high-dose chemotherapy, especially regimens involving the use of alkylating agents and anthracyclines, as well as children younger than 5 years of age at the time of treatment are at increased risk for higher incidence and more severe dental and craniofacial abnormalities.[205,206]

Use of Bisphosphonate Therapy in Children

Bisphosphonates (BPs) are increasingly being prescribed in children for diseases associated with primary (e.g., osteogenesis imperfecta) or secondary osteoporosis (e.g., chronic corticosteroid therapy). BP-induced osteonecrosis of the jaws and the associated risk factors (e.g., age, diabetes) are well described in adults, but information in children is lacking. In a recent systematic review of the risk of BP-induced osteonecrosis of the jaw, the authors found no reported case of osteonecrosis in children.[207] The authors proposed that the risk of BP-induced osteonecrosis of the jaws was minimal in children for the following reasons: (1) BPs are typically used for genetic bone conditions in children and thus cannot effectively alter the biologic characteristics of the defective bone; (2) BPs do not reduce bone growth and trabecular bone formation in children; and (3) the higher bone turnover in children results in the increased likelihood of BPs being released into the circulation and excreted out of the system. The findings of this review should be interpreted with caution, as the majority of the studies included were on children with genetic bone diseases.[207] As such, their conclusions may not apply to those are on long-term BP treatment for secondary osteoporosis. In addition, the studies in the review either had small sample sizes or did not include individuals with risk factors (e.g., dental pathology) for the development of BP-induced osteonecrosis of the jaws.

Orofacial Pain in Children

Temporomandibular dysfunction and headaches are relatively common in school-age children and adolescents. However, it is difficult to estimate the prevalence due to the wide ranges reported in studies. A discussion of the etiology, diagnosis, and treatment is outside the scope of this chapter; readers are advised to refer to the guideline by the American Academy of Pediatric Dentistry on "Acquired Temporomandibular Disorders in Infants, Children and Adolescents" for an in-depth review.[208]

Neuropathic orofacial pain conditions without an identifiable organic cause (e.g., trauma, tumor) are rare in the pediatric population and the literature is limited to case reports.[209] As such, the diagnosis and treatment principles are largely extrapolated from the adult literature and are similar to those in adults.

DISTURBANCES IN TOOTH EXFOLIATION AND ERUPTION PATTERNS

Early Exfoliation of Teeth

The early exfoliation of deciduous or permanent teeth in the absence of trauma may be associated with an underlying systemic disease.[210,211] At times, this may be the first presentation of the underlying systemic condition. Table 25-15 summarizes the key systemic and oral findings.

Delayed Eruption of Teeth

Delayed tooth eruption is more often a localized problem rather than a symptom of an underlying systemic disease. Table 25-16 lists the systemic and local causes of delayed tooth eruption.[224]

Table 25-15 Systemic causes for early tooth exfoliation.

Condition	Cause	Key Systemic Findings	Oral Findings
Congenital			
Immunologic Dysfunction			
Chediak–Higashi syndrome[211]	Mutation of the *CHS1/LYST* gene is postulated to result in a dysfunction in lysosome transport	• Partial oculocutaneous albinism and other ocular manifestations, e.g., nystagmus, strabismus • Immunologic and hematologic abnormalities, e.g., anemia, neutropenia, thrombocytopenia • Recurrent skin and respiratory infections • Hepatomegaly • Splenomegaly • Paresthesia • High risk of hemophagocytic lymphohistiocytosis	• Severe gingival inflammation and early-onset rapidly progressive periodontitis • Oral ulcerations
Cyclic neutropenia[212]	Mutation (majority of cases) of the *ELANE* gene results in defective neutrophil function	• Cyclic decrease in neutrophil counts (21-day cycle, but may range from 14 to 35 days) • Each episode is accompanied by malaise, fatigue, fever, pharyngitis, and stomatitis • Recurrent skin and respiratory infections • Diagnosis is confirmed by an acute neutrophil count of <200 cells/μl in three regularly spaced cycles	• Severe periodontitis • In cyclic neutropenia, each episode often manifests with recurrent aphthous-like ulcerations and gingivitis
Severe congenital neutropenia (infantile genetic agranulocytosis, Kostmann's disease)[211]		• Severe neutropenia (neutrophil count <500 cells/μl) present at birth or within 1 year of life • Recurrent bacterial infections • Global developmental delay • Seizures	
Leukocyte adhesion deficiency syndrome[211]	Mutation of the *ITGB2* gene (primarily) results in defective CD18 and impaired T-cell function	• Absent or minimal pus formation • Leukocytosis • Impaired wound healing • Recurrent bacterial infections, usually of the skin and mucosal surfaces • Delayed separation of umbilical cord	• Severe gingival inflammation and early-onset periodontitis • Opportunistic oral infections • Oral ulcerations
Papillon–Lefevre syndrome[211]	Mutation of the *CTSC* gene affects the production of serine proteinases in immune cells, resulting in defective function	• Hyperkeratosis of palms and soles • Increased risk of recurrent skin, respiratory, and systemic infections • Nail dystrophy	• Severe early-onset periodontitis (at 1–2 years of age), resulting in the loss of all deciduous teeth by 4–5 years of age and all permanent teeth by 14 years of age • Atrophy of alveolar ridges • Hypodontia

Condition	Cause	Key Systemic Findings	Oral Findings
Congenital			
Haim–Munk syndrome[211]		• Acro-osteolysis • Arachnodactyly • Hyperkeratosis of palms and soles • Onychogryphosis • Osteolytic defects of the phalanges of the hand • Recurrent pyogenic infections	• Severe early-onset progressive periodontitis affecting both deciduous and permanent dentitions
Periodontal Ehlers–Danlos syndrome (formerly type VIII)[211,213]	Mutations of the *C1S* and *C1R* genes result in C1s or C1r deficiencies and altered immune function	• Elastic skin • Hyperpigmented atrophic scars • Joint hypermobility • Short stature	• Severe early-onset generalized periodontitis leading to loss of teeth before 30 years of age • Gingival enlargement with varying degrees of hyperkeratosis • Lack of attached gingiva • Dental abnormalities, e.g., hypodontia, microdontia
Trisomy 21 (Down syndrome)[211]	–	• Characteristic dysmorphic facies • Intellectual disability • Atlanto-axial instability • Cardiovascular defects; most commonly complete atrioventricular septal defect • Growth abnormalities (e.g., short stature) • Eye and hearing problems • Hypothyroidism • Obstructive sleep apnea • Immunologic dysfunction • Increased risk of acute leukemia • Increased risk for gastrointestinal tract abnormalities (e.g., duodenal atresia or stenosis)	• Moderate to severe periodontitis due to altered immune function • Dental abnormalities, e.g., hypodontia, microdontia, taurodontism • Benign migratory glossitis (geographic tongue) • Tongue anomalies: fissured tongue, macroglossia • High-arched palate • May be associated with delayed tooth eruption
Unstable periodontitis stage 4 grade C with molar incisor pattern (formerly known as localized aggressive periodontitis)[214,215]	Multifactorial in origin; likely polygenic and influenced by environmental factors resulting in deficient immune response	• No associated systemic findings	• Increased susceptibility to aggressive periodontitis – Localized disease: affects incisors and first molars – Generalized disease: affects ≥3 teeth other than the first molars and incisors

(*Continued*)

Table 25-15 (Continued)

Condition	Cause	Key Systemic Findings	Oral Findings
Congenital			
Periodontium Defects			
Acatalasia (acatalasemia)[216]	Mutation of the *CAT* gene results in a lack of catalase enzyme, which is important for hydrogen peroxide metabolism	• Most are asymptomatic	• Early tooth loss due to the inability to degrade hydrogen peroxide produced by oral bacteria, resulting in periodontal tissue hypoxemia and necrosis • Oral ulcerations
Coffin–Lowry syndrome[217]	Mutation of the *RPS6KA3* gene results in a dysfunctional growth factor–regulated protein kinase	• Dysmorphic facial features, e.g., hypertelorism, thick lips, frontal bossing, anteverted nares • Broad tapering fingers • Brachydactyly • Hearing deficit • Global developmental disability • Paroxysmal movement disorder • Joint hyperflexibility • Skeletal abnormalities, e.g., scoliosis, kyphosis, delayed skeletal maturation • Short stature	• Early tooth loss is postulated to be due to hypoplastic root cementum • Dental abnormalities, e.g., hypodontia, microdontia • High-arched and narrow palate • May be associated with delayed tooth eruption
Hajdu–Cheney syndrome[218]	Mutation of the *NOTCH2* gene results in abnormal bone development and remodeling	• Acro-osteolysis of the distal phalanges • Characteristic dysmorphic facies • Bowing of the long bones • Renal cysts • Severe osteoporosis • Short stature • Vertebral abnormalities	• Early tooth loss is thought to be due to defective cementum, hypoplastic roots, and severe periodontitis (cause unclear) • May be associated with delayed tooth eruption • Cleft palate or high-arched palate
Hypophosphatasia[211]	Mutation of the *ALPL* gene results in an abnormal production of tissue-nonspecific alkaline phosphatase and poor skeletal and dental mineralization	• Clinical presentations range from mild to severe depending on type • Types: perinatal, prenatal benign, infantile, childhood, adult, and odontohypophosphatasia • Lethal perinatal and infantile types are the most severe and are associated with high mortality • Perinatal type: skeleton fails to form in utero, high mortality (i.e., stillborn or within first few days of life) due to respiratory failure resulting from chest deformities and undeveloped lungs	• Early tooth loss before 5 years of age is attributed to reduced amount or total lack of cementum on tooth root surface (one of the first signs) • Enamel hypoplasia • Enlarged pulp chambers

Condition	Cause	Key Systemic Findings	Oral Findings
Congenital			
		• Prenatal benign type: limb shortening and bowing, but often shows spontaneous improvement during the third trimester of pregnancy • Infantile type: symptoms become apparent at 6 months, respiratory complications, premature craniosynostosis, widespread demineralization • Childhood type: highly variable features, skeletal deformities (e.g., bowed legs), short stature, and waddling gait • Odontohypophosphatasia: only has dental findings characterized by premature loss of deciduous and permanent teeth	
X-linked hypophosphatemic rickets[219]	Mutation of the *PHEX* gene results in decreased serum potassium levels due to abnormal excretion of phosphate from the kidneys, leading to soft, weak bones	• Bowed legs • Craniosynostosis • Joint/bone pain • Muscle pain and weakness • Osteoarthritis • Osteomalacia • Rickets • Short stature	• Tooth extraction often necessitated due to the development of spontaneous dental abscess in the absence of trauma or decay. The cause of abscess is proposed to be due to bacteria infiltrating and infecting the pulp via the enamel and dentine microclefts in the tooth • Other enamel defects, e.g., hypoplasia • Large pulp chambers with pulp horns extending to the dentine-enamel junction
Dentin dysplasia type 1[220]	Mutation of the *SMOC2* gene	• None	• Early tooth loss attributed to short or absent roots, resulting in tooth mobility and early exfoliation • Periapical radiolucencies in sound teeth • Pulp obliteration

(*Continued*)

Table 25-15 (Continued)

Condition	Cause	Key Systemic Findings	Oral Findings
Congenital			
Acquired Causes			
Acrodynia (Pink disease)[221]	Infantile mercury poisoning	Early signs • Change in temperament, e.g., irritability, restlessness, melancholy • Tips of fingers, toes, and nose appear pinkish, eventually turning darker with patchy areas of ischemia Later signs • Alopecia • Desquamation of palms and soles • Nail abnormalities • Neurological abnormalities, e.g., neuritis, abnormal reflexes • Photophobia • Profuse perspiration • Swelling of fingers and toes • Pruritis and pain in hands and feet	• Tooth loss and jaw necrosis in severe cases • Gingivitis • Inflammation and ulceration of oral mucosa
Langerhans cell histiocytosis (LCH)[222]	Malignant proliferation of the Langerhans cells	• Clinical presentation depends on number of sites and extent of involvement • Bone followed by skin are the most commonly involved systems • Single-system LCH involves only one organ system and may be unifocal or multifocal – Typically does not have systemic signs and symptoms • Multisystem LCH has ≥2 organ systems involved – Involvement of hematopoietic system, liver, and/or spleen is associated with poorer prognosis	• Bone destruction leading to tooth mobility and eventual tooth loss • Jaw radiolucencies • Oral ulcers • Gingival lesions secondary to bony extension to soft tissue (more common) or primary soft tissue disease (less common)
Scurvy[223]	Vitamin C deficiency results in impaired collagen synthesis	• Arthralgia • Easy bruising • Hemarthrosis • Impaired wound healing • Nonspecific signs and symptoms, e.g., myalgia, malaise	• Increased tooth mobility and early tooth loss due to periodontium defects from impaired collagen synthesis

Table 25-16 Systemic and localized causes of delayed tooth eruption.

Systemic Causes	Localized Causes
Endocrine diseases • Congenital hypothyroidism (cretinism) • Hypoparathyroidism • Hypopituitarism • Pseudohypoparathyroidism type 1A (Albright hereditary osteodystrophy)	Causes related to the permanent tooth successor • Congenitally absent • Dilaceration • Ectopic eruption
Chronic drug therapy • Bisphosphonate therapy • Medications that inhibit prostaglandins pathway, e.g., antineoplastic chemotherapy	Obstruction due to • Fibrous gingival tissue and/or gingival enlargement • Odontogenic and nonodontogenic tumors and cysts • Odontome • Supernumerary tooth
Malnutrition	Chronic local infection
Premature birth	Malocclusion
Primary failure of eruption	Oral facial cleft
Genetic conditions (not an exhaustive list) • Amelogenesis imperfecta • Apert syndrome • Cherubism • Chondroectodermal dysplasia (Ellis van Creveld syndrome) • Cleidocranial dysplasia • Familiar adenomatous polyposis • Infantile osteopetrosis (Albers–Schonberg disease) • McCune–Albright syndrome • Mucopolysaccharidosis • Trisomy 21 (Down syndrome)

Geriatric Oral Medicine

Katharine Ciarrocca, DMD, MSEd
Christine Downey, DDS, MS

Population aging—the shift in distribution of a nation's population to older ages—is occurring globally, with nearly all countries worldwide demonstrating population growth in older persons.[1] In 2019, there were 703 million persons aged 65 years or over globally, with this number projected to more than double to 1.5 billion by 2050.[2] People are living longer, and for the first time in recorded history most individuals can expect to live at least into their 60s, with current global life expectancy at birth being 72.3 years.[2] Population aging was first evident in higher-income countries, such as Japan, where 30% of the population is already older than 60 years.[2] However, low- and middle-income countries (such as China and Iran) are currently experiencing the greatest rate of population aging.[2] Even more pronounced is the increase in the world's population over 80 years, which nearly tripled in the past 30 years to nearly 143 million and is projected to triple again to 426 million by 2050.[2] In countries such as the United States, the number of people in the "oldest old" age group (>85 years) is projected to reach 18 million and account for 4.5% of the US population by 2050, up from 2.5% in 2030.[3,4] Finally, living to 100 is becoming increasingly common. Worldwide there are approximately 533,000 centenarians, with the United States having the highest absolute number at 72,000.[5] Japan has the highest rate of centenarians, who account for 48 in every 1000 Japanese.[5,6]

The growth in the number of older adults worldwide can be attributed to a variety of factors. First, advances in medicine and public health have led to a notable increase in life expectancy. A significant reason for the "graying" of the population is the aging of the baby boomer generation. For example, in the United States, the first baby boomer turned 65 in 2011. The last baby boomer will turn 65 in 2030,

Burket's Oral Medicine, Thirteenth Edition. Edited by Michael Glick, Martin S. Greenberg, Peter B. Lockhart, and Stephen J. Challacombe.

creating a demographic where one in every five Americans will be over the age of 65 (see Figure 26-1).[7] With this dramatic change in the global landscape and the improved medical management of disease, oral healthcare professionals must possess the tools and knowledge to treat older adults comprehensively, keeping in mind their oral manifestations of systemic disease and their age-related specific oral changes.

CONCEPTS OF AGING

The age of 65 years was selected as the dividing line between middle-aged and elderly individuals in the late 1880s in Germany as a criterion for Social Security, and was adopted worldwide, mainly for the determination of pension and retirement systems.[8] It is now the accepted chronologic age for the elderly; this number is arbitrary, as aging is both chronologic and functional. The chronologic definition of age is simply a number. The functional definition, however, is based on the ability of the individual to travel to seek services. This assessment of how a person functions in daily life makes the functional definition of age much more appropriate than a chronologic one.[9] There are three functional age classifications:

- Functionally independent older adults or those who are physically well despite advanced age.
- Frail older adults or those at high risk for major adverse outcomes.
- Functionally dependent older adults or those who have experienced deterioration of physical capacities and must rely on assistance from others.[9]

The majority of older adults (78%) live in the community, approximately 5% of these people are homebound, and another 17% have a major limitation in mobility due to a chronic condition.[10,11] This leaves about 70% of the entire elderly population living in the community and capable of traveling to seek services independently, including to the dental office for oral healthcare.

Aging, systemic illness, and its' management directly influence oral health, function, and the provision of dental care.[12,13]

Because older adults are more likely to utilize dental healthcare services compared with previous older generations,[14,15] oral health professionals must be able to recognize, diagnose, and manage oral conditions in the aging patient. This chapter will provide background on the etiology, clinical manifestations, and treatment of common oral conditions that affect older individuals. In addition, a comprehensive review of age-related oral changes and the impact they have on oral health and the provision of dental care will be performed.

GERIATRIC PATIENT ASSESSMENT

The health assessment of an older adult can be quite different and significantly more complicated than the work-up of a younger patient. A geriatric assessment differs from a standard evaluation, because it includes nonmedical areas that emphasize functional capacity and quality of life, yielding a more complete and relevant list of medical problems, functional problems, and psychosocial issues. A variety of validated tools can make geriatric assessment more specific for older patients, as these instruments evaluate domains such as activities of daily living (ADLs), hearing, fecal and urinary continence, balance, and cognition; none of which is typically evaluated in a younger patient.[16] This assessment should also include a thorough review of prescription and over-the-counter medications and supplements, and also review of immunization status. An interprofessional team, which can include a primary care provider, nutritionist, social worker, pharmacist, psychologist, physical and occupational therapists, and oral healthcare professional, yields a more complete and relevant list of medical problems, functional problems, and psychosocial issues and therefore provides more comprehensive, whole-person, person-centered care.[17]

Dental treatment planning can also be complicated, as a multitude of factors affect decision-making and provision of care. Limitations due to social, economic, financial, family, medical, physical, and transportation constraints must all be considered when formulating a comprehensive oral healthcare plan for an older patient.[18] Treatment plan sequencing and communication of the plan can be challenging due to the variety of issues that complicate the progression of care. The final outcome can be difficult to predict, and therefore the treatment plan must be dynamic. Patient health may change as treatment proceeds, thus resulting in new treatment modifications that necessitate reassessment as well as communication based on these needs. Patients, their family, and their caregivers must continually be informed about their oral condition and the fact that treatment needs may change as treatment progresses. Optimal dental care for the geriatric patient requires an individualized approach that includes modifying factors and circumstances, such as disability that affects self-care or length of appointment.[19]

Utilizing a systematic approach when assessing older patients can aid in the development and delivery of comprehensive treatment. This approach starts with an assessment that answers several basic questions specific to older adults:

- How does the patient function in their environment?
- What role does pharmacotherapy play in the patient's medical and oral health?
- What social support systems for the patient exist?
- What diverse sociologic variables exist?
- How does oral healthcare fit into the patient's environment?

Dental management of the geriatric patient is consistent with any medically complex patient and involves the evaluation of four risks and subsequent modifications to the provision of dental care. Risk of infection, risk of bleeding, risk of drug actions and interactions, and risk of medical emergency during dental care need to be evaluated before routine dental treatment begins.[20] The elderly can be immunosuppressed or nonadherent with medications and instructions, therefore placing them at increased risk of infection. In addition, they may be taking anticoagulation medications or have a systemic disease that alters hemostasis. Depending on the invasiveness of the procedure, patients can be at increased risk of bleeding. The elderly are often taking more medications, are more sensitive to medications, may need renal dose adjustment, and have difficulty with drug compliance and accuracy.[21] Finally, it is imperative to evaluate the ability to withstand treatment based on systemic disease and compliance in control of the disease, and also to ensure that the dental team is prepared for a potential emergency.

A multidimensional assessment tool for planning oral healthcare for the older patient has been developed by the American Academy of Oral Medicine.[22] This tool is called OSCAR, a five-item mnemonic for Oral, Systemic, Capability, Autonomy, and Reality. OSCAR serves to guide dentists in identifying the dental, medical, pharmacologic, functional, ethical, and fiscal factors that need to be considered before dental treatment of older patients. This approach enables the clinician to evaluate each older patient in a comprehensive manner, incorporating all factors that may affect care.

The OSCAR approach starts with patients' oral needs and can include issues such as oral mucosal disease and periodontal and dental problems. Assessment of systemic factors is next and incorporates medical problems, medications, and collaboration with other healthcare providers to develop the treatment plan. Evaluating patients' capability is very important and involves the assessment of functional capacity, ability to move and be moved, and even their skill in performing oral hygiene. Next is evaluation of patients' autonomy, which

assesses decision-making ability, ability to communicate and understand, and even the ability to consent to care. Lastly, reality refers to financial issues, life expectancy, prognosis, and ability to perform oral hygiene and maintain oral health, which would affect the dental treatment plan. Taking each of these facets into consideration enables the clinician to provide patient-centered care that is specific for each older patient (see Table 26-1).[22]

PHARMACOTHERAPEUTICS IN OLDER ADULTS

Older adults make up approximately 15% of the US population, but are responsible for one-third of all prescribed medications.[23] Furthermore, it is projected that by 2040 older adults will be consumers of 40% of prescribed medications.[24] Due to increased medication exposure, older adults are at greater risk for drug-related complications. Problems such as drug–drug interactions, adverse drug reactions (ADRs), undermedication, polypharmacy (use of multiple medications or use of more medications than appropriate), and nonadherence are common among this population.[25] In addition, numerous changes occur as a result of physiologic aging that alter the way medications are absorbed, distributed, metabolized, and eliminated.[26] Medications therefore may need to be prescribed differently in this population by carefully choosing medications to avoid adverse effects or drug interactions, and adjusting doses to allow for functional changes of organs, such as the liver and the kidneys. Finally, certain medications may not be safe to use at all in older adults, and these are delineated in the Beers List of Medications to Avoid in Older Adults.[27] (A more in-depth understanding of the Beers List is addressed in what follows.)

Table 26-1 OSCAR approach to evaluation and treatment of the older dental patient.

Areas of Concern	
Oral	Dentition, restorations, fixed and/or removable prostheses, periodontium, oral mucosa, salivary glands
Systemic	Medical problem list, medications, age-related changes, interprofessional communication
Capability	Ability to perform instrumental activities of daily living, activities of daily living, caregivers, oral hygiene, transportation, mobility
Autonomy	Decision-making ability, consent to care, dependence on others for decisions
Reality	Financial limitation, life expectancy, prognosis, ability to maintain dental treatment, medical stability

Source: Adapted from Laudenbach J, Jacobsen PL, Mohammad AR, et al. *Clinician's Guide: Oral Health in Geriatric Patients*, 3rd edn. Seattle, WA: American Academy of Oral Medicine; 2011.

Pharmacokinetics

The pharmacokinetics of medications—absorption, distribution, metabolism, and elimination—can be altered due to the aging process. The *absorption* of medications is least affected. Most drugs are absorbed passively, simply by being in the stomach or intestine. If absorption is affected in older adults, it is usually decreased due to an increased amount of acid in the stomach, decreased movement of the muscles of the digestive system, or decreased surface area for absorption.[28,29] Many medications are not significantly affected by these changes, but the coadministration of certain medications, such as antacids, can further decrease absorption. As a consequence of the age-related changes in body composition, drug *distribution* can be affected. Drugs that are mainly water-soluble tend to have smaller volumes of distribution, resulting in higher serum levels in older people. Lipid-soluble medications have higher volumes of distribution, resulting in a prolongation of half-life.[29] Aging is associated with a reduction in first-pass *metabolism*, likely due to a reduction of liver mass and blood flow. The result is a decrease in the bioavailability of medications that undergo an extensive first-pass effect.[28,29] Medications that are prodrugs, however, need to be activated in the liver and hence their activation might be reduced.

Drug *elimination* is affected by aging due to a decline in renal function. As the body ages, there may be:

- Decreased kidney size.
- Decreased blood flow to the kidneys.
- Long-standing disease, such as diabetes or hypertension.[29]

The medication dose or dosing frequency may need to be altered; usually less frequent administration is needed, as it will take the body longer to eliminate the medication.

Pharmacodynamics

The pharmacodynamics of medications—the drug's action on the body—can also be affected by the aging process. As we age, multiple changes occur, such as changes in body composition (increased body fat, decreased lean muscle mass, and decreased body water), which can affect frequency of administration and dosage of medication. Medications that are lipophilic may have prolonged effects due to the increased amount of body fat. Drugs that are hydrophilic

may have a more rapid increase in concentrations in the blood because there is less water. These changes often necessitate lower dosing of medication.[28, 29] Drugs that are highly protein bound, however, have less protein upon which to bind, therefore more of that medication may be required for it to be effective. Finally, as adults age they may experience decreased or enhanced effects of drugs compared to younger populations. Changes occur at the medication's receptor site of action and can ultimately affect the way the body responds to the medication. For example, some older patients are susceptible to medications that cause sedation as a side effect. Sedation can have multiple comorbidities: risk of falls, confusion, and the inability to perform daily tasks.[28,29]

Polypharmacy

Polypharmacy is the use of multiple medications and/or the administration of more medications than are clinically indicated.[30,31] Polypharmacy may also be described as the use of one medication to treat the side effects of another medication, rather than changing to medication that may be better tolerated.[32] Polypharmacy is common among geriatric patients: 87% report taking one prescription medication, 36% report taking five or more prescription medications, and 38% use over-the-counter medications.[32] The likelihood of receiving a prescription increases with age, and polypharmacy may increase the incidence of ADRs as well as drug–drug interactions. Adverse drug events are responsible for one in six older adults being hospitalized.[33]

Medication Adherence

Medication adherence is the extent to which a patient's use of medications coincides with medical or health advice. Medication adherence is a significant problem among the geriatric population. Over 70% of Medicare beneficiaries take prescription medications, but as many as 30% are nonadherent.[34] Complex medication regimens, misunderstanding medication importance, forgetting to take medication, not getting medication refilled, worry about side effects, lack of understanding of indication, and cost all may contribute to decreased adherence.[34] Underprescribing appropriate medication can also occur in the medical management of older patients. Some medications may be underutilized for conditions such as pain, because of concerns about adverse effects or polypharmacy in the geriatric population.[35] Overall, concerns related to comorbidities, adverse drug events, limited life expectancy, and poor risk-to-benefit ratio can all be reasons why prescribers are more hesitant to write for indicated medications.[36]

The Beers Criteria

The Beers Criteria for Potentially Inappropriate Medication Use in Older Adults was originally developed in 1991 by the late geriatrician Mark Beers as a catalogue of medications that cause adverse drug events in older adults due to their pharmacologic properties and the physiologic changes of aging.[28] Beers developed a list of medications, doses, and durations that should be avoided in patients older than 65 years in nursing homes. The list was created from expert consensus through extensive literature review. Since 2012, Beers Criteria have been revised every three years in order to be applicable to all adults 65 and older regardless of where they reside, and include criteria specific to diagnosis and condition. In 2019, the American Geriatrics Society (AGS), utilizing an enhanced, evidence-based methodology, published updated AGS Beers Criteria® to improve medication safety in older adults.[27] Each criterion on the list was rated by quality and strength of evidence, using the American College of Physicians' Guideline Grading System.[28] For the 2019 update, an interdisciplinary expert panel reviewed the evidence published since the last update (2015) to determine whether new criteria should be added or existing criteria should be removed or undergo changes to their recommendation, rationale, level of evidence, or strength of recommendation. Five criteria were used to eliminate 25 medications from the list published in 2015:

- Medications that are potentially inappropriate in most older adults.
- Those that should typically be avoided in older adults with certain conditions.
- Drugs to use with caution.
- Drug–drug interactions.
- Drug dose adjustment based on kidney function.[27]

Printable Beers Pocket Cards are available for download.[36]

Tools for Medication Assessment

Medication use in older adults can be complicated. Each person is different and all geriatric patients may not have the same degree of impairment, so an individualized approach is of the utmost importance. Evaluation of medications in the geriatric population is vital to ensure that medications are used appropriately and safely. Studies have shown that as many as 40% of nursing home residents in the United States were prescribed inappropriate medications.[37]

There are both implicit and explicit tools used to assess medication appropriateness. Implicit tools utilize patient-specific information and prescriber clinical judgment and experience

to address questions, statements, and algorithms in order to optimize medication regimens.[38] Implicit tools enable healthcare providers to identify both the medications that should be avoided as well as the incorrect doses, drug interactions, and patient preference. Examples of implicit tools—the Medication Appropriateness Index (MAI) and the ARMOR tool—are discussed in this section.[38,39] Explicit tools, on the other hand, do not consider patient-specific factors in determining medication appropriateness and comprise lists of medications developed by consensus panels after extensive literature and database review. An example of an explicit tool is the AGS Beers Criteria previously discussed.[27] Explicit tools can be used by anyone regardless of discipline to determine the appropriateness of prescribing, but are limited to medications recognized by the tools' developers. In contrast, implicit tools can be applied to any medication, but require clinical judgment and an understanding of physiology and pharmacology.

The MAI is a tool that uses implicit criteria to rate medications in order to reduce polypharmacy and inappropriate prescribing.[38] Its is very reliable and is structured in a way to evaluate medication use in geriatrics. Even when different clinicians evaluate the regimen, the results are generally similar. The MAI covers 10 elements of appropriate prescribing.[38] It is useful in a variety of situations, including patients in the community and hospital settings.[38]

The ARMOR tool is used to Assess, Review, Minimize, Optimize, and Reassess medication regimens (see Table 26-2).[39] The goal of ARMOR is to improve a patient's functional status and mobility. The tool was designed for nursing home residents receiving more than nine medications, seen for initial assessment, with falls or behavioral disturbance, or who are admitted for rehabilitation.[39] This tool was tested in a long-term care facility and was evaluated by a multidisciplinary team from medicine, nursing, physical/occupational therapy, recreational therapy, and social work. The ARMOR tool can also be utilized for all geriatric individuals and has led to a reduction in polypharmacy, cost of care, and hospitalization.[39]

Table 26-2 ARMOR tool of medication assessment.

ARMOR
Assess the patient for the total number of medications with a potential for adverse effects (beta blockers, antidepressants, antipsychotics, pain medications, medications on the Beers criteria)
Review medications for possible drug–drug interactions, drug–disease interactions, pharmacodynamic (how drugs act in the body) interactions, impact on function, and adverse effects
Minimize the number of nonessential medications, particularly medications with a clear lack of evidence, or if the risk outweighs the benefits of using the medication
Optimize therapy. Evaluate duplicate treatments, adjust doses for kidney or liver function, and adjust doses to achieve treatment goals
Reassess the patient and medications using information such as heart rate, blood pressure, oxygen saturation, functional status, cognitive status, and medication compliance

Source: Adapted from Haque R. ARMOR: a tool to evaluate polypharmacy in elderly persons. *Ann Longterm Care.* 2009;17:26–30.

Geriatric patients are more likely to be on multiple medications, many of which can complicate the provision of oral care. It is therefore imperative for oral healthcare professionals to evaluate patient medications in the context of pharmacokinetics and pharmacodynamics, potential adverse reactions, and complications as a part of the comprehensive oral/medical evaluation. A 2018 study showed that over 75% of patients surveyed are aware of the importance medications have in interacting with dental health and treatment, and consequently disclose all medications prior to dental care.[40] The dental team can therefore provide evaluation of medication adherence and reconciliation as part of whole-person care.

HEALTH LITERACY

Health literacy is defined as "the degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decision.s"[41] Health literacy is not only the ability to read, as it also involves listening, analyzing, and decision-making together in healthcare situations. Patients may be well educated and knowledgeable in any number of areas, but may have limited knowledge about health and healthcare. Findings of the 2003 National Assessment of Adult Literacy revealed that although the majority of adults in the United States had intermediate or proficient literacy, 36% had only basic or below basic health literacy.[42]

Results of this survey also revealed that compared to adults in younger age groups, adults aged 65 years and older had lower average health literacy. Among adults aged 60 years and older, 71% have difficulty using print materials, 80% have difficulty using documents such as forms or charts, and 68% have difficulty interpreting numbers and performing calculations.[42] In addition, estimates suggest that 66% of older adults are not able to understand information received about their prescription medications.[43] Activities requiring health literacy include communicating with clinicians about health and illness, reading and understanding health information, taking medications, making appointments, and filling out medical forms.[42,43]

Health literacy is especially important among the geriatric population because it affects a patient's ability to navigate

Table 26-3 Teach-Back method: confirmation of understanding.

Do not ask a patient "Do you understand?"
Ask patients to explain or demonstrate
Ask questions that begin with "how" and "what," rather than closed-ended, yes/no questions
Organize information so that the most important points stand out and repeat this information
Ensure agreement and understanding about the care plan. This is essential to achieving adherence

Source: Adapted from Stein PS, Aalboe JA, Savage MW, Scott AM. Strategies for communicating with older dental patients. *J Am Dent Assoc*. 2014;145(2):159–164.

the healthcare system, share personal and health information with providers, engage in self-care in chronic disease management, and even adopt health-promoting behaviors. Low health literacy is associated with increased use of inpatient and emergency care, decreased use of preventive and primary care, and deficits in self-care. Limited health literacy also leads to underutilization of services, poor understanding of health, poor health outcomes, and increased healthcare costs.[44]

The entire oral healthcare team must be aware and sensitive to the effect health literacy has on the provision of care.[44,45] Some simple strategies are as follows:

- Explain things clearly to the patient using nonscientific, plain language, starting with the most important information first.
- Emphasize one to three points and encourage questions.
- Provide written instructions for important information and provide useful educational materials.
- Use the teach-back method to confirm the patient's understanding. This approach has the provider ask the patient to describe and/or demonstrate the information that has been explained. This is accomplished by asking open-ended questions (e.g., do not ask the patient, "Do you understand?").[46,47]
- Ensure agreement and understanding about the care plan; this is essential to achieving adherence (see Table 26-3).[47]

COMMON CHRONIC CONDITIONS AND LEADING CAUSES OF DEATH

Advances in medical treatment and effective public health strategies have contributed to a striking increase in average life expectancy. Since 1900, global average life expectancy has more than doubled and is now above 70 years.[48] In the United States, diseases that were fatal 100 years ago are no longer leading causes of death. Since 1910, heart disease has been the leading cause of death every year except 1918–1920, when there was an influenza epidemic. Since 1938, cancer has been the second leading cause of death every year. Other chronic diseases such as stroke, chronic respiratory diseases, Alzheimer disease, and diabetes continue to be the most common chronic diseases for those aged ≥65 years in the United States (Figure 26-2).[49]

Approximately one in three adults globally suffers from multiple chronic diseases. The societal burden of chronic diseases impacts healthcare expenditures, primary care and specialist provider access, and both emergency department and hospital admissions. The burden of chronic disease on the afflicted individual is substantial, causing disability, unemployment, financial burden, and worsening quality of life.[50]

At first there may be difficulty with instrumental activities of daily living (IADLs), such as money management, grocery shopping, preparing meals, and taking medications properly.[51] As physical and/or mental ability declines, the capability to perform the most basic activities (ADLs) is affected, which can include tasks such as personal hygiene, self-feeding, getting dressed, and toileting. The inability to perform ADLs can alter social engagement with family and friends. Restriction of mobility in the home and of engagement in the community can greatly narrow an older person's world and ability to do the things that bring pleasure and satisfaction. The inability to care for oneself in a safe and appropriate manner leads to further dependence on others and very often to the need for care in an institutional setting (see Table 26-4).[51]

AGE-RELATED SYSTEMIC CHANGES

Changing demographics and improved medical management of disease are placing increased demand on oral healthcare professionals for improved knowledge of both oral manifestations of disease and the provision of dental care for patients with systemic disease. Aging is influenced by genetic factors, lifestyle choices, and environmental exposures, but the predominant physiology of aging is characterized by a breakdown in maintenance of certain molecular structures and pathways, with resultant loss of physiologic reserves needed to handle challenges to homeostasis.[52] As people live longer and as organ systems gradually decline, there is an increase in chronic conditions and illnesses that influence the provision of oral care. The diseases themselves, as well as their treatment, can affect the oral cavity. In addition, chronic impairments, such as hearing or visual or orthopedic disability, can directly affect oral health and impair dental treatment.[52] Simple steps can be taken by dental professionals to help improve communication, oral care, and maintenance.

MOST COMMON SYSTEMIC DISEASES IN OLDER ADULTS

The most common systemic diseases among older adults include hypertension and cardiovascular diseases, arthritis, chronic obstructive pulmonary disease, diabetes mellitus, depression, chronic kidney disease, and Alzheimer disease and dementia.[53] These medical conditions are discussed in detail in various chapters throughout this book. However, two of the most common chronic diseases deserve particular mention within the geriatric context, dementia and arthritis, as they most often affect the elderly.

Dementia

Dementias are a considerable problem among the elderly population. Worldwide, an estimated 50 million people are currently living with dementia. This number is projected to reach 82 million by 2030 and 152 million by 2050.[54] Dementias comprise many illnesses, with the most common being Alzheimer disease and vascular dementia, both of which are characterized by mental and physical decline.[55] With increased severity of dementia, there is progressive cognitive and memory loss, development of social and behavioral problems, and inability to perform daily activities. Progression of dementia is accompanied by a gradual inability to perform self-care (including adequate oral hygiene), self-neglect, and loss of cognitive and motor skills.[56] Persons with dementia often have impaired oral health as a result of poor oral hygiene, reduced salivary flow, more gingival plaque, bleeding, and calculus compared to age- and gender-matched adults.[56] Further, poor gingival health and oral hygiene have been found to increase with the severity of dementia.[57]

Oral care, treatment planning, and behavioral management for persons with dementia must be designed with consideration of the severity of disease and must involve family members or caregivers.[58] Aggrssive preventive and interceptive steps need to be formulated to preserve existing oral health early in the disease process. As dementia progresses, treatment becomes problem based, recall and preventive measures are more frequently needed, and the role of the

caregiver becomes more critical in providing daily oral hygiene and assessing symptoms that arise.[58,59] In severe dementia, complex and time-consuming dental treatment should be avoided and the emphasis should be on keeping the patient pain free, nourished and hydrated.

A comprehensive preventive dental plan is crucial in patients with dementia, as is involving the caregiver as a co-therapist. Patients with dementia may forget oral hygiene, dental appointments, and instructions, unless the caregiver is involved. Dental treatment is best if provided in the morning, when cooperation tends to be greatest, with the usual caretakers present. Treating the patient in an upright or semi-upright position may aid in the prevention of aspiration and postural hypotension.[58,59]

Arthritis

It is estimated that nearly half of all people older than 65 years have arthritis that causes limitation of activity.[60] Patients with arthritis often have diminished manual dexterity that affects maintenance of oral hygiene. Utilizing modified oral hygiene tools can enable improved oral hygiene.[61] Toothbrushes with specially adapted handles (e.g., a bicycle handle grip or the addition of a tennis ball) enable patients to hold and maneuver the brush more easily. In addition, these patients may benefit from electric or sonic toothbrushes to lower the burden of oral hygiene.[61,62]

Patients with arthritis are best treated in the late morning or early afternoon, as joint stiffness and pain tend to improve during the day. Supine positioning may be uncomfortable for them, and they may need neck and leg support. Finally, arthritis patients may need assistance ambulating as well as transporting into and out of the dental chair. Caution must be taken to minimize adverse outcomes, such as falls, as well as to maximize patient comfort.

AGE-RELATED ORAL CHANGES

Age alone does not play a major role in impaired oral health. However, there are age-related oral changes that can predispose older individuals to oral disease. Decay, gingivitis, periodontitis, mucosal diseases, salivary dysfunction, and resorptive bone disease can worsen or be exacerbated by systemic conditions and their treatment.[62,63] Oral diseases give rise to pathogens that can become aspirated into the lungs, causing serious, even life-threatening consequences. Systemic, mucocutaneous, dermatologic, and neurologic diseases can manifest initially in the oral cavity, predisposing older individuals to additional oral problems. Oral healthcare providers must therefore be able to recognize, diagnose, and treat oral conditions in elderly patients that are caused by age-related changes and systemic influences (see Table 26-5).[62]

Oral Motor and Sensory Function

Not only does the sense of smell diminish with age, but the ability to discriminate between smells decreases as well. More than 75% of people over the age of 80 years have evidence of major olfactory deterioration, with that decline being most significant after the age of 70.[64] Taste disorders are far less prevalent than olfactory losses with age. Gustatory dysfunction may be attributed to the normal aging process, but many times a perceived defect in taste is actually a primary defect in olfaction. Other frequent causes of taste dysfunction are upper respiratory infection, head injury, drug

Table 26-5 Common structural and functional oral effects in older adults.

Oral Structure or Function	Associated Oral Effects Related to Age
Oral mucosa	Cancers Vesiculobullous diseases Ulcerative diseases Inflammatory diseases
Dentition	Root caries Coronal caries Attrition Fracture/chipping
Periodontium	Gingivitis Periodontitis Abscesses Tooth loss
Salivary glands	Hypofunction Cancers
Sensory function	Olfactory dysfunction Dysgeusia
Motor dysfunction	Dysphagia Aspiration Masticatory muscle weakness
Pain sensation	Atypical facial pain Burning mouth syndrome Trigeminal neuralgia Postherpetic neuralgia Temporomandibular disorders
Removable prosthesis	Atrophic mandible Ill-fitting dentures Inflammatory lesions secondary to ill-fitting dentures Poor denture hygiene

Source: Adapted from De Rossi SS, Slaughter YA. Oral changes in older patients: a clinician's guide. *Quintessence.* 2007;38(9):773–780.

use, and idiopathic causes.[64,65] Mastication problems associated with tooth loss, ill-fitting dentures, or reduction in saliva production can also inhibit proper taste sensation. Patients who have diminished food recognition and enjoyment as well as altered smell and taste function can therefore have quality-of-life issues and malnutrition.[65] Oral healthcare professionals can serve an important role in nutritional counseling to prevent malnutrition, dehydration, and diminished quality of life.

Alterations in mastication, swallowing, and oral muscular posture occur with aging. The most commonly reported oral motor dysfunction is altered mastication.[64] Even fully dentate elderly patients are less able to prepare food for swallowing due to decreased muscular strength.[62] This muscle weakness can be exacerbated by various systemic diseases such as Parkinson's disease, a history of head and neck cancer and its treatment, multiple sclerosis, and cerebrovascular accidents. Subsequent effects on swallowing and deglutition may lead to choking and aspiration.[66] Motor issues may cause challenges to restorative dental treatment, therefore extra time should be allowed and extra patience should be exercised. In addition, the dentist should eliminate dental-related factors that might further inhibit the ability to eat properly. Finally, referral to appropriate healthcare providers is important in cases where interventions beyond the scope of dental care are needed. Speech and swallow experts, otolaryngologists, and nutritionists can provide beneficial information and treatment to elderly patients suffering from oral and maxillofacial motor and sensory dysfunction.

Orofacial Pain

An accurate diagnosis of a painful condition is often more difficult in the elderly due to a greater frequency of chronic diseases and altered pain response.[67] Understanding the nature and prevalence of pain in this group is paramount to a correct diagnosis, being cautious to avoid the oversimplification that "pain decreases with age."[68] The most prevalent types of pain in the orofacial complex are associated with the dentition, periodontium, oral mucosa, and bone. In addition, peripheral neuropathies such as burning mouth syndrome and atypical odontalgia are particularly common among the elderly population.[68] Extraoral pain disorders are similarly common with aging and may include trigeminal neuralgia, postherpetic neuralgia, various degenerative joint diseases of the temporomandibular joint, and persistent dentoalveolar pain from a neuropathic process (such as atypical facial pain or persistent idiopathic facial pain).[69] See Chapters 11 and 13 for more detailed explanation and management of various orofacial pain disorders.

Many elderly patients have diminished pulpal sensitivity.[70] A prompt and correct diagnosis is key, as it is important to minimize treatment and avoid unnecessary therapy in patients with dentoalveolar pain that is neuropathic in origin.[69] Pain assessment can be made by means of pain scales and specific open- and closed-ended questions. In patients who suffer from temporomandibular pain, appointments should be short and have frequent jaw rest. In patients with neuralgia, avoidance of trigger areas is imperative. Some practitioners may underestimate the severity of pain in older adults, and subsequently not prescribe appropriate analgesics when indicated.[71] In general, management of acute or chronic orofacial pain in geriatric patients is not significantly different than younger counterparts; however, it requires thorough examination and management, often involving multiple healthcare providers.

Dentition

Geriatric dental care is no longer simply denture care. For example, in the United States, only 13% of adults in the age 65–74 group were edentulous in 2009–2012, whereas this same age group had 55.4% edentulism in 1957–1958.[72] As people live longer and retain more natural teeth, the complexity of treatment increases and can include complex restorative procedures, aesthetic dentistry, and implants. Age-related changes to the dentition, such as occlusal attrition, pulpal recession, fibrosis, and decreased cellularity, may lead to diminished tooth sensitivity and reduced perception of painful stimuli.[70] Cementum thickness and pulp dimensions are also reduced with age.[70] Over time, dentin undergoes a reduction in thermal, osmotic, and electrical sensitivity and pain perception to caries decreases.[70] In addition, staining, chipping, and increased susceptibility to tooth fracture are common in older patients.

Caries is the most common tooth-related pathology.[70,73] For example, in the United States, nearly all adults (96%) aged 65 years or older have had a cavity; 1 in 5 has untreated tooth decay.[74] Root caries occurs as a result of increased gingival recession, salivary gland dysfunction, less effective oral hygiene, and diminished oral motor function. The risk factors for root caries include root exposure, dry mouth, oral hygiene status, bacterial virulence, and fluoride exposure.[73] Mandibular molars, premolars, and maxillary canines are most commonly affected, with the surfaces involved most often being facial and proximal.

Strategies to prevent root caries include gingival recession prevention, plaque control, use of multiple fluoride sources (including rinses, sprays, mouthwashes, and varnishes), dietary and nutritional counseling, and improvement of salivary flow.[75,76] Fluoride provides important antimicrobial and remineralization actions and also alters tooth surface energy.[75] Fluoride has the ability to concentrate in carious lesions as well as increase salivary pH. Several systematic

reviews have demonstrated the use of silver diamine fluoride (SDF) as a successful treatment strategy in preventing and arresting root caries in older adults.[76–78]

Restorative management of root caries involves multiple factors: isolation, gingival morphology, lesion location, preparation design, and choice of restorative material. Rubber dam is an ideal form of isolation; however, due to the often subgingival extension of root caries, cotton roll isolation or a VAC ejector system may be indicated. Removing gingival obstructions with a gingivectomy, retraction cord, or even a full-thickness flap may also be indicated. Restorative materials must be evaluated for advantages and disadvantages for each patient and lesion:

- Amalgam is effective when isolation is poor, but requires gross mechanical retention and has minimal plaque resistance.
- Glass ionomer cures quickly, needs moderate isolation, has sufficient chemical bonding, and has good plaque resistance.
- Composite resin has strict isolation requirements for bonding, has poor plaque resistance, and requires a rubber dam.[74]

Restorative maintenance includes a low-carbohydrate diet, patient education with intense hygiene instruction, and frequent recall. Addressing the cause of decay through a caries risk assessment as well as utilizing remineralization therapies both in the dental office and at home can aid in maintenance. Fluoride-releasing restorative materials should also be considered when evaluating treatment options.[75] Finally, conservative treatment plans such as the use of SDF in high caries-risk patients, especially among those who are unable to maintain their restorations, is vital.

Periodontal Tissues

Aging can be associated with healthy periodontium over the life course, resulting in a high level of tooth retention and function. Older adults who receive consistent dental care retain more teeth than those who do not, but this consistent care is not always sufficient to prevent the progression of periodontal disease with comparable success to younger counterparts.[79] The interplay of compositional change of plaque and the reaction of the periodontium to the plaque together with systemic diseases, their complications, and pharmaceutical management counter the degree of success seen in younger individuals.[80] Gingival recession with loss of periodontal attachment and poor oral hygiene predisposes the aging patient to tooth loss and masticatory insufficiency. Problems with deglutition soon follow, which can then lead to serious consequences such as dehydration and malnutrition.[79] Periodontal disease requires more frequent recall and more conservative restorative treatment plans.[80] Home care can be difficult due to psychomotor deficiencies, but can be aided by adaptation to hygiene products specific for this population. Toothbrushes with modified handles, electric toothbrushes, three-sided brushes, finger toothbrushes, and suction brushes provide creative approaches to consistent oral hygiene. Education is at the core of prevention, both for the patient and for the caregiver.

Oral Mucosa

The clinical appearance of oral mucosa in healthy older adults is indistinguishable from that in younger patients. Changes over time, including mucosal trauma, mucosal diseases, oral habits, and salivary gland hypofunction, can alter the clinical appearance and character of oral tissues. Declining immunologic responsiveness with age further increases susceptibility to oral mucosal infection and trauma.[52,81] Systemic disease and a variety of medications can also result in oral mucosal disorders. Finally, the oral epithelium becomes thinner, loses elasticity, and atrophies with age, making it more susceptible to pathology.[81] A brief discussion of the more common oral mucosal disorders seen in the elderly demographic follows. More in-depth discussions of each topic are found in Chapters 3, 4, and 6.

Traumatic Ulcers

Traumatic ulcerations of the oral mucosa most frequently affect the labial and buccal mucosa and are associated with lip and cheek biting, factitial habits, motor dysfunction, pressure necrosis, improper hygiene, broken teeth, irritation by faulty restorations, and ill-fitting removable prostheses.[63] Traumatic ulcerations appear as shallow ulcerations with a necrotic center and varying degrees of erythema at the periphery. Treatment of these lesions involves identifying the etiology and removing it. If no resolution occurs within a two-week period, an incisional biopsy for histologic diagnosis is prudent, as chronic traumatic lesions can be indistinguishable from oral cancer. Palliation with topical emollients and anesthetics may be helpful.

Lichen Planus

One of the more common ulcerative disorders of the oral mucosa is lichen planus, which also includes lichenoid reactions from medications. Although the etiology may be idiopathic, virally induced, or drug related, most lichenoid lesions are likely due to some precipitating event that leads to a T cell–mediated chronic inflammatory response in the oral tissues, resulting in a reticular striated, plaque-like or ulcerative mucosal condition.[82] The possibility of lichenoid

reactions to dental materials also exists. Lichen planus should be diagnosed with biopsy, as there is an associated malignant transformation in patients with chronic oral lichen planus.[82] Patients diagnosed with lichen planus should be counseled as to the increased risk of malignant transformation and the need for biannual reevaluation even if asymptomatic. More frequent recall is also needed in patients with desquamative gingivitis, because painful, sore, and tender gingiva often affect oral hygiene. See Chapter 4 for an in-depth, detailed discussion of lichen planus and lichenoid reactions.

Inflammatory Lesions

Inflammatory lesions in older adults occur often as a result of poorly fitting dentures.[83] Papillary hyperplasia is a common finding in patients with loose maxillary dentures. Clinically, these lesions represent multiple, polypoid, and papillary nodules, found typically on the hard palate, giving a cobblestone appearance. There also may be comorbid candidiasis.[83] Treatment includes decreased or discontinued use of the denture. Tissue conditioners may reduce papillary hyperplasia, along with concomitant treatment with an antifungal agent. Occasionally, surgical removal of the hyperplastic tissue and/or construction of new prostheses may be indicated. Another denture-related inflammatory lesion is epulis fissurata, which appears as hyperplastic, redundant tissue in the vestibule due to overextended denture flanges. Dentures become overextended because of resorption of the alveolar bone or significant weight loss.[83] Hyperplastic granulation tissue surrounds the denture flange and can be associated with pain, bleeding, and ulceration. Small lesions may resolve if denture flanges are reduced. However, surgical excision is necessary for larger fissurata prior to rebasing or relining a denture.

Candidiasis

Older patients are at increased risk of developing intraoral candida infections due to systemic disease, poor immune function, medication- or disease-induced dry mouth, and removable prostheses.[80] Pseudomembranous candidiasis is the most common clinical presentation and appears as a white plaque on any intraoral mucosal surface that can be wiped away, leaving an erythematous base. Less commonly, candida infections appear as generalized, diffuse erythema throughout the oral tissues. Patients may complain of pain or burning in the oral cavity as well as a change in taste sensation, but many cases are asymptomatic. The diagnosis of intraoral candidiasis includes a thorough review of systems along with disease history and can be made clinically in many instances.[80] Direct cytologic smear for periodic–acid Schiff staining is helpful to confirm a diagnosis. In severely debilitated patients, extension of the yeast to the esophagus and trachea may lead to significant morbidity and mortality. Use of both topical and systemic antifungals is indicated, as well as direct topical treatment of any prostheses.

Angular Cheilitis

Angular cheilitis is a common variant of a candida infection that is seen very commonly in the older patient. Angular cheilitis can occur not only due to candidiasis, but also due to diminished occlusal vertical dimension or nutritional deficiencies, such as vitamin B or iron deficiencies.[80,83] Commonly, patients have wrinkled and sagging skin at the lip commissures, with desiccation and mucosal cracking along the corner of the vermillion border. The most effective treatment includes a combination antifungal and steroid cream applied to the affected areas several times daily. To prevent chronic symptoms, vitamin deficiencies should be excluded and vertical dimension of occlusion issues should be eliminated. For further information on oral candidiasis, refer to Chapter 4.

Vesiculobullous Disease

Pemphigus vulgaris is a serious life-threatening autoimmune vesiculobullous disorder that usually affects individuals after their fifth and sixth decades of life (see Chapter 3). *Cicatricial or mucous membrane pemphigoid* is another immunologically mediated vesiculobullous disorder that primarily affects older women (see Chapter 3). Early and accurate diagnosis with biopsy for both routine and direct immunofluorescence study is vital. Dental management considerations include more frequent hygiene recall and careful use of removable prostheses to avoid exacerbation of mucosal lesions. Older patients afflicted with pemphigus or pemphigoid require the same topical and/or systemic treatments as their younger counterparts; however, drug–drug interactions and comorbid systemic disease must be considered when choosing treatment.[84]

Recurrent herpes labialis, recurrent intraoral herpes, and *herpes zoster* reactivation along any of the three distributions of the trigeminal nerve can cause vesiculobullous ulcerations and significant oral pain in the older patient.[85] It is important for the dentist to avoid elective dental care during these acute flares and to consider prophylactic antiviral medications in patients with a history of reactivation of the virus and oral lesions secondary to dental treatment. Treatment of recurrent herpetic lesions is more effective when started in the prodromal stage before lesions ulcerate and crust. Topical ointments and creams as well as systemic antiviral therapies are often indicated. Occasionally, prophylactic systemic antiviral therapy may be appropriate. Herpes zoster, or shingles, most commonly occurs in people who are

over 50 and those who are immunosuppressed.[86] The shingles vaccine is recommended by the Advisory Committee on Immunization Practices to reduce the risk of shingles and its associated pain in people 60 years old or older.[86]

See Chapter 3 for detailed explanations of these and other vesiculobullous diseases.

Oropharyngeal Cancer

Incidence rates of oral cancer increase with age. Over 50,000 new oral cavity and pharyngeal cancers were diagnosed in 2020, comprising 2.9% of all cancer diagnoses.[87] Nearly 11,000 Americans will die from this disease in that same year.[87] Oral cancer has an overall five-year survival rate of approximately 66.2%—a rate that increases significantly with advanced stageing.[87] Typical sites of oral malignancy in the elderly include the tongue, lips, buccal mucosa, floor of mouth, and posterior oropharynx. The most common risk factor other than increased age is the use of tobacco and alcohol. Oral malignant lesions are typically squamous cell carcinomas and can appear as diffuse, poorly defined exophytic masses that can metastasize to regional lymph nodes before involving distant organs.

An oral cancer screening examination should be performed at every dental visit, as well as reinforcement of prevention by means of limiting risk factors such as sun exposure, alcohol intake, and tobacco use.[88] Patients diagnosed with and treated for oropharyngeal cancer will have extensive acute and long-term complications related to cancer treatment. For explanation of these side effects and their management, see Chapter 8.

Salivary Glands

Salivary glands are known to undergo histologic changes with age. Secretory components of the glands are replaced by fibrous and adipose tissue, making them less effective at producing saliva.[89] Clinically significant decreases in major salivary gland flow do not occur in healthy older people, although age-related changes in salivary quality and electrolytes have been demonstrated. [89] Changes in salivary quantity and quality cannot be attributed only to aging, as it is more likely that changes in saliva occur due to the effects of medications, polypharmacy, and systemic disease.[90] Diminished salivary output can cause dental decay, oral mucosal infections, sensory disturbances, speech dysfunction, decreased nutritional intake, and difficulty in chewing, swallowing, and denture retention.[90]

An appropriate diagnosis for oral dryness is vital, as there is a plethora of both salivary and nonsalivary causes.[91] In addition, the management of salivary gland hypofunction and xerostomia is multidisciplinary and multimodal, requiring communication and collaboration among multiple clinicians, the patient, and the patient's caregiver.[92] A comprehensive discussion of salivary gland diseases, decreased salivary flow, and management is found in Chapter 9.

INSTITUTIONALIZED OLDER ADULTS

Although most of the world's population lives independently, a significant number of older adults are completely dependent for all aspects of life. Approximately 1.3 million elderly reside in 15,600 nursing homes in the United States.[11] These individuals are likely to have diminished physical capabilities as well as cognitive impairment, which together can compromise general and oral health status. Multiple studies have reported that large proportions of nursing home residents have a host of dental diseases and rarely seek dental care services.[11] Currently, on admission to a nursing home, residents are to receive a comprehensive health assessment that includes an oral evaluation. This evaluation is federally mandated for all facilities that receive either Medicaid or Medicare reimbursement, which is about 98% of all US long-term care facilities.[11] Admission oral evaluations are typically performed by dietitians, clinical nurse assistants, or other healthcare professionals, who are not necessarily able to accurately identify oral problems and cannot always recommend appropriate follow-up care. In addition, oral healthcare is not adequately considered in most protocols on personal hygiene for the elderly in hospitals or long-term care units.[11]

Oral disease is rarely life-threatening. However, it plays an essential role in the management of medical problems, nutrition, social interaction, and the quality of life of older adults. For example, in 2000, the link between oral health and general health was brought to the forefront when the US Surgeon General released a report on *Oral Health in America*.[93,94] This report highlighted the "silent epidemic" of oral disease that affects the most vulnerable citizens in the United States, among whom are the elderly. Multiple studies support the notion that institutionalized subjects are at greater risk not only of developing pneumonia, but also of having dental plaque colonization by respiratory pathogens.[95] Although federal legislation that funds payments to nursing homes for the care and housing of their residents requires that there should be no oral neglect, in the absence of a consensus definition of oral neglect there can be no systematic enforcement of this legislative mandate.[96] A consensus definition of oral neglect would provide minimum standards for the oral health status of nursing home residents, operational oral health standards for nursing home

administrators, enforceable guidelines for agencies responsible for quality, and provide the general public with a clear statement of dentistry's ethical and professional stance on this topic.[96]

SPECIAL CONSIDERATIONS FOR COMMUNICATION AND ORAL HYGIENE INSTRUCTION

Older adults have various functional and behavioral changes that require special consideration during dental treatment and oral hygiene education. Communication between oral healthcare provider and patient very often needs to be adjusted so the patient gleans the most out of both the treatment and the instruction.[47] There can be slowing of speed of thought or associations in older adults, hence making suggestions gradually, even over a series of appointments, and adapting the patient's current approach to make it more effective are valuable.[47] Many times older adults have difficulty in timing sequential events, therefore their skills become separate movements. In this situation, it is best to guide the patient's demonstration of their oral hygiene to avoid embarrassment.[47] The rate of learning changes with age, even though the ability to learn does not.

There are useful strategies in teaching oral hygiene for the aging patient. See Table 26-6 for a summary of different approaches.[61]

Table 26-6 Strategies for teaching oral hygiene practices in the aging patient.

Bridging	Involves engaging the individual's senses, especially sight and touch, to help understand the task you are trying to do for them
Chaining	The caregiver begins the oral hygiene task and the individual then helps to finish it
Hand over hand	Technique that helps to improve sensory awareness of takes and gives individuals the sensation that they are performing the task with you
Rescuing	Used to help with completing hygiene tasks for individuals with dementia
Distraction	Involves placing a familiar item in the individual's hands during oral hygiene care

Source: Adapted from Weening-Verbree L, Huisman-de Waal G, van Dusseldorp L, van Achterberg T, Schoonhoven L. Oral health care in older people in long term care facilities: a systematic review of implementation strategies. *Int J Nurs Stud*. 2013;50(4):569–582.

CONCLUSION

As the global population ages and as medical management of disease continually improves, the landscape of oral healthcare will also change. Oral healthcare professionals must possess the tools and knowledge to manage oral manifestations of systemic disease and age-related oral changes. Older adults are more susceptible to medical conditions that directly and/or indirectly lead to malnutrition, altered communication, increased susceptibility to infection, and diminished quality of life. Increased medication usage alone puts this population at greater risk for complications due to drug interactions, polypharmacy, and medication compliance. In addition, this age group has social determinants of health that have an impact on comprehensive dental care. Oral healthcare professionals play an important role in whole-person care by performing a systematic, comprehensive oral and medical evaluation of the geriatric patient, enabling the dental team to be an essential component in screening for disease, disease control, medical risk assessment, and medication adherence and reconciliation.

The Role of Genetics in Oral Medicine

Olga A. Korczeniewska, BA, PhD
Thomas C. Hart, BA, DDS, PhD
Scott R. Diehl, BS, PhD

BASIC HUMAN GENETIC PRINCIPLES

History of Genetics and the Human Genome Project

Since the dawn of civilization, humans have been aware of heredity and applied its principles to improve crops and domestic animals. Pedigrees of horses and possibly inherited characteristics were found on a Babylonian tablet more than 6000 years old.[1] However, the mechanism by which a genotype resulted in a phenotype was first described only about 150 years ago, when Gregor Mendel discovered independent assortment of traits through his cross-pollination experiments between variants of the garden pea. Most of the mechanisms of heredity remained a mystery until the nineteenth century, when genetics as a science began. It was the identification of genes, the fundamental units of heredity, which brought genetics into being. In the twentieth century, tremendous strides were undertaken to understand the nature of genes and their function. In 1905, English biologist William Bateson introduced the word "genetics" to describe the study of heredity and the science of variation.[2] In 1908, British physician Archibald Garrod applied genetic knowledge to human diseases and disorders. Garrod proposed that the human disease alkaptonuria was caused by "inborn errors of metabolism," suggesting for the first time that genes had molecular action at the cell level.[1] In 1909, Danish botanist, plant physiologist, and geneticist Wilhelm Johannsen introduced the term gene to denote the basic unit of heredity. In 1944, molecular biologist Oswald Avery showed that genes and chromosomes were composed on deoxyribonucleic acid (DNA). Ironically, for most of the twentieth century, clinicians viewed genetics as a somewhat esoteric academic specialty.

A major breakthrough occurred in 1953, when American genetics and biophysicist James D. Watson and British biophysicist Francis Crick and Maurice Wilkins discovered a double helix model for DNA structure.[3,4] Watson, Crick, and Wilkins shared the 1962 Nobel Prize in Physiology or Medicine for their discovery. Watson and Crick's discovery has helped researchers to understand human life more closely. In 1958, American molecular biologist Mathew Meselson and American geneticist Franklin W. Stahl for the first time demonstrated experimentally the strand separation method for DNA replication (semiconservative method).[5] In the 1970s, American biologists Allan M. Maxam and Walter Gilbert and English biochemist Frederick

Burket's Oral Medicine, Thirteenth Edition. Edited by Michael Glick, Martin S. Greenberg, Peter B. Lockhart, and Stephen J. Challacombe.

Sanger pioneered DNA sequencing techniques, for which Gilbert and Sanger shared the 1980 Nobel Prize in Chemistry. In 1983, American biochemist Kary B. Mullis invented polymerase chain reaction (PCR), a simple technique that allows a specific piece of DNA to be copied billions of times in a few hours.[6] In recognition of their invention, Mullis and Michael Smith shared the 1993 Nobel Prize in Chemistry.

On October 1, 1990, an international team of researchers began the Human Genome Project (HGP), which aimed at sequencing and mapping all of the human genes, known as the genome. Completion of the HGP in April 2003 for the first time provided the ability to read nature's complete genetic blueprint for building a human being.[7–10] Meanwhile, rapid advances in high-throughput sequencing and bioinformatics analyses made the "$1000 genome" (the cost to read the sequence of nearly a person's entire DNA sequence of ca. 3 billion DNA bases) a reality. This, in turn, greatly expanded the potential use of DNA sequencing as a tool for diagnostics and prognosis that emphasizes individualized or *personalized* health care.[11–13] In 2008, the 1000 Genomes Project was initiated through an international collaboration in which researchers aimed to sequence the genomes of a large number of people from different ethnic groups worldwide. Completion of the 1000 Genomes Project in 2015 enabled the creation of a catalog of genetic variations.[14,15]

Even though the completion of the HGP and the 1000 Genomes Project as well as the enormous public interest in genomics did not abruptly change or transform the fields of medicine and dentistry, the growing and evolving body of knowledge and information has significantly expanded how we think about and use human genetics in medicine and dentistry. Completion of the HGP has had a profound impact on genetic prediction of individual risks of disease and responsiveness to drugs.[16,17] Knowledge of the human genome sequence has enabled the development of designer drugs, based on a genomic approach to targeting molecular pathways disrupted in disease.[17–19] Genomic medicine holds the ultimate promise of revolutionizing the diagnosis and treatment of many illnesses.[20]

DNA Makes RNA Makes Protein

Genetics is the study of genes at all levels, including their function in the cell and the ways in which they are transmitted from parents to offspring. Modern genetics focuses on deoxyribonucleic acid (DNA), the chemical substance that genes are made of, and the ways in which it affects the chemical reactions.

All genetic diseases involve errors occurring at the level of the cell, for example DNA replication errors or errors in translation of genes into proteins. These errors often produce single-gene disorders. Errors occurring during cell division may results in disorders involving entire chromosomes.

Human somatic cells are diploid: they contain two copies of each chromosome, one from the mother and one from the father, for a total of 23 pairs (46 chromosomes). Of the 23 pairs of chromosomes, 22 pairs (numbered 1–22 from largest to smallest) are autosomal chromosomes and 1 pair is sex chromosomes. In a normal male, the sex chromosomes are a Y chromosome from the father and an X chromosome from the mother. Normal females have two X chromosomes. Gametes (egg and sperm cells) are haploid and contain a single copy of chromosomes (23 chromosomes).

Deoxyribonucleic Acid (DNA)

DNA is the genetic blueprint for making all proteins in the body. The discovery of the molecular structure of DNA revealed that it was made of a long chain of nucleotides arranged in two strands, forming a spiral called a double helix. Nucleotides are the building blocks of DNA that are made up of three components: a phosphate group, a 5-carbon sugar, and a nitrogenous base. The four nitrogenous bases in DNA are adenine (A), guanine (G), cytosine (C), and thymine (T), which is replaced by uracil (U) in ribonucleic acid (RNA). Adenine and guanine are purine bases and cytosine, thymine and uracil, and pyrimidine bases. The information in DNA is stored as a code of these four chemical bases that pair up with each other via hydrogen bonds, such that A pairs with T via a double hydrogen bond and C pairs with G via a triple hydrogen bond. The complementary base pairing is important during DNA replication, in which DNA polymerase enzyme uses a single strand of the double-stranded DNA molecule as a template for the synthesis of a new, complementary strand, making an identical copy of DNA. Different sequences of nucleotide bases specify different proteins. Therefore, the order of the bases determines the information for building and maintaining an organism.

The majority of human DNA (approximately 3 billion nucleotide pairs per haploid genome) is packaged in the cell nucleus by coiling around a histone protein core to form a nucleosome, which then forms a solenoid that makes up the chromatin loops. Some DNA is also stored in the mitochondria (16,569 nucleotide pairs that encode 9 genes). A small portion of human DNA (1%–2%) encodes functional genes. Humans are estimated to have 20,000–25,000 functional genes, which are sequences of DNA that code for RNA or proteins. The vast majority of the human genome is not as yet informative, which includes pseudogenes (19,000 identified human pseudogenes), or repetitive DNA sequences.[9,12,13]

From Genes to Proteins

DNA contains instructions for making proteins. It resides and is replicated in the cell nucleus; however, protein synthesis takes place in the cytoplasm. Therefore, information/instructions contained in DNA have to be "transported" into

cytoplasm, where they can direct the process of protein synthesis. A series of steps must occur before proteins are made from DNA. First, information contained in a piece of DNA sequence (gene) is transcribed to messenger RNA (mRNA) by RNA polymerase II enzyme. Transcription occurs in the cell nucleus and involves making an mRNA copy of a gene encoded within the DNA template through complementary base pairing. The DNA sequence of a gene has several elements: (1) a start sequence, which begins mRNA transcription; (2) a promoter sequence, which is located upstream (before) the start sequence and contains transcription factor binding sites that act as switches that can turn transcription "on" or "off"; and (3) enhancers or repressors, which are typically 2000 nucleotides long and are located further upstream from a start site. These additional control elements regulate the rate, amplitude, or quantity of transcription by responding to DNA-binding proteins, hormones, certain types of vitamins, for example retinoic acid, or growth hormones. The body of a gene contains (1) exons, which are coding DNA sequences that produce protein products; (2) introns, which are noncoding sequences separating exons; and (3) a stop sequence that terminates transcription.

The transcription process begins with RNA polymerase II enzyme binding to a promoter site on the DNA and pulling a portion of a DNA strand apart. Exposed unmatched DNA bases become a template for the sequence of the primary mRNA transcript. Before the primary mRNA transcript leaves the nucleus it undergoes splicing, in which nuclear enzymes remove sections of the RNA (introns) and the remaining sections (exons) are spliced together to form the functional mRNA. After the gene splicing is complete, mature mRNA transcript leaves the nucleus and migrates into the cytoplasm, where it is translated into a protein. Genes that encode ribosomal RNA (rRNA) and transfer RNA (tRNA) are also transcribed and migrate to the cytoplasm, where they facilitate protein synthesis. Some genes contain alternative splice sites, allowing the primary transcript to be spliced in different ways. Alternative splicing produces different protein products from the same primary transcript. The process of alternative splicing is common, therefore the proteome reflecting the human genome (20,000–25,000 genes) well exceeds the number of genes in the human genome. For example, the *AMELX* or *AMELY* gene encodes amelogenin, which is the major protein forming enamel extracellular matrix. In human and other mammals, there are six to eight different isoforms of amelogenin, differing in molecular weights and cross-reactive with anti-amelogenin rabbit antibodies. These different amelogenin proteins were shown to be produced by alternative splicing of the *AMEL* gene and not, as previously believed, by post-translational modifications.[21,22] Another example of the effects of alternative splicing on phenotype is dentinogenesis. The dentin sialophosphoprotein gene (*DSPP*) encodes two different noncollagenous proteins: (1) dentin sialoprotein and (2) dentin phosphoprotein.[23,24] Mutations in type I collagen and/or *DSPP* genes produce five different patterns of dentinogenesis imperfects (inherited dentin defects).[23,24]

Translation is the process in which mRNA provides a template for the synthesis of a precise sequence of amino acids known as polypeptide or protein. Translation and protein synthesis occur at a ribosome. A tRNA bound to a particular amino acid contains an anticodon that pairs with a codon in mRNA. During translation, tRNAs and their attached amino acids arrive at the ribosomes. The linear sequence of codons of mRNA determines the order in which amino acids are added into a protein. There are 20 different types of amino acids that are encoded by units of 3 mRNA bases known as codons. Of the 64 possible codons, 3 (UAA, UGA, and UAG) signal the end of a gene and are known as stop codons. The remaining 61 codons are functional codons and specify amino acids. There are 64 possible codons ($4\ \text{mRNA bases}^{3\ \text{triplets}} = 64$) and only 20 amino acids, which means that most amino acids can be encoded by more than one codon. Therefore, genetic code is degenerate. Replication of one strand of DNA to a copy strand of DNA, transcription of DNA into mRNA, and translation of mRNA into proteins are cellular processes critical for biologic activity (Figure 27-1).

Regulation of Gene Expression

All somatic cells have exactly the same DNA sequence; however, there is a large variety of different cell types making different proteins. This is because cells differ at which genes are actively expressed. For example, muscle cells have a different set of genes that are turned on in the nucleus and a different set of proteins that function in the cytoplasm than do for example nerve cells. In most cells only a small fraction of genes is actively transcribed and most genes are transcribed only in specific tissues at specific points in time. For example, the globin genes are transcribed in the progenitors of red blood cells where they help to form hemoglobin, and the low-density lipoprotein receptor genes are transcribed in liver cells. Some genes, called housekeeping genes, are transcribed in all cells of the body, as they encode key products necessary for a cell's maintenance and metabolism. A variety of mechanisms regulate gene expression, which can be broadly divided into transcriptional regulation, post-transcriptional regulation, and epigenetic mechanisms.

Inherited Variation

Transcriptional Regulation of Gene Expression

Gene expression is initiated by transcription factors binding to a promoter region of a gene. General transcription factors are used by all genes, and specific transcription factors

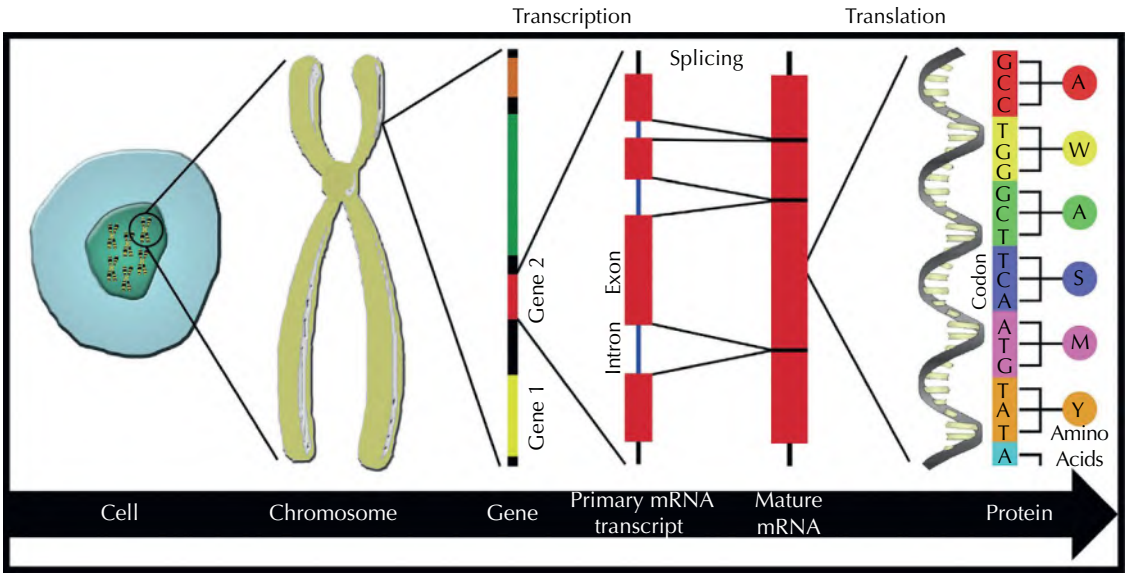

Figure 27-1 Central dogma of molecular biology: from DNA through mRNA to protein. Majority of human DNA resides in the cell nucleus and is organized in chromosomes. Chromosomes contain thousands of genes that are sequences of nucleotides along the chromosome (colored blocks). Genes on a chromosome are separated by noncoding DNA (black blocks). Each genes contains exons, which are coding DNA sequences that produce proteins (red blocs in the primary mRNA transcript), and introns, which are noncoding sequences separating exons (blue lines in the primary mRNA transcript). The primary mRNA transcript is transcribed from the DNA blue print in the nucleus. The primary mRNA contains both exons and introns and undergoes splicing to create mature mRNA transcript. Splicing occurs in the nucleus and involves removal of introns by nuclear splicing enzymes and splicing exons together. Mature mRNA leaves the nucleus and translocate into the cytoplasm to serve as a template for making proteins. In the cytoplasm, the mature mRNA is read in triplicates of nucleotides (codons) that are translated into amino acids (building blocks of proteins) (colored circles).

initiate transcription of only certain genes at specific points in time. Transcription factors contain DNA-binding motifs that allow them to interact with specific DNA sequences. Basal transcription levels can be modulated by binding of transcription factors to other regulatory regions such as enhancers and silencers, located thousands of bases away from the transcribed gene. Enhancers do not directly interact with a transcribed gene, but are bound by specific transcription factors (activators) that bind to a second class of specific transcription factors (co-activators) that in turn bind to general transcription factor complex, enhancing the expression of specific genes at specific points in time. Silencers repress the transcription of genes. Mutations in genes encoding transcription factors as well as mutations in enhancer, silencer, or promoter sequences can result in faulty expression of vital genes, leading to genetic disease. For example, tooth agenesis (oligodontia or hypodontia) is caused by mutations in one or more transcription factors (e.g., MSX1, MSX2, DLX5, PAX9) that may result in inhibition, arrest, or retarded tooth development.[25–28]

A number of morphoregulatory master genes encoding highly conserved transcription factors such as *HOX* (homeotic) genes, *PAX* genes, and *T-Box* genes have been identified. These transcription factors are highly conserved from fish to humans and bind with specific nucleic acid sequence motifs with high affinity. They are major regulators of animal development.[29] Mutations in either the *FOXC1* or the *PITX2* homeobox genes have been found in 40% of Axenfeld–Rieger syndrome (ARS), an autosomal dominant developmental disorder with anomalies of the anterior segment of the eyes, iris hypoplasia, tooth anomalies, craniofacial dysmorphogenesis, cardiac defects, limb anomalies, pituitary anomalies, intellectual disabilities, and neurosensory defects (Figure 27-2).[30]

Post-transcriptional Regulation of Gene Expression This form of gene regulation includes mechanisms of RNA processing (splicing), mRNA transport, mRNA stability, and translation. For example, alterations in RNA splicing may result in different isoforms of a gene. MicroRNA regulation is another mechanism of post-transcriptional regulation. MicroRNAs (miRNA) are 17–27 nucleotide-long RNA molecules that are not translated into proteins. MiRNAs can downregulate the expression of genes they are complementary to by binding to their mRNA transcript. MiRNAs play a crucial role in the control of gene expression. Dysregulation of miRNA expression results in grossly aberrant gene expression, leading to disease,[31–36] and altered miRNA expression has been associated with the progression of cancer.[37,38]

Figure 27-2 Clinical presentation of Axenfeld–Rieger syndrome (ARS). Mutations in PITX2 (pituitary homeobox transcription factor 2) and/or FOXC1 (forkhead box transcription factor C1) result in ARS, which represents a spectrum of diseases and disorders, including those of the dentition (i.e., extreme dental hypoplasia, as shown in this figure). *Source:* Courtesy of Dr. Carl Allen.

Epigenetic Control

Epigenetic mechanisms play an essential functional role in the regulation of transcription. Genetic control of gene expression depends on changes in DNA sequence. Epigenetic changes are heritable (from cell to daughter cell, or from parent to child) changes that do not depend on changes in genome sequence. Epigenetic controls are post-translational modifications of chromosomal proteins, such as methylation and acetylation, which regulate human conditions via gene–gene and gene–environment influences.

Pretranscriptional Regulation of Gene Expression DNA is wrapped around histone proteins forming chromatin (a highly organized and densely packaged structure). Chromatin remodeling enzymes alter the folding and basic structure of chromatin, making it more open. Euchromatin is an open structure accessible to transcription factors and therefore transcriptionally active. Histone acetylation is a dynamic epigenetic modification that regulates gene expression. This lysine modification is reversibly controlled by histone acetyltransferases, which add acetyl groups to lysine residues of histones, and deacetylases, which remove the acetyl groups from lysine residues. Addition of acetyl groups reduces histone binding to DNA, helping decondense the chromatin and promoting transcription.

DNA methylation is another epigenetic mechanism that plays an important role in gene regulation.[39] It is controlled by DNA methyl transferase enzymes (DNMTs) that add methyl groups to the DNA molecule. Methylation can change the activity of a gene and, when located in a gene promoter, it typically suppresses transcription of that gene.

Additionally, gene actions depend on interaction with the environment. Monozygotic (MZ) twins are genetically identical. However, as MZ twins develop and age they become phenotypically discordant, for example they differ in susceptibilities to diseases and even in anthropometric measurements. Epigenetic regulation can explain phenotypic discordance in MZ twins. Studies of a large cohort of MZ twins found that while they are epigenetically (DNA methylation and histone acetylation profiles) indistinguishable early in life, older MZ twins differ drastically in their overall content and genomic distribution of 5-methylcytosine DNA and histone acetylation, and therefore in their gene expression profiles.[40,41] Epigenetic control of gene expression provides an explanation for how different phenotypes (e.g., arthritis, osteoporosis, periodontal disease, fibromyalgia, Alzheimer's disease and other forms of dementia) can originate from the identical genotype.

TYPES OF DNA VARIATION

All genetic variation results from a process known as mutation, which is defined as a permanent change in the DNA sequence that can range in size from a single DNA base pair affecting a single gene to a large segment of a chromosome affecting many genes. The effects of gene mutations on health vary depending on where they occur and whether they alter the function of essential proteins. Mutations can be classified into hereditary and acquired (somatic) mutations.[42] Hereditary mutations are inherited from a parent and are present in every cell of the body throughout a person's life. Hereditary mutations are also called germline mutations because they are present in a parent's gametes (either egg or sperm) and therefore in each cell of an offspring that grows out of the fertilized egg.[42] Acquired (somatic) mutations occur at some point during a person's life and are present only in some cells. They can occur as a result of environmental exposures such as ultraviolet radiation from the sun, or as a result of an error made in DNA replication during cell division. Acquired mutations cannot be passed to the next generation.[42]

De novo (new) mutations can be either hereditary or somatic. De novo hereditary mutations arise when a mutation occurs in a person's egg or sperm cell but is not present in any of the other cells, or when a mutation occurs in the fertilized egg shortly after fertilization. The de novo hereditary mutations are present in every cell of a growing embryo. De novo hereditary mutations may explain genetic disorders in which an affected child has a mutation in every cell in the body but the parents do not, and there is no family history of the disorder.[42]

Mosaicism occurs when a somatic mutation occurs in a single cell early in embryonic development when the embryo includes several cells, but is not present in a parent's egg or sperm cells, or in the fertilized egg. As cells divide, the cell containing the mutation will give rise to altered cells, while other cells will not. Mosaicism may or may not cause health problems, depending on the type of mutation and the number of cells affected.[42]

Mutations are also classified based on their size, ranging from changes of a single base (point mutations or single nucleotide polymorphisms, abbreviated SNPs; Figure 27-3), to insertions and deletions of two or more bases up to a dozen or more bases, or copy number variations (CNVs) up to chromosomal rearrangements involving millions of DNA bases.

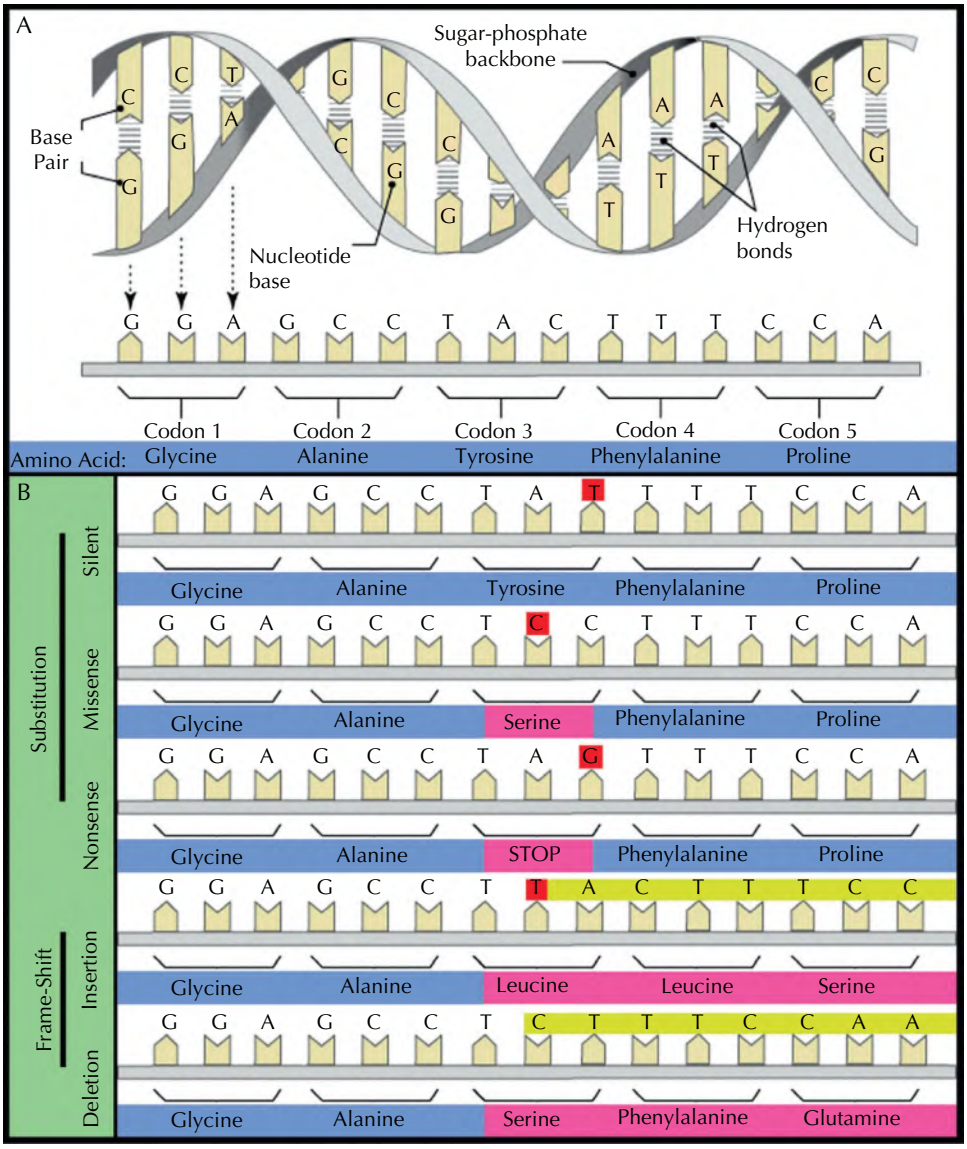

Figure 27-3 A. Molecular composition of DNA. DNA is composed of a phosphate–sugar backbone and four nitrogenous bases: adenine (A), cytosine (C), guanine (G), and thymine (T). Adenine always pairs with thymine and guanine always pairs with cytosine. The order of bases determines information encoded in a gene. Nucleotides are read in triplicates called codons and each codon codes for one amino acid (building blocks of proteins). B. Five major types of mutations. Silent mutations result in no change in the encoded amino acid sequence, as multiple codons can code for the same amino acid. In missense mutations, a single nucleotide change results in a change of encoded amino acid. Nonsense mutations occur when a single nucleotide change results in the formation of a stop codon (TAA, TAG, and TGA), leading to premature termination of translation and therefore a shortened protein product. Frame-shift mutations (insertions or deletions) shift a reading frame by shifting nucleotide positions in each triplet codon. They result in a change of the encoded amino acid sequences from the point of mutation. Mutated nucleotides are highlighted in yellow and affected amino acids are highlighted in pink.

Single Nucleotide Polymorphisms

SNPs are the most common type of genetic variation among humans. As the name implies, a SNP is a single base pair change in the DNA sequence at a particular location, for example a SNP may replace a cytosine (C) nucleotide for a thymine (T) nucleotide in a certain stretch of DNA. The frequency of SNPs is on average one in every 1000 nucleotides, resulting in approximately 4–5 million SNPs in a person's genome.[42] SNPs within a gene or its regulatory region may affect the function of the gene and thus have a more direct role in disease. Some SNPs may affect an individual's response to certain drugs, susceptibility to environmental factors, and risk of developing a particular disease. Most SNPs have no effect on health or development.[42] Depending on the effects of an SNP on the encoded amino acid, SNPs can be classified as synonymous (silent) or nonsynonymous. A synonymous SNP occurs when a single base pair change does not result in a change in the amino acid in the protein encoded by a gene. Nonsynonymous SNPs can be further classified as missense or nonsense. A missense SNP occurs when a change in one DNA base pair results in the substitution of one amino acid for another in the protein made by a gene. Examples of human conditions caused by missense mutations are hemoglobinopathies such as sickle cell anemia (typically caused by a single missense mutation resulting in a substitution of valine for glutamic acid at position 6 of the β-globin) and osteogenesis imperfecta. A nonsense SNP occurs when a change in one DNA base pair results in a stop codon prematurely signaling the cell to stop building a protein. This may result in a shortened protein that may function improperly or not at all.[43] SNPs can act as biologic markers, helping scientists locate genes associated with a disease. Genome-wide association studies (GWAS) have been used to scan markers (SNPs) across genomes of many people to find genetic variations associated with a particular disease (Figure 27-4). GWAS are particularly useful in finding genetic variations contributing to common, complex diseases, such as asthma,[44,45] cancer,[46] diabetes,[47] and heart disease.[48]

Insertions and Deletions

Insertion and deletion mutations result in a change of the number of DNA bases in a gene by either adding or removing a piece of DNA, respectively. These mutations can range in size from small (insertion or deletion of a single or a few base pairs) to large (entire gene insertion or deletion). Insertions and deletions are also known as frame-shift mutations, as they can affect the codon reading frame depending on the number of nucleotides inserted or deleted. Depending on the size and location, insertions and deletions can affect protein function.

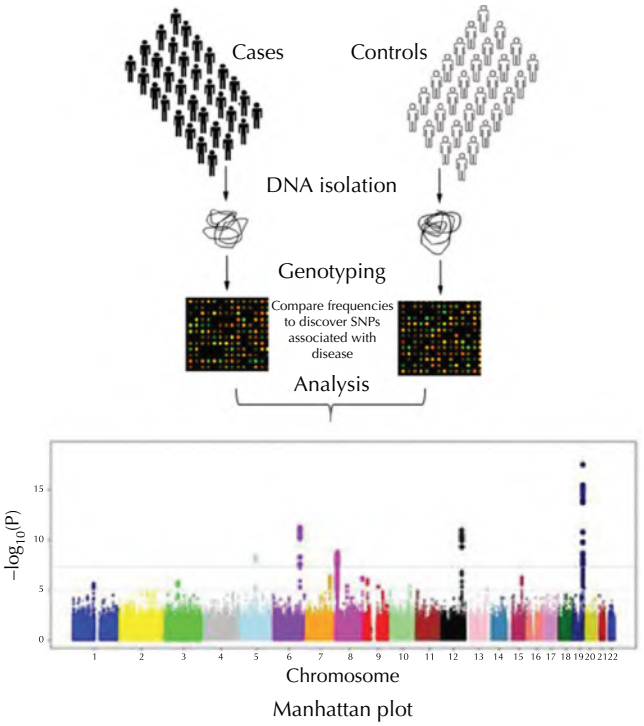

Figure 27-4 Genome-wide association study (GWAS). GWAS aim at comparing frequencies of a large number of SNPs between cohorts of age- and sex-matched cases and controls. For this reason, DNA is isolated from each individual and genotypes of SNPs are determined on microarrays and subjected to statistical analysis to determine if some alleles are significantly more frequent in either cases or controls. The results of GWAS are usually represented as a "Manhattan" plot (shown at the foot of the figure), where each dot represents an SNP, the horizontal axis indicating chromosomes and the vertical axis indicating the statistical significance of disease association. A P-value $<5 \times 10^{-8}$ (horizontal line) is generally considered as being statistically significant at the genome-wide level.

Copy Number Variations

CNVs are a type of genetic variation characterized by a variable number of copies of gene(s). The human genome has two copies of most genes (one copy from each parent). In some cases the number of copies vary, and one, three, or more copies of a gene are present. CNVs account for a significant amount of genetic differences between individuals. Much of the variation due to CNV does not affect health and development, but some variations may affect a person's risk of developing a disease or response to certain drugs. Examples of disorders caused by CNVs include Williams–Beuren syndrome (an autosomal dominant condition caused by deletion of the 7q11.23 locus), Gaucher disease (an autosomal recessive condition caused by deletion of the *NPHP1* gene), and intellectual disability (an X-linked condition

caused by duplication of the *HUWE1* gene). CNVs in the *CYP2D6* gene can affect the response to about 30 drugs, including opioids, tamoxifen, and antipsychotics.[49]

Chromosomal Rearrangements

Chromosomal mutations can range from changes in chromosomal structure when fragments of chromosomes get rearranged, missing, or duplicated to changes in chromosome numbers (aneuploidy). Chromosomal rearrangements include translocations, duplications, deletions, and inversions. Translocations occur when a fragment of one chromosome breaks off and attaches to another chromosome. Translocations can be balanced (no genetic material is gained or lost in a cell) or unbalanced (there is a gain or loss of genetic material in a cell). Duplications occur when a part of a chromosome is copied too many times, resulting in extra copies of genetic material from the duplicated segment. Chromosomal deletions result in loss of genetic material anywhere along the chromosome. Aneuploidy refers to a gain or loss of chromosomes from the normal 46.

Changes in chromosome structure or the number of chromosomes lead to problems with the growth, development, and function of the body's system. Examples of conditions caused by changes in chromosome number include Down syndrome (trisomy 21), which results from the presence of an extra copy of chromosome 21, and Turner syndrome (monosomy of the X chromosome), which is caused by a deletion of one of the X chromosomes in a female. Conditions caused by chromosomal rearrangement include William syndrome, which is caused by a deletion of a region on chromosome 7 (7q11.23, the Williams–Beuren syndrome critical region) containing the elastin gene, and Potocki–Lupski syndrome, caused by duplication of a region on chromosome 17 (17p11.2).

GENETIC DISEASES AND DISORDERS

Most diseases have a genetic component and it is believed that genes play a role in over 10,000 human diseases.[50,51] It is estimated that approximately 1 in 10 people in the United States—almost 30 million people—has a rare disease, equivalent to the number of people who have diabetes. Although individually rare on a population level, over 5000 single-gene disorders (called Mendelian disorders because they follow predictable inheritance patterns) have been identified.[51] Thousands of these disorders have some phenotypic effect on the oral cavity/craniofacial complex and are therefore seen by dentists. For many of these conditions, (e.g., most forms of amelogenesis imperfecta and isolated cleft palate), the major clinical findings are seen in the oral cavity. For others (e.g., syndromic forms of dentinogenesis imperfecta and syndromic forms of orofacial clefting), the condition may manifest dental as well as significant extraoral findings (e.g., vascular, bone, kidney), meaning these conditions are best managed by an interdisciplinary healthcare team. For some of these conditions the dental findings are the most apparent, and the dentist may be the first to recognize that a genetic condition exists in an individual and/or family.[52] Dentists may be the first healthcare provider to detect certain genetic disorders due to their seeing patients across critical times of growth and development.[53] Thus, it is important for dental health professionals to have an understanding of basic genetic concepts.[54]

As our understanding of the genetic basis of diseases improves, the amount of clinically relevant genetic information increases. Web-based databases that continually catalog and update this information are important resources that allow clinicians to rapidly scan the available information and identify resources to help manage patients (Table 27-1). Online Mendelian Inheritance in Man (OMIM) is a comprehensive, authoritative compendium of human genes and genetic phenotypes that is freely available and can help develop differential diagnoses.[51] This database offers overviews of information on all known Mendelian disorders and over 15,000 genes. It focuses on the relationship between phenotype and genotype and is updated daily. Clinicians can use the database to enter clinical findings and help check and develop a differential diagnosis for genetic conditions of interest. Table 27-2 lists information from the OMIM database for many of the conditions discussed in this section.

Like all healthcare providers, dentists are facing an increase in the application of genetic knowledge in clinical practice. The ability to take a family history to construct a three-generation pedigree can be important to make a correct diagnosis for both dental and nondental conditions. Disorders of the teeth and periodontium can be inherited. Seemingly isolated dental defects may have extraoral health consequences. Making a correct diagnosis is crucial for a discussion of phenotypic consequences, management, and genetic counseling for recurrence risks. Recurrence is the risk of having a second child in a later pregnancy affected by the same disease or health condition. Sometimes clinical evaluation is enough to establish a diagnosis, but at other times genetic testing is needed.

The decrease in cost to sequence DNA has resulted in increased sequencing of the exome (focusing on the 2% of the genome that codes for proteins) and genome (the entire 3 billion base pairs of DNA). Such sequencing has revealed pathogenic variants underlying conditions such as amelogenesis imperfecta,[55] tooth agenesis,[56] latent transforming growth factor–beta-binding protein 3 (*LTBP3*)-related disorders,[57]

and genes not previously known to be involved in tooth development. *LTBP3* pathogenic variants are associated with amelogenesis imperfecta, short stature, and predisposition to thoracic aortic aneurysms and dissections.[58] Thus, the association of amelogenesis imperfecta and short stature should prompt consideration of referral for cardiac evaluation. Other dental phenotypes may also prompt referral for evaluation. For example, oligodontia can be associated with colon cancer.[59] The finding of amelogenesis imperfecta and gingival hyperplasia in an individual may suggest referral for renal imaging.[60] Knowledge of the underlying genetic defect can be important in developing treatment plans, such as dental treatment for amelogenesis imperfecta (https://www.dentistry.unc.edu/dentalprofessionals/resources/defects/ai).

As shown in Figure 27-3, a variety of DNA nucleotide sequence changes can occur. With the availability of inexpensive DNA sequencing, many thousands of human genomes have been sequenced, revealing hundreds of thousands of DNA sequence variants. The challenge is to determine which of these are important and have a biologic or phenotypic consequence when present. When a sequence change is identified, it must be evaluated to determine whether the change, or variant, produces a phenotype and is therefore pathogenic. Guidelines have been published to aid

Table 27-2 Examples of dental-craniofacial genetic conditions from the Online Mendelian Inheritance in Man (OMIM) database. Information includes syndrome name, associated OMIM syndrome number, mode of inheritance, and tooth/oral findings. The name of each specific gene(s) involved in the etiology, gene symbol, chromosomal location, and OMIM gene number are included.

in the interpretation of sequence variants.[61] A five-scale classification system is used: pathogenic, likely pathogenic, variant of uncertain significance, likely benign, and benign. The term mutation and polymorphism are no longer used in order to be clearer regarding the functional consequence of identified variants. In general, the term pathogenic variant is now used instead of the term mutation. As more individuals have their genomes sequenced, variants may be reclassified. A recent study found that approximately 25% of variants of uncertain significance have been reclassified over time, including upgrades and downgrades.[62]

Mendelian Diseases and Disorders

Human disorders can be inherited in a variety of ways. Genetic disorders are broadly characterized into three categories: Mendelian, chromosomal, and multifactorial or complex. Mendelian disorders follow predictable inheritance patterns and are typically rare on a population basis. Chromosomal disorders may be sporadic or inherited and involve numeric (addition or deletion of whole chromosomes) or structural aberrations (addition, deletion, or rearrangement of less than a whole chromosome). Finally, multiple genes and/or environmental factors play a role in phenotypes such as many common forms of oral clefting, periodontitis, diabetes, hypertension, and so on. These are known as multifactorial or complex traits. Many genes may be involved in the etiology of complex traits, with the contributions of most genes being relatively small, and individually not sufficient to cause disease.

Modes of Inheritance

Mendelian disorders are those that follow predictable inheritance patterns and are due to pathogenic variants in single genes. Disorders can be inherited as autosomal (gene is located on a non-sex chromosome) or sex-linked (gene is on the X or Y chromosome) traits. Dominant or recessive refers to the number of pathogenic variants needed to express the phenotype: one for dominant and two for recessive.

In autosomal dominant disorders, both males and females are affected. Male-to-male transmission can occur. Often there are affected individuals in each generation (known as vertical transmission). Examples of autosomal dominant disorders include achondroplasia, the most common form of short-limbed dwarfism, and amelogenesis imperfecta, a disorder that affects the quality and/or quantity of tooth enamel. An individual with an autosomal dominant disorder has a 50% risk of passing on the pathogenic variant to their offspring. While many individuals with a dominant disorder will have inherited a pathogenic variant from an affected parent, others will have the disorder due to a new mutation, also called a de novo mutation. In this case, the affected person has a 50% chance of passing on the pathogenic variant to their children, but their parents are not likely to have another affected child. Approximately 80% of individuals with achondroplasia have a de novo mutation.[63] Some autosomal disorders exhibit reduced penetrance and/or variable expressivity. Reduced penetrance means that some individuals with a pathogenic variant will not express the phenotype. In a condition with 80% penetrance, it means that 20% of individuals who have a pathogenic variant will not express the phenotype. Variable expressivity means that individuals who have a pathogenic variant may be mildly or severely affected, even within the same family. Van der Woude syndrome (VWS) involves congenital, usually bilateral, lip pits and cleft lip with or without cleft palate and is caused by pathogenic variants in *IRF6*. Penetrance has been estimated at 92% and variable expressivity is observed.[64] Mixed clefting—an unusual occurrence in which one family member has isolated cleft palate and another family member has cleft lip with or without cleft palate—occurs in VWS. Tricho dento osseous syndrome (TDO) is an autosomal dominant condition that derives its name from the three primarily affected tissues: hair, teeth, and bone. Due to the pleiotropic effects of *DLX3* mutation, development of enamel, dentin, and bone is affected. Detailed clinical characterization of individuals with TDO (confirmed *DLX3* gene mutation) from multiple families shows marked variability in the hair, tooth, and bone phenotype (Figure 27-5). In some individuals the enamel is very thin, and teeth are smaller and appear widely spaced. Some affected individuals have significant taurodontism, with large, elongated pulp chambers. Bones of the skull and long bones show increased thickness and density with age, which is evident radiographically. Affected individuals have distinct curly hair that straightens in later childhood in almost 50% of cases. Dentin defects can also be inherited as autosomal dominant traits, either as isolated or syndromic forms. Pathogenic variants in *DSPP* underlie isolated forms of dentinogenesis imperfecta and dentin dysplasia type II (Figure 27-6). It is now thought that these disorders represent a continuum, with dentin dysplasia type II on the mild end and dentinogenesis type III on the severe end. Variable expressivity is also observed. Reduced penetrance and variable expressivity can make genetic counseling challenging.

In autosomal recessive inheritance, typically each parent is a carrier of a recessive allele and does not show any phenotype. When a child inherits the recessive allele from each parent, the child will express the phenotype. Both males and females are affected. Often only a single generation may be affected (known as horizontal transmission). Consanguinity (reproduction between close relatives descended from a common ancestor) increases the possibility of an individual inheriting the same recessive allele from each parent. The higher the degree of relationship between the parents, the

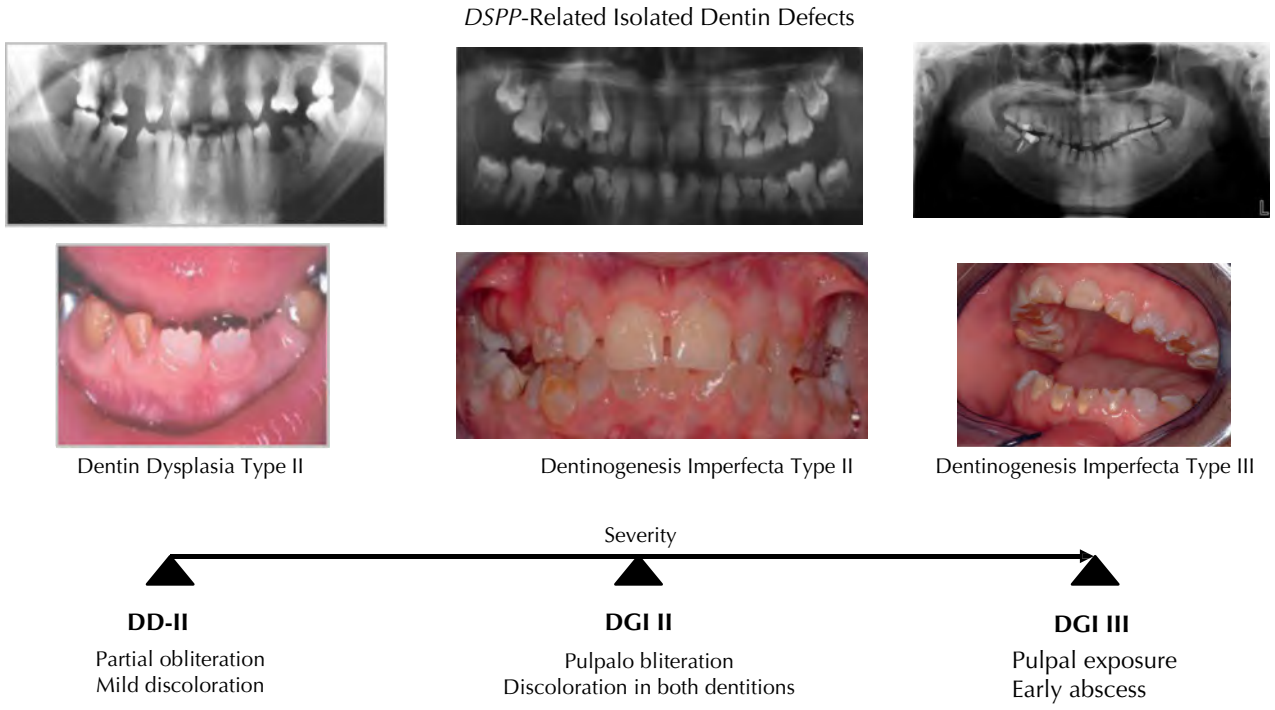

Figure 27-6 *DSPP*-related dentin disorders. Pathogenic variants in *DSPP* can result in dentin dysplasia type II, dentinogenesis imperfecta type II, and dentinogenesis imperfecta type III. All are inherited as autosomal dominant disorders. It is now felt that these conditions represent a continuum of severity, from dentin dysplasia type II on the mild end to dentinogenesis imperfecta type III on the severe end.

higher the risk for each parent to be a carrier. Examples of autosomal recessive traits include cystic fibrosis, sickle cell anemia, amelogenesis imperfecta, and Papillon–Lefèvre syndrome. Offspring of a couple where both are carriers for the same autosomal recessive disorder have a 25% chance of being affected, a 50% chance of being a carrier, and a 25% chance of the wild type (not affected nor a carrier). If an affected individual has two copies of the same pathogenic variant, the individual is said to be homozygous. If an affected individual inherited a different pathogenic variant from each parent, the individual is said to be compound heterozygous. Only very rarely are children affected by a recessive disorder when only one parent is a carrier. In this case, both copies of the chromosome have been inherited from the carrier parent and none from the other parent, a condition known as uniparental disomy. In this situation, recurrence risk is very low. Papillon–Lefèvre syndrome is a recessive condition caused by pathogenic variants of the *CTSC* gene that encodes for the cathepsin C enzyme. These pathogenic variants cause loss of function of the cysteine protease, necessary to activate serine proteases, which function in the inflammatory response. Carriers with only one *CTSC* mutation generally have about half the normal activity of cathepsin C and experience no clinical problems. Individuals who inherit pathogenic variants in both copies of this gene have no cathepsin C enzyme activity (additive inheritance of enzyme activity, since one mutation reduces the activity by half). However, such homozygous genotypes develop early-onset aggressive periodontitis with significant oral bone loss and premature loss of primary teeth (recessive inheritance of the clinical condition or disease). After exfoliation of primary teeth, the periodontium heals and can appear healthy. Eruption of secondary teeth is typically associated with inflammation and progressive destruction of the periodontium with premature loss of the secondary dentition, although third molars are sometimes spared (Figure 27-7).

In X-linked conditions, the causative gene is on the X chromosome. Most X-linked disorders are inherited as X-linked recessive traits, but a few are inherited as X-linked dominant traits. Females have two X chromosomes and therefore can be homozygous, heterozygous, or compound heterozygous. Because males have a single X chromosome, they are hemizygous with respect to X-linked traits. The presence of male-to-male transmission excludes X-linked inheritance.

An example of an X-linked dominant condition is incontinentia pigmenti (IP), which is characterized by skin lesions, hypodontia and malformed teeth, alopecia, and dystrophic nails.[65] The phenotype is due to loss of function variants in *IKBKG*. Affected males are not observed due to male lethality. About 65% of affected females have IP as a result of a de novo pathogenic variant. Daughters of an affected heterozygous female have a 50% chance of inheriting the pathogenic variant and being affected. Among liveborn children of a woman with IP, the expected ratio is 1/3 unaffected females,

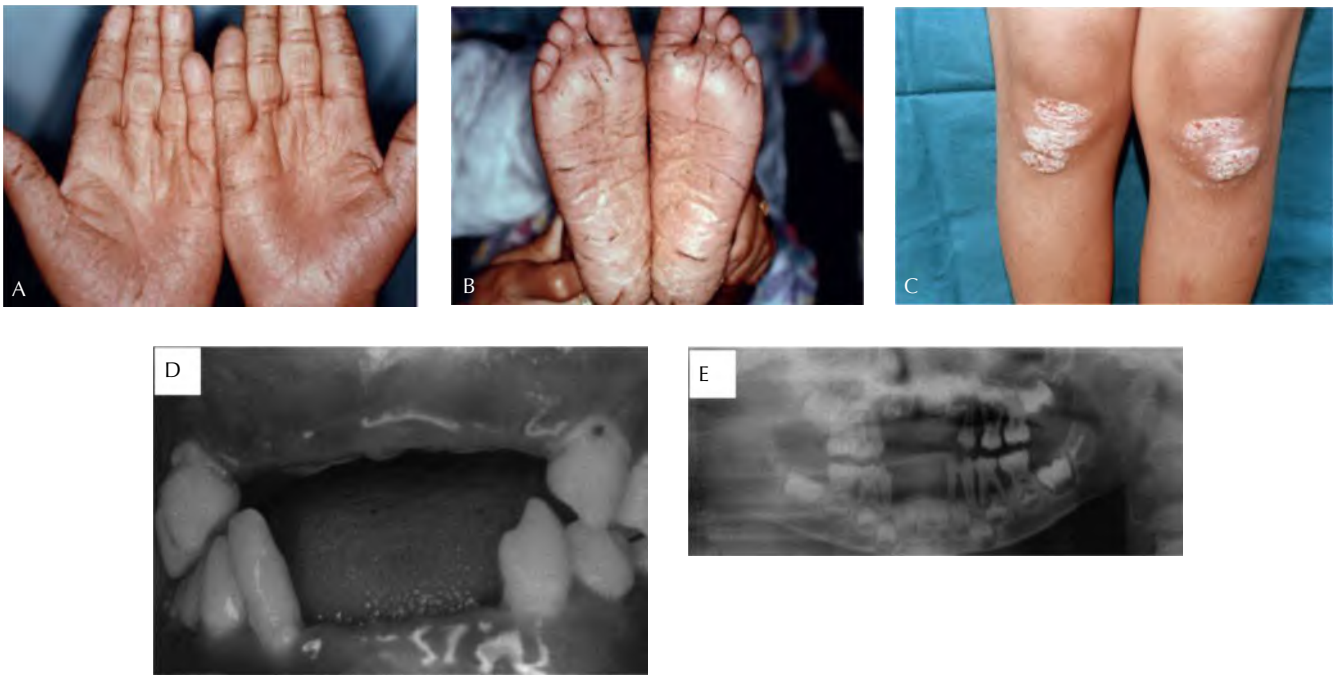

Figure 27-7 Clinical and radiographic findings of an individual with Papillon–Lefèvre syndrome. A. Hyperkeratosis of the palms (mild). B. Hyperkeratosis and fissures on the soles. C. Hyperkeratosis of transgressions on knees. D. Premature loss of teeth due to periodontitis. E. Severe bone loss around primary molars.

1/3 affected females, and 1/3 unaffected males. An X-linked dominant condition that dentists may be consulted on is hypophosphatemic rickets due to a mutation in the *PHEX* gene. Affected individuals have low blood levels of phosphate. Phosphate is necessary for proper mineralization of bones and teeth. In addition to short stature and growth retardation, affected individuals have defective enamel and dentin mineralization, resulting in recurrent abscesses, endodontic problems, and premature tooth loss.[66]

Examples of X-linked recessive conditions are hemophilia and Duchenne muscular dystrophy (DMD). For X-linked recessive traits, the incidence of the trait is much higher in males than in females. Heterozygous females are usually unaffected. For some conditions, a significant number of isolated cases are due to new mutations. A woman who is a carrier of an X-linked trait has a 50% chance of transmitting it to each of her offspring. Each of her sons will be affected if they inherit the pathogenic variant because males are hemizygous (they only have one X chromosome). The phenotype of daughters who inherit the pathogenic variant depends upon X inactivation, also called lyonization. Because females have two X chromosomes, they inactivate most genes on one X chromosome, so that gene dosage is fairly comparable between males and females. This process is typically random, occurs early in embryonic development, and, once established, all descendants of that cell have the same X chromosome inactivated. Sometimes there is skewing of X inactivation, with one X chromosome preferentially inactivated. Females can be affected with X-linked recessive traits through a variety of mechanisms, with skewed X inactivation typically the most common.[67] Other causes include uniparental disomy from an affected father or carrier mother, consanguinity, assortative mating between a carrier female and an affected male, and hemizygosity (the affected female also has Turner syndrome).

Lyonization can be apparent in females with pathogenic variants in *AMELX*, the gene that encodes amelogenin, the predominant protein in enamel. These females are carriers of a wild-type allele that produces healthy enamel crystals and an allele with a pathogenic variant that causes faulty enamel development, resulting in amelogenesis imperfecta. Affected females often exhibit vertical banding of their enamel: alternating columns of normal and defective enamel (Figure 27-8). In the column of normal enamel, the wild-type X is active and the X with the pathogenic variant is inactive. In the column of abnormal enamel, the opposite is true: the wild-type X is inactive and the X with the pathogenic variant is active. Some females in the family who inherit the pathogenic variant may not exhibit this banding if skewed X inactivation occurs. Their enamel may look

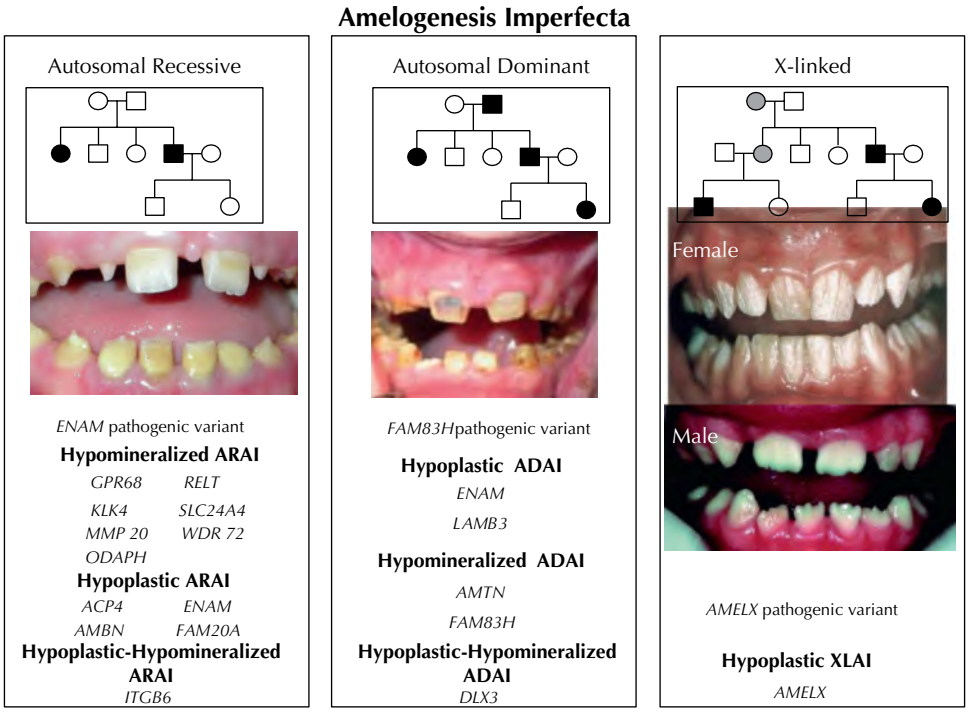

Figure 27-8 Amelogenesis imperfecta. Amelogenesis imperfecta (AI) is transmitted by three Mendelian modes of inheritance. Genes for the pathogenic variants that have been identified for each of the Mendelian modes of transmission are illustrated. Clinical photographs illustrating representative clinical cases for each mode of transmission are shown. normal (wild-type X is preferentially active) or like that of affected males (X with pathogenic variant is preferentially active).

Gonadal mosaicism is common in some X-linked conditions, such as DMD. In this situation, the mother of an affected boy does not have the pathogenic variant in her blood and the recurrence risk would be presumed to be low. If she has a second affected son, it is clear that she has the pathogenic variant in her gonads, since the odds of having two de novo mutations would be extremely low. Gonadal mosaicism is estimated at 15% for DMD.[68]

Mechanisms of Disease

As shown in Table 27-3, there are various mechanisms of disease. Recessive conditions typically result from a loss of function. An example is amelogenesis imperfecta due to mutations in *MMP20*. MMP20 is a matrix metalloproteinase that degrades amelogenin, the major protein component of dental enamel matrix. Proper removal of the enamel matrix is necessary to allow enamel mineralization. The pathogenic variants of *MMP20* produce a protein that is unable to degrade amelogenin properly. Another example is Papillon–Lefèvre syndrome (PLS). In PLS, pathogenic variants in the *CTSC* gene produce inactive cathepsin C protein. Carriers have about 50% of normal cathepsin C activity, which is enough to enable normal biologic function. Affected individuals have little or no functional cathepsin C and cannot activate serine proteases. While genetic (DNA) testing of the *CTSC* gene can be used to test for PLS, it is also possible to test for cathepsin C enzyme activity to test for PLS.[69]

Dominant disorders can result from a variety of mechanisms. The first is a gain of function. In this case, the mutant protein has a new functional capability and performs a new function, or does its usual function to a greater extent. This is the mechanism for achondroplasia. The FGFR3 protein is a receptor that normally helps limit growth. Pathogenic variants in *FGFR3* cause constitutive (constant) activation of the receptor, resulting in overlimitation of growth.

Another mechanism is haploinsufficiency. In this situation, the normal (wild-type) protein is made, but in only half the normal amount. This quantity is "insufficient" for normal function, and results in phenotypic consequences, including diseases. An example is osteogenesis imperfecta (OI) without dentinogenesis imperfecta. This type of OI is associated with null alleles, meaning no protein is made from that allele. The type 1 collagen that is produced from the wild-type allele is not enough to prevent brittle bones.

Dominant negative means that a mutant protein is made and interferes with the wild-type protein's function. This is the mechanism underlying osteogenesis imperfecta types 2, 3, and 4 and some forms of type 1 OI. For example, if a missense substitution occurs in one of the chains for type I collagen, typically a glycine residue replaced by another amino acid, then both wild-type and mutant proteins are made. Because collagen is a triple helix, incorporation of the mutant protein into the helix prevents normal helical formation. The net result is that only 25% of the collagen helical molecules are normal. In this case, dentinogenesis imperfecta also occurs and often this dental manifestation is the most penetrant finding (Figure 27-9).[52]

Chromosomal Rearrangements

Humans have 23 pairs of chromosomes: 22 autosomes (chromosomes 1, 2, 3, . . . 22) and the sex chromosomes (X and Y). One member of each pair is inherited from the mother (maternal) and one from the father (paternal). Sometimes there can be differences in chromosome number and/or structure. Individuals with chromosomal disorders often resemble each other more than their own family members.

Numeric variants in whole chromosomes are further classified into gains (extra chromosomes like Down

Table 27-3 Mechanisms of disease.

Mechanism	Explanation	Example
Loss of function	Protein cannot do its job	Amelogenesis imperfecta due to mutations in *MMP20*. MMP20 is a matrix metalloproteinase that degrades amelogenin. Pathogenic variants produce a protein that is unable to degrade amelogenin appropriately.
Gain of function	Protein does new job or does usual job to greater extent	Achondroplasia. FGFR3 is a receptor involved in limiting growth. Pathogenic variants in *FGFR3* cause constitutive activation of the receptor, resulting in too much growth restriction.
Haploinsufficiency	Only normal protein is made, but the amount (~50%) is not enough to do the job completely	Type 1: osteogenesis imperfecta without dentinogenesis imperfecta.
Dominant negative	The mutant protein interferes with the normal protein doing its job	Type 1: osteogenesis imperfecta with dentinogenesis imperfecta.

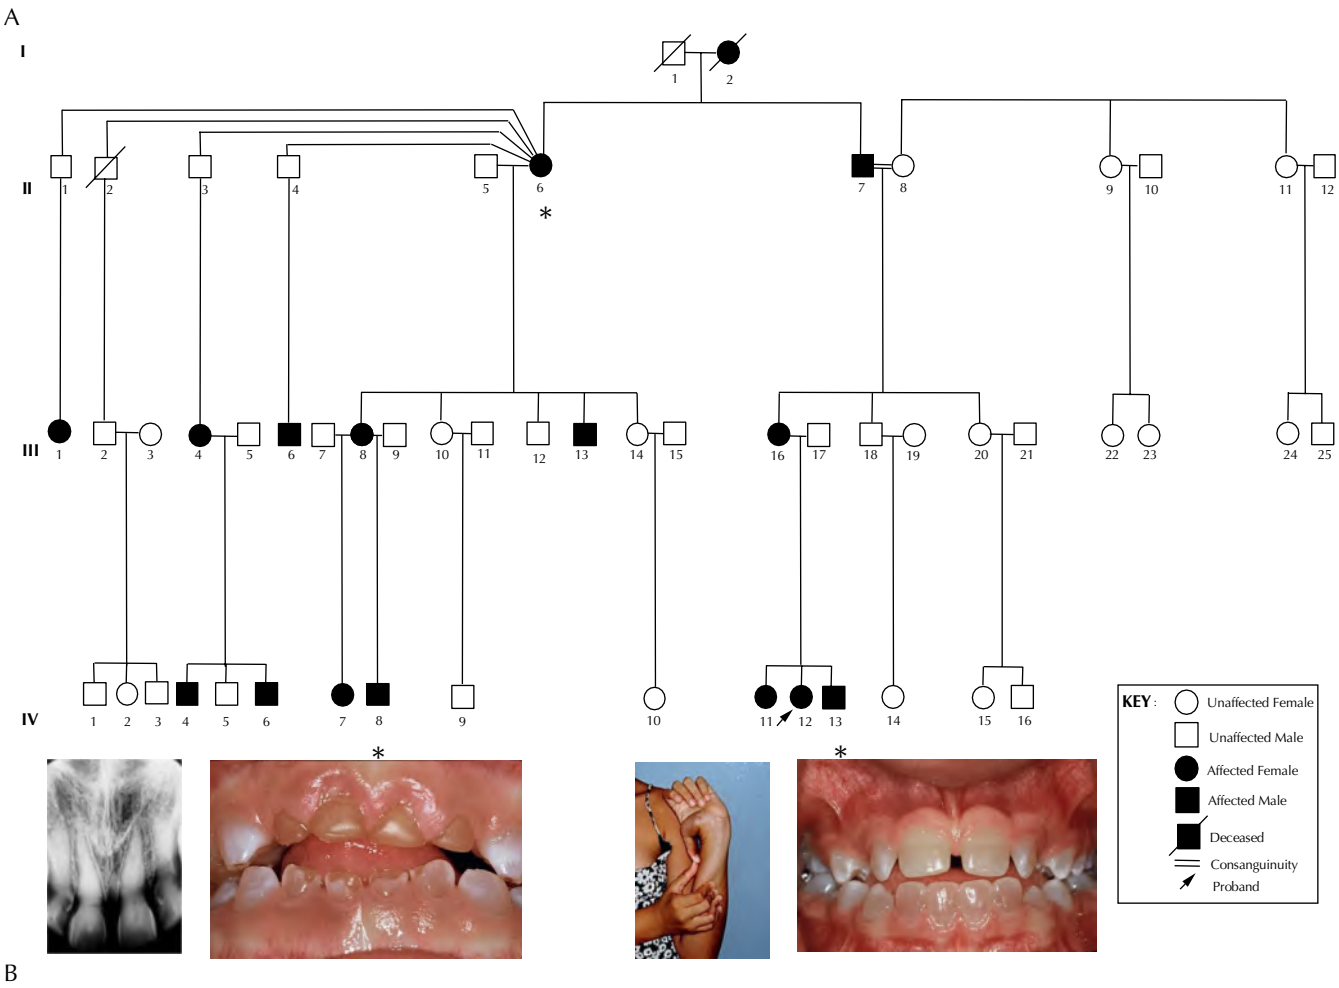

Figure 27-9 osteogenesis imperfecta with dentinogenesis imperfecta. (A) The pedigree of the family demonstrating autosomal dominant inheritance. All affected individuals had dentinogenesis imperfecta. Variable expressivity was observed regarding joint pain, hyperextensible joints, and increased bone fractures with moderate trauma. *Source:* Modified from Pallos D, Hart PS, Cortelli JR, et al. Novel COL1A1 mutation (G559C) [correction of G599C] associated with mild osteogenesis imperfecta and dentinogenesis imperfecta. *Arch Oral Biol*. 2001;46:459–470. (B) From left to right: radiograph showing bulbous crowns with prominent cervical constrictions and shortened roots, affected primary dentition, hyperextensible joints, affected permanent dentition.

syndrome due to trisomy 21) or losses (missing chromosomes like Turner syndrome due to monosomy X). These conditions are called aneuploidy, reflecting that the total number of chromosomes is different than 46 (the euploid number in humans). Aneuploidy of most chromosomes is not compatible with life. Aneuploidy is typically associated with phenotypic consequences, although they can mild as seen with 48,XYY and 48,XXX individuals. Many of these conditions, including Down syndrome, have craniofacial manifestations.

There are many types of structural variants of chromosomes that involve parts of chromosomes. Structural variants of chromosomes may involve one or more chromosomes and include translocations, inversions, deletions, insertions, and ring and supernumerary chromosomes.[70] The amount of genetic material involved in a chromosomal abnormality can be large, containing many genes, or small, involving only a few genes. When large they can be visualized under the microscope, but when smaller, involving fewer than 5–10 million nucleotide base pairs, they can only be detected using molecular cytogenetic techniques such as microarray. Often the carrier of a structural variant is phenotypically normal and only comes to medical attention because of infertility or recurrent pregnancy loss.[71]

Wolf–Hirschhorn syndrome (WHS) is an example of a chromosomal structural variant associated with craniofacial dysmorphism. The disorder is due to a deletion of the short arm of chromosome 4. Affected individuals have intellectual disability, hypotonia, seizures, developmental and growth delay, and a characteristic facial appearance, known as the

Greek warrior helmet appearance.[72] The size of the deletion can vary between individuals, but typically at least three genes are deleted: NSD2, LETM1, and MSX1.[73] It is believed that haploinsufficiency for MSX1 underlies the dental abnormalities often seen in individuals with WHS, including tooth agenesis and retained primary molars. Cleft lip with or without cleft palate is observed in 30% of cases.

As mentioned above in the Mendelian disorder section, sometimes one parent contributes both members of a pair of chromosomes and the other parent does not contribute a copy. This is called uniparental disomy (UPD) and has implications for dominant, recessive, and imprinting disorders (discussed below). UPD is a mechanism by which a child can have a recessive condition for which only one of their parents is a carrier. It can also lead to homozygosity for dominant traits.[74]

Imprinting Disorders

Some genes in the human genome are only expressed from either the maternal or paternal allele. The other parent's allele is silenced, such as by methylation of the genomic DNA.[75] The silenced allele is said to be imprinted. During gametogenesis, the imprints must be erased and reestablished based upon the sex of the individual. In essence, the chromosome inherited from the parent of the opposite sex must be reimprinted. For example, a female has to reimprint the chromosome she inherits from her father to a female pattern in her gonads; males have to reimprint maternal chromosomes in their gonads. When genes are only expressed from one parental allele, failure to inherit a chromosome from the parent whose allele is active, failure to reestablish imprints during gametogenesis, or abnormal silencing or removal of methylation will result in a phenotypic consequence.

Examples of imprinting disorders include Prader–Willi and Angelman syndromes, both involving genes on chromosome 15. In this region of 15q11, most genes are expressed from the father's (paternal) allele. In about 70% of cases of Prader–Willi syndrome (PWS), a de novo deletion occurs on the chromosome 15 transmitted by the father.[76] Because the genes in this region are only expressed from the father's allele, which has been deleted in the father's allele passed to the child, no gene expression occurs. Another 25% of PWS occurs because of maternal UPD. In this case, although there are two copies of chromosome 15 present and the chromosomes are structurally intact, the offspring's genes in the 15q11 region are silenced on both chromosomes, since they both were inherited from the mother. It is the inability to produce these gene products that results in the PWS phenotype: severe hypotonia and feeding difficulties in early infancy, followed by hyperphagia and gradual development of morbid obesity. The saliva is also very thick and sticky.[77] De novo deletions and UPD are associated with a very low risk of recurrence. The same is not true for individuals who cannot reset the imprinting pattern based upon their own sex. A man who is unable to reimprint the chromosome 15 he inherited from his mother to a male pattern will also have a child with PWS, because the genes that should be expressed from the paternal allele remain methylated and therefore silenced. Importantly, in this case the recurrence risk can be as high as 50%.

Another imprinting disorder is Beckwith–Wiedemann syndrome (BWS), an overgrowth disorder associated with macrosomia, omphalocele, macroglossia, and visceromegaly.[78] BWS is associated with abnormal gene expression of two imprinted domains on chromosome 11p15.5. Analogous to the 15q11 region, on chromosome 11p15.5 there are genes expressed solely from the maternal allele and other genes expressed solely from the paternal allele. Approximately 50% of BWS cases involve abnormal methylation of genes in this region, including either gain or loss of methylation. Another 20% involve paternal UPD. Most individuals with BWS are sporadic cases, but 15% have a family history consistent with a parent of origin autosomal dominant transmission.

Mitochondrial Disorders

The major function of mitochondria is to carry out oxidative phosphorylation. Mitochondria are the only animal cellular organelles that contain their own DNA. Mitochondrial DNA (mtDNA) is inherited almost exclusively from the mother. mtDNA is a small, circular molecule of 16,569 nucleotides that encodes 37 genes, including 13 polypeptides necessary for the oxidative phosphorylation (OXPHOS) complexes I and III–V. The remaining genes code for transfer RNA (tRNA) and ribosomal RNA (rRNA). mtDNA uses nonuniversal codons, meaning the codons are different than those used by nuclear DNA-encoded genes. Each mitochondrion contains multiple copies of mtDNA and there are hundreds to thousands of mitochondria per cell, depending upon the energy needs of the cell. mtDNA has a high mutation rate because of limited proofreading and repair, and the lack of protective histone proteins. Mitochondria segregate randomly during cell division, so cells can end up with varying levels of mtDNA containing pathogenic variants. Heteroplasmy refers to the presence of both wild-type and mutant mtDNA in a given mitochondrion. Many of the mitochondrial disorders need a certain level of mutant mtDNA before phenotypic consequences occur, known as the threshold effect. It is important to remember that because of random mitotic segregation, analysis of the mutant load in peripheral blood cells may not reflect the level in affected tissue like muscle.

The other 84 components of the OXPHOS complexes are encoded by nuclear genes, mutations of which can also lead to mitochondrial dysfunction. Recently mutations in the nuclear gene *MRPS28,* which encodes the small mitoribosomal subunit protein bS1m, were identified in a patient with intrauterine growth retardation, dysmorphic facies, and developmental delay.[79]

It is estimated that 1 in 5000 adults has a mitochondrial disorder.[80] Mitochondrial disorders can affect almost every tissue and may occur at any age. The symptoms can be nonspecific and depend on which tissues are affected. Often more than one organ is involved. Because of mitotic segregation, there can be extreme variability of phenotype within a family. A recent study found that patients consult multiple physicians, on average eight, before a diagnosis of mitochondrial disorder is made.[81] During this diagnostic odyssey, patients undergo multiple, often unnecessary, tests and are often given conflicting diagnoses.

Multifactorial Disorders

In contrast to Mendelian disorders, most chronic diseases are etiologically complex and are caused by interactions of genes and environment. These are known as multifactorial traits and represent conditions such as diabetes, heart disease, and hypertension. The risk of developing these conditions results from the interactions of major and minor genes, and epigenetic and environmental factors. In contrast to Mendelian disorders, where a single pathogenic variant in a gene can result in a disorder, complex disorders often involve contributions from many genes. Unlike Mendelian conditions, the contribution of individual genes is very small, and the contribution of any one gene is not sufficient to cause disease alone. It is the threshold effect of interactions of many genes and environmental factors that causes disease.

Oral clefts are an example of multifactorial traits. In contrast to the Mendelian disorders, recurrence risks for multifactorial traits are increased by the number of affected individuals, the severity of the defect, and potentially the sex of the affected parent and/or child. Most affected children have unaffected parents, but a more severely affected parent is more likely to have an affected child. If the two sexes have a different probability of being affected, the less likely sex, if affected, is the more likely sex to produce an affected offspring. For example, if a child with an isolated cleft has no other affected first- or second-degree relative, the recurrence risk is 2%–5%. If a first-degree relative of the child is also affected with an isolated cleft, then the risk for an offspring or sibling is 8%–10%. If both parents are affected with a cleft, the empiric risk for a cleft in the offspring ranges from 25% to 50%, similar to the risk for Mendelian disorders. Cleft lip and palate occurs in about 1 in 1000 births and represents 50% of all clefts. The frequency varies by racial groups, with higher rates in Asians and certain groups of Native Americans and lower rates in American Americans. Up to 13% of cases present with other birth defects. Isolated cleft palate occurs in about 1 in 2000 babies and represents about 30% of all clefts. All racial groups have a similar risk, but it occurs more often in female children. Isolated cleft lip, representing about 20% of all clefts, occurs more often in male children. Pathogenic variants in many genes have been determined to cause syndromic cleft lip with or without cleft palate and cleft palate. Some of these same genes have been implicated in nonsyndromic cleft lip with or without cleft palate and cleft palate. Synergistic heterozygosity (being heterozygous at two different genes), epigenetic factors, and environmental influences may combine with specific genetic variants to produce nonsyndromic clefting

Phenotypic and Genetic Heterogeneity

As shown in Table 27-4, there are a variety of types of heterogeneity seen with human genetic disorders. Genetic heterogeneity refers to the production of the same phenotype by different genetic mechanisms. An example is amelogenesis imperfecta, which can be caused by loss of function pathogenic variants in *MMP20* or gain of function variants in *FAM83H*.

Clinical heterogeneity refers to different phenotypes resulting from pathogenic variants in the same gene. Pathogenic variants in *SOS1* can result in hereditary gingival fibromatosis type 1, an autosomal dominant isolated form of gingival overgrowth. Other pathogenic variants in *SOS1* cause Noonan syndrome, an autosomal dominant disorder characterized by a typical facial appearance, short stature, developmental delay, and congenital heart defects.

Table 27-4 Type of heterogeneity seen in human disorders.

Type	Explanation	Example
Allelic	Multiple pathogenic variants in the same gene produce the phenotype	22 different pathogenic variants in *ENAM* cause amelogenesis imperfecta
Clinical	Different phenotypes result from pathogenic variants in the same gene	Hereditary gingival fibromatosis type 1 and Noonan syndrome due to pathogenic variants in *SOS1*
Genetic	Same phenotype is produced by different genetic mechanisms	Amelogenesis imperfecta can be caused by loss of function and gain of function pathogenic variants
Locus	Same phenotype is produced by pathogenic variants in different genes	Amelogenesis imperfecta is caused by pathogenic variants in at least 17 genes

Allelic heterogeneity refers to the same phenotype caused by different pathogenic variants in the same gene. This can be illustrated by amelogenesis imperfecta, where 27 different pathogenic variants in the *FAM83H* gene have been identified.[82] Another example of allelic heterogeneity is illustrated by the 22 pathogenic variants in the *ENAM* gene that also cause amelogenesis imperfecta.[83]

Locus heterogeneity refers to the same phenotype arising from pathogenic variants in different genes. While the above example of mutations in the *FAM83H* gene illustrate allelic heterogeneity, the fact that pathogenic variants in *FAM83H* and *ENAM* both cause amelogenesis imperfecta is an example of locus heterogeneity. In fact, amelogenesis imperfecta can result from pathogenic variants in at least 17 different genes (Table 27-5; Figure 27-8). Sometimes the clinical and radiographic appearance of enamel and mode of inheritance can be used to narrow down the list of potentially causative genes for amelogenesis imperfecta. Unless there is a clear X-linked inheritance, there are at least 5 genes associated with autosomal dominant inheritance and at least 13 genes associated with autosomal recessive inheritance of amelogenesis imperfecta.

Sometimes individuals with the same pathogenic variant can have different phenotypic features. In the most extreme form, some individuals who have inherited a pathogenic variant for an autosomal dominant trait do not show any features of the disorder, and it is only after the birth of an affected child that it is recognized that they have the pathogenic variant. This is an example on nonpenetrance: an individual has a pathogenic variant but does not express the phenotype. Another example is variable expressivity, where individuals with the same dominant pathogenic variant, sometimes even within the same family, have very different phenotypes. Sometimes even monozygotic twins can be discordant for a genetic disorder, where one twin is affected and one is not.[84]

Table 27-5 Genes that cause amelogenesis imperfecta.

Gene	Chromosome	Phenotype	Mode of Inheritance
LAMB3	1	Hypoplastic	Autosomal dominant
ITGB6	2	Hypoplastic/ hypomineralized	Autosomal recessive
AMTN	4	Hypomineralized	Autosomal dominant
AMBN	4	Hypoplastic	Autosomal recessive
ENAM	4	Hypoplastic	Autosomal dominant and autosomal recessive
ODAPH	4	Hypomaturation	Autosomal recessive
FAM83H	8	Hypomineralized	Autosomal dominant
RELT	11	Hypocalcified	Autosomal recessive
MMP20	11	Hypomaturation	Autosomal recessive
GPR68	14	Hypomaturation	Autosomal recessive
SLC24A4	14	Hypomaturation	Autosomal recessive
WDR72	15	Hypomaturation	Autosomal recessive
DLX3	15	Hypomaturation/ hypoplastic	Autosomal dominant
FAM20A	17	Hypoplastic	Autosomal recessive
ACP4	19	Hypoplastic	Autosomal recessive
KLK4	19	Hypomaturation	Autosomal recessive
AMELX	X	Hypoplastic/ hypomaturation	X-linked

Phenocopies

A phenocopy is an environmentally induced phenotype that looks like a genetic disorder. An example is gingival overgrowth. Gingival overgrowth can occur as an isolated autosomal dominant trait, as part of a syndrome, or as the result of certain medications, including cyclosporin, calcium-channel blockers, and phenytoin (Figure 27-10).[85] Not everyone who takes the drug will develop gingival overgrowth, which is an unwanted side effect. Cessation of medicine will result in resolution of the overgrowth over time without the need for surgical treatment. Genetic forms of gingival overgrowth typically require surgical intervention unless very mild. It is important to distinguish phenocopies, which can often be elucidated by a thorough clinical and family history, including duration of symptoms, whether anyone else in the family is similarly affected, and changes to medications.[86]

GENOMICS IN THE FUTURE

Knowledge of the effects of genetic variation continues to increase at an exponential pace in advancing our understanding of both basic biologic mechanisms and risk of most health conditions addressed by the field of oral medicine. Along with these advances come "growing pains" as scientist-clinicians press the limits (and occasionally step beyond solid ground) of what these powerful data can and cannot tell us about disease diagnosis, risk, prognosis, and optimizing treatments and prevention. For many simple (single-gene) conditions, genetic tests provide solid answers, as shown in examples presented in this chapter. However, for complex phenotypes such as dental caries and periodontitis, the associations with one or a few genetic variants reported thus far are neither sufficiently strong nor consistent enough across studies to provide any clinical utility for use in patients. It remains uncertain whether the much larger genetic studies currently underway, incorporating measures of subjects' microbiomes, diet, and other risk factors, may ultimately lead to genetic tests that will be useful in the clinic for these complex conditions.

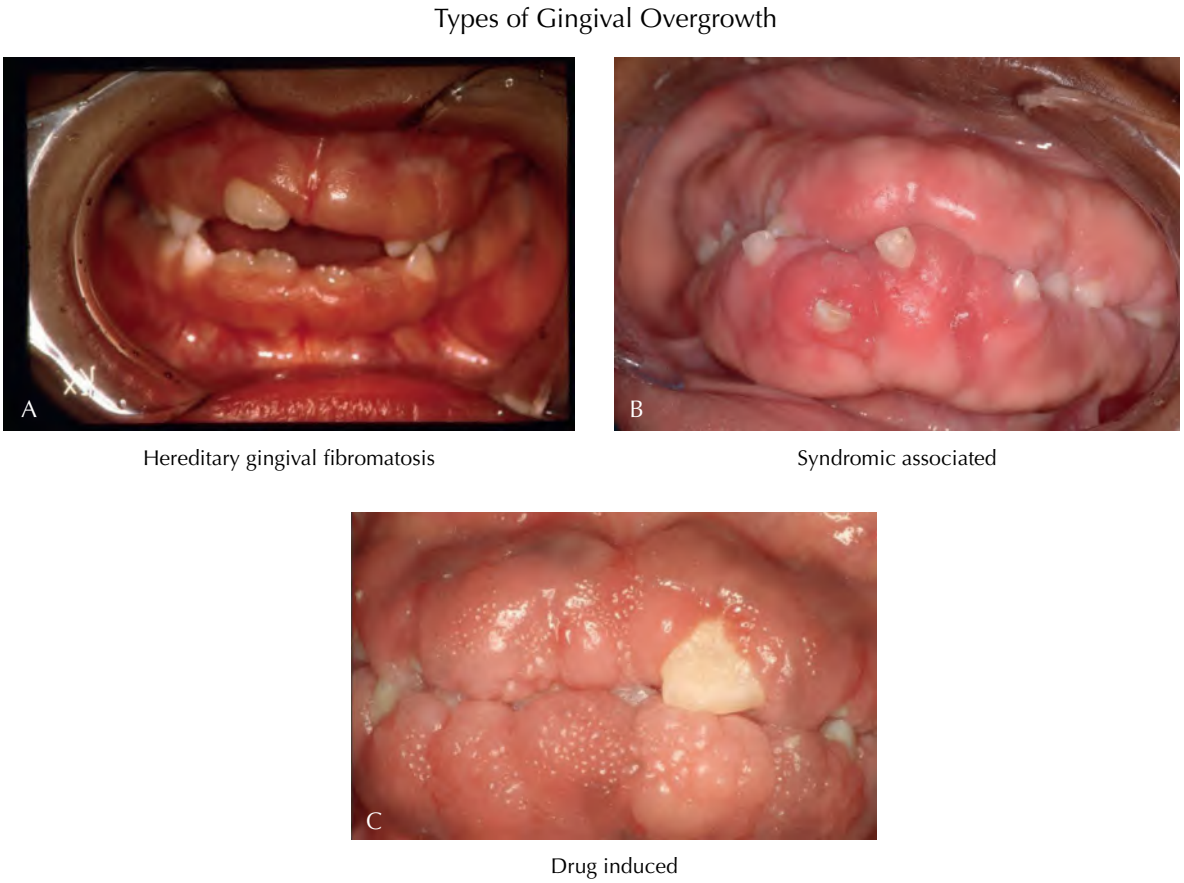

Figure 27-10 Examples of gingival overgrowth. (A) This individual has an autosomal dominant isolated form of gingival overgrowth, termed hereditary gingival overgrowth type I, due to pathogenic variants in *SOS1*. (B) This individual has a syndromic form of gingival overgrowth (Zimmermann–Laband syndrome), meaning they have other phenotypic features in addition to gingival overgrowth. (C) This individual has gingival overgrowth as a side effect of medication: calcium-channel blocker and cyclosporin. This is known as a phenocopy.

Laboratory Medicine and Diagnostic Pathology

Brian C. Muzyka, DMD, MS, MBA
John Christie, MD, PhD
Bobby Collins, DDS, MS

Pathology has traditionally been divided into laboratory medicine and anatomic pathology. Laboratory medicine is the division of medical science dealing with the qualitative and quantitative assessment or analysis of blood (formed elements and fluid components) and other cells and body fluids, while anatomic pathology involves the determination of disease through gross and microscopic examination of tissue. Clinical chemistry, microbiology, hematology, immunology, molecular diagnostics, cytology, toxicology, therapeutic drug monitoring, genetics, and histology are various components of laboratory medicine.

Diagnostic testing is performed on samples of blood, tissue, and other cells and bodily fluids to provide the clinician with information about a person's health, such as establishing a diagnosis of a condition or disease; screening for disease in asymptomatic patients; and excluding the diagnosis of a disease or condition or monitoring therapy.

The need for this chapter on laboratory medicine in a textbook of oral medicine stems from the National Academy of Medicine report in 2015, which indicated that the medical history of almost every adult in the United States contains a minimum of one diagnostic error.[1] It is difficult to determine the impact of laboratory testing on medical decisions. Historically it has been accepted that 70% of medical decisions are a direct result of laboratory testing.[1] More recently, reports of the use of laboratory tests in patient care medical decisions ranged from 38% for general internists and 29% for family physicians.[2] The percentage of medical decisions made as a direct result of laboratory results is apparently less than the historically estimated 70%, but clearly laboratory testing plays a major role in the provision of healthcare. The Centers for Medicare and Medicaid Services (CMS) estimate that the overall spending on healthcare in the United States in 2017 was $3.5 trillion. National healthcare spending in the United States is projected to grow at an average rate of 5.5% per year for 2018–2027 and to reach nearly $6.0 trillion by 2027.[3] Laboratory testing accounts for approximately $97 billion, 28% of overall US healthcare spending per year. In

Burket's Oral Medicine, Thirteenth Edition. Edited by Michael Glick, Martin S. Greenberg, Peter B. Lockhart, and Stephen J. Challacombe.

2027, the estimated economic impact of laboratory testing in the United States will approach $1.68 trillion.

A significant proportion of diagnostic errors in medical histories are due to problems with ordering, performing, reporting, and interpreting laboratory tests. Unfortunately, schools of medicine, dentistry, and allied health do not routinely provide formal courses in laboratory medicine. With the increasing complexity of laboratory testing and little clinically oriented support from practitioners of laboratory medicine, medical, dental, pharmacy, and nursing professionals are confused and uncertain about the proper use of laboratory results.

The aims of this chapter are to provide an introduction to the general principles of laboratory medicine, which should be a part of every oral healthcare professional's knowledge base, as well as help fulfill two of the goals of the Institute of Medicine report: to employ more effective teamwork in the diagnostic process and to enhance healthcare professionals' education and training in the diagnostic process (Table 28-1). Laboratory testing includes three steps: preanalytic—activities such as test ordering and sample collection that take place before actual testing; analytic—laboratory performance of the test; and postanalytic—the process of reporting and interpreting the result. As the analytic phase of laboratory testing is highly regulated and under tight quality control, most laboratory-associated errors occur in the preanalytic and postanalytic stages. For this reason and also for the reason that those two areas are most affected by the decisions of medical/dental professionals, this chapter will focus on the preanalytic and postanalytic stages of laboratory testing.

PREANALYTIC PHASE OF LABORATORY TESTING

Appropriate laboratory testing is defined as "ordering of the right test, using the right method, at the right time, to the right patient, with the right costs and producing the right outcome."[4] The increasing emphasis on the appropriateness of laboratory testing is shown by the development of

Table 28-1 Institute of medicine september 2015 diagnosis recommendations.

Goal 1: Facilitate more effective teamwork in the diagnostic process among health care professionals, patients, and their families	
Recommendation 1A In recognition that the diagnostic process is a dynamic team-based activity, health care organizations should ensure that health care professionals have the appropriate knowledge, skills, resources, and support to engage in teamwork in the diagnostic process. To accomplish this, they should facilitate and support: • Interprofessional and intraprofessional teamwork in the diagnostic process. • Collaboration among pathologists, radiologists, other diagnosticians, and treating health care professionals to improve diagnostic testing processes.	Recommendation 1B Health care professionals and organizations should partner with patients and their families as diagnostic team members and facilitate patient and family engagement in the diagnostic process, aligned with their needs, values, and preferences. To accomplish this, they should: • Provide patients with opportunities to learn about the diagnostic process. • Create environments in which patients and their families are comfortable engaging in the diagnostic process and sharing feedback and concerns about diagnostic errors and near misses. • Ensure patient access to electronic health records (EHRs), including clinical notes and diagnostic testing results, to facilitate patient engagement in the diagnostic process and patient review of health records for accuracy. • Identify opportunities to include patients and their families in efforts to improve the diagnostic process by learning from diagnostic errors and near misses.
Goal 2: Enhance health care professional education and training in the diagnostic process	
Recommendation 2A Educators should ensure that curricula and training programs across the career trajectory: • Address performance in the diagnostic process, including areas such as clinical reasoning; teamwork; communication with patients, their families, and other health care professionals; appropriate use of diagnostic tests and the application of these results on subsequent decision making; and use of health information technology (IT). • Employ educational approaches that are aligned with evidence from the learning sciences.	Recommendation 2B Health care professional certification and accreditation organizations should ensure that health care professionals have and maintain the competencies needed for effective performance in the diagnostic process, including the areas listed in Recommendation 2A.

Table 28-1 (Continued)

Goal 3: Ensure that health information technologies support patients and health care professionals in the diagnostic process			
Recommendation 3A Health IT vendors and the Office of the National Coordinator for Health Information Technology (ONC) should work together with users to ensure that health IT used in the diagnostic process demonstrates usability, incorporates human factors knowledge, integrates measurement capability, fits well within clinical workflow, provides clinical decision support, and facilitates the timely flow of information among patients and health care professionals involved in the diagnostic process.	Recommendation 3B ONC should require health IT vendors to meet standards for interoperability among different health IT systems to support effective, efficient, and structured flow of patient information across care settings to facilitate the diagnostic process by 2018.	Recommendation 3C The Secretary of the U.S. Department of Health and Human Services (HHS) should require health IT vendors to: • Routinely submit their products for independent evaluation and notify users about potential adverse effects on the diagnostic process related to the use of their products. • Permit and support the free exchange of information about real-time user experiences with health IT design and implementation that adversely affect the diagnostic process.	
Goal 4: Develop and deploy approaches to identify, learn from, and reduce diagnostic errors and near misses in clinical practice			
Recommendation 4A Accreditation organizations and the Medicare conditions of participation should require that health care organizations have programs in place to monitor the diagnostic process and identify, learn from, and reduce diagnostic errors and near misses in a timely fashion. Proven approaches should be incorporated into updates of these requirements.	Recommendation 4B Health care organizations should: • Monitor the diagnostic process and identify, learn from, and reduce diagnostic errors and near misses as a component of their research, quality improvement, and patient safety programs. • Implement procedures and practices to provide systematic feedback on diagnostic performance to individual health care professionals, care teams, and clinical and organizational leaders.	Recommendation 4C HHS should provide funding for a designated subset of health care systems to conduct routine postmortem examinations on a representative sample of patient deaths.	Recommendation 4D Health care professional societies should identify opportunities to improve accurate and timely diagnoses and reduce diagnostic errors in their specialties.
Goal 5: Establish a work system and culture that supports the diagnostic process and improvements in diagnostic performance			
Recommendation 5 Health care organizations should: • Adopt policies and practices that promote a non-punitive culture that values open discussion and feedback on diagnostic performance. • Design the work system in which the diagnostic process occurs to support the work and activities of patients, their families, and health care professionals and to facilitate accurate and timely diagnoses. • Develop and implement processes to ensure effective and timely communication between diagnostic testing health care professionals and treating health care professionals across all health care delivery settings.			

(*Continued*)

Table 28-1 (Continued)

Goal 6: Develop a reporting environment and medical liability system that facilitates improved diagnosis by learning from diagnostic errors and near misses			
Recommendation 6A The Agency for Healthcare Research and Quality (AHRQ) or other appropriate agencies or independent entities should encourage and facilitate the voluntary reporting of diagnostic errors and near misses.	Recommendation 6B AHRQ should evaluate the effectiveness of patient safety organizations (PSOs) as a major mechanism for voluntary reporting and learning from these events and modify the PSO common formats for reporting of patient safety events to include diagnostic errors and near misses.	Recommendation 6C States, in collaboration with other stakeholders (health care organizations, professional liability insurance carriers, state and federal policy makers, patient advocacy groups, and medical malpractice plaintiff and defense attorneys), should promote a legal environment that facilitates the timely identification, disclosure, and learning from diagnostic errors. Specifically, they should: • Encourage the adoption of communication and resolution programs (CRPs) with legal protections for disclosures and apologies under state laws. • Conduct demonstration projects of alternative approaches to the resolution of medical injuries, including administrative health courts and safe harbors for adherence to evidenced-based clinical practice guidelines.	Recommendation 6D Professional liability insurance carriers and captive insurers should collaborate with health care professionals on opportunities to improve diagnostic performance through education, training, and practice improvement approaches and increase participation in such programs.
Goal 7: Design a payment and care delivery environment that supports the diagnostic process			
Recommendation 7A As long as fee schedules remain a predominant mechanism for determining clinician payment, the Centers for Medicare & Medicaid Services (CMS) and other payers should: • Create current procedural terminology (CPT) codes and provide coverage for additional evaluation and management activities not currently coded or covered, including time spent by pathologists, radiologists, and other clinicians in advising ordering clinicians on the selection, use, and interpretation of diagnostic testing for specific patients. • Reorient relative value fees to more appropriately value the time spent with patients in evaluation and management activities. • Modify documentation guidelines for evaluation and management services to improve the accuracy of information in the EHR and to support decision making in the diagnostic process.		Recommendation 7B CMS and other payers should assess the impact of payment and care delivery models on the diagnostic process, the occurrence of diagnostic errors, and learning from these errors.	
Goal 8: Provide dedicated funding for research on the diagnostic process and diagnostic errors			
Recommendation 8A Federal agencies, including HHS, the U.S. Department of Veterans Affairs, and the United States Department of Defense, should: • Develop a coordinated research agenda on the diagnostic process and diagnostic errors by the end of 2016. • Commit dedicated funding to implementing this research agenda.		Recommendation 8B The federal government should pursue and encourage opportunities for public–private partnerships among a broad range of stakeholders, such as the Patient-Centered Outcomes Research Institute, foundations, the diagnostic testing and health IT industries, health care organizations, and professional liability insurers to support research on the diagnostic process and diagnostic errors.

initiatives such as the "Choosing Wisely" campaign (www.choosingwisely.org), developed by the American Board of Medicine, and laboratory stewardship programs such as PLUGS (**P**atient-centered **L**aboratory **U**tilization **G**uidance **S**ervice), started by Seattle Children's Hospital and found in many hospitals (www.schplugs.org).[5,6]

In order to reduce or eliminate activities that have little benefit or can cause harm, Choosing Wisely focuses on what not to do rather than on positive advice about what to do. The recommendations from Choosing Wisely are helpful and, as a result, many medical specialty societies have adapted Choosing Wisely and include it as part of their medical specialty website.

In patient care, the first step in ordering the appropriate laboratory test is to determine whether a test should be ordered. In 1994, Dr. Catherine DeAngelis, the first woman editor of the *Journal of the American Medical Association,* made a pithy comment that summarizes the whole issue very succinctly: "Remember ordering a laboratory test is a bit like picking your nose in public: you must consider what you will do if you find something."[7] Hooper and his colleagues put the same sentiment in slightly different language: "Before ordering a test, decide what you will do if it is either positive or negative. If both answers are the same, then don't do the test."[8]

Lee in the 25th edition of *Goodman-Cecil Medicine* had the following comments about laboratory testing that provide more detailed advice about ordering laboratory tests:

> The interpretation of test results depends on what is already known about the patient.
>
> No test is perfect. Clinicians should be familiar with their diagnostic performance and never believe that a test "forces" them to pursue a specific management strategy.
>
> Tests should be ordered if they may provide additional information beyond that already available.
>
> Tests should be ordered if there is a reasonable chance that the data will influence patient care.
>
> Two tests that provide similar information should not be used.
>
> In choosing between two tests that provide similar data, use the one that has lower cost and/or causes less discomfort and inconvenience to the patient.
>
> Clinicians should seek all the information provided by the test, not just an abnormal or normal result.
>
> The cost-effectiveness of strategies using noninvasive tests should be considered in a manner similar to that of therapeutic strategies.[9]

Consideration of which laboratory test to order involves examination of parameters of the specific assay that determine the diagnostic usefulness of the test. In determining the usefulness of a test, the concepts of sensitivity and specificity come into play. In a population of patients in which the correct disease status is already known, sensitivity is the percentage testing positive in a population with disease (positive in disease), while specificity is the percentage testing negative in a population without disease (negative in health). For most commercially available assays, the sensitivity and specificity of a particular test are listed in the literature provided by the manufacturer. However, the sensitivity and specificity measures provided by the manufacturer are obtained under ideal conditions that are generally not found in clinical use. Generally, in "real-life" situations, the actual sensitivity and specificity of a particular assay are less than those indicated in the manufacturer's instructions for the test. As a general rule, a diagnostic assay should have performance characteristics that minimize false positives and false negatives. However, the clinical implications of a test result may determine which test is most useful in a specific situation. For patients who potentially have a serious, possibly incurable disease, the diagnostic test should have high specificity so as to minimize the number of false positive results. On the other hand, an assay that maximizes sensitivity should be used to diagnose serious but curable diseases. A second confirmatory assay may then be used.

When choosing between the sensitivity and specificity of a laboratory test for a condition, clinicians may find the mnemonic "SpIn and SnOut" helpful. Specificity, abbreviated as Sp, is used to rule in the condition (SpIn). Sensitivity, abbreviated as Sn, is used to rule out the condition (SnOut) (see Figure 28-1).

The actual usefulness of a laboratory test is better predicted by the positive and negative predictive values. The positive predictive value (PPV) of a test is the percentage of all positive results that are true positives and is calculated using the formula:

$$\text{PPV} = \left[\text{True positives} / (\text{True positives} + \text{False positives})\right] \times 100$$

The negative predictive value (NPV) is the percentage of all negative results that are true negatives and is calculated using the formula:

$$\text{NPV} = \left[\text{True negatives} / \left(\text{True negatives} + \text{False negatives}\right)\right] \times 100$$

A good test should have both high positive and negative predictive values. The predictive values for any test depend not only on the sensitivity and specificity of the test, but also on the prevalence of the disease for the diagnostic laboratory assay.

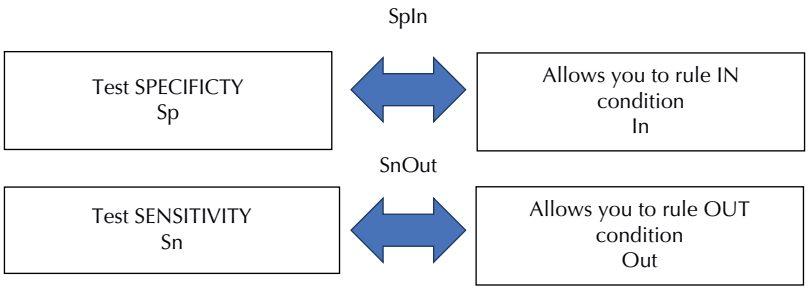

Figure 28-1 Mnemonic for Differentiating between Sensitivity and Specificity.

Using systemic lupus erythematosus (SLE) and the antinuclear antibody (ANA) test as an example:

> The sensitivity and specificity for ANA in the diagnosis of SLE are 95% and 90%, respectively; testing for SLE with ANA in all patients presenting to a primary care practice (assume prevalence of $\leq$1%), the PPV and NPV are 9% and >99%, respectively. In a rheumatology clinic in which only patients with clinical features of SLE (assume prevalence of 30%) are tested with ANA, the PPV and NPV of the test are 80% and 96%, respectively.

Understanding PPV and NPV is important for the dental healthcare team. Dental advertising and dental salespersons may try to sell tests for diagnosis of caries, periodontal disease, oral cancer, or other diseases and conditions to general dental practices. Moreover, these tests may be advertised for direct sale to the public. Whether the test is used for screening or diagnosis depends on the characteristics of the assay: high sensitivity for screening tests and high specificity for exclusion of a diagnosis. Preferably those characteristics should be obtained from published literature and not from the detail sheet accompanying the materials for performance of the assay. Dental practitioners using these tests need to be aware of the predictive value of these tests in their own patient populations and determine whether or not these tests are useful, and whether these assays are more appropriate for screening than for diagnostic purposes.

The diagnostic accuracy of a particular test is provided by knowledge of the sensitivity and specificity for that assay. However, these values do not give any indication about the effect the result has on the likelihood that the patient has the disease for which the test is performed. The relationship between the clinical suspicion—that is, the pre-test probability—that a patient has a disease compared to the chance that the patient has the disease after a particular test is performed—that is, the post-test probability—is given by the formula:

$$\text{Post-test probability} = \text{LR} \times \left(\text{pre-test probability}\right)$$

where LR is the likelihood ratio.

The pre-test probability is the clinician's estimate that the patient has the disease. This probability is estimated from the prevalence of the disease in the population from which the patient comes and the history and physical examination.

The LR of a positive result is calculated by the following equation:

$$\text{LR of a positive result} = \text{Sensitivity} / \left(1 - \text{Specificity}\right)$$

The LR of a negative result is calculated by the following equation:

$$\text{LR of a negative result} = \left(1 - \text{Sensitivity}\right) / \text{Specificity}$$

The diagnostic or testing threshold of a test is the point at which clinical suspicion for disease is so low that the results of the laboratory test will not alter that low probability. If the test has a low diagnostic threshold even if the test is positive, it is most likely a false positive result and the patient should not be treated for that disease. The therapeutic or treatment threshold is the point at which clinical suspicion is high enough that the results of the assay will not significantly increase the likelihood that the patient has the disease. Laboratory tests should be ordered when the pre-test probability of the patient having the disease lies between the diagnostic and the therapeutic threshold (see Figure 28-2). These thresholds are generally determined by published analyses. An example of determination of these break-points is seen in two papers dealing with Lyme disease testing.[10,11] In these papers, the diagnostic or testing threshold was 0.20 (a patient with nonspecific arthritis) and the therapeutic threshold was 0.8 (a patient from a geographic area endemic for Lyme disease with either erythema migrans or a combination of arthritis, history of a rash resembling erythema migrans, and a previous tick bite).

Diagnostic testing can be performed in a multitude of locations. Laboratories with a large menu of diagnostic tests generally include those laboratories found in larger hospitals, hospital systems, and commercial laboratories, such a Quest Diagnostics or LabCorp. Most hospitals and large healthcare centers have in-house laboratories. These in-house laboratories may offer a full spectrum of laboratory testing or may be limited to more routinely used assays, and the in-house laboratory may send out less commonly used

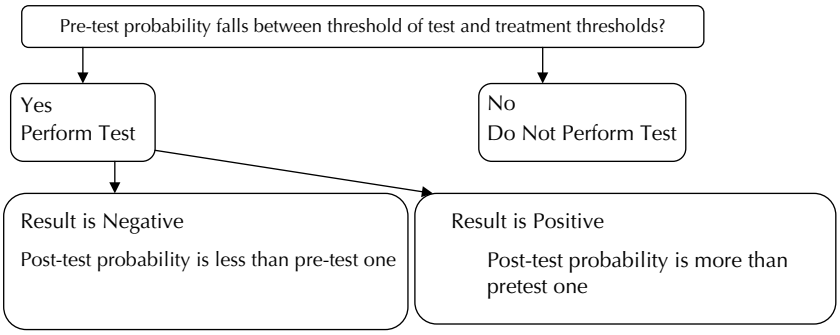

Figure 28-2 Diagnostic tree for ordering a test.

assays to a commercial laboratory. Diagnostic testing also occurs in smaller labs found in providers' offices, healthcare centers, urgent care centers, or other locations such as pharmacies. In the outpatient nonhospital setting, specimens are generally obtained from patients and sent to a centralized regional lab for analysis.

In the United States, diagnostic laboratories are required to be licensed and certified. On October 31, 1988, the US Congress enacted the Clinical Laboratory Improvement Amendments of 1988 (Pub. L. 100-578) (CLIA'88), codified at 42 U.S.C. 263.[12] This act, more generally known as CLIA, established quality standards for laboratory testing to ensure the accuracy, reliability, and timeliness of patient test results regardless of the location of the testing site, and requires laboratories to be CLIA certified. CLIA certification is important, as a clinical laboratory must be CLIA certified to receive reimbursement from Medicare or Medicaid. In the United States, Medicare payments for lab tests totaled $6.8 billion in 2016 and reimbursement for services provided is certainly an incentive for laboratories to obtain and maintain their CLIA certification.

Point-of-Care Testing

Office laboratories often use point-of-care (POC) assays as the basis for much of their testing. Point-of-care testing (POCT), defined as any testing that occurs outside of a central laboratory, is becoming a more common and accepted practice in the healthcare industry. POCT offers several advantages over traditional, more regulated laboratory testing, including increased accessibility to diagnostic testing for many populations, especially in rural and remote settings; minimal sample volumes required to perform the assay; real-time test results; and, most importantly, the ability of nonlaboratory personnel to perform these assays. However, the instructions for these POC tests must be followed precisely; and, as in more traditional laboratories, there must be documentation of training, performance of controls and instrument checks, and correct performance of procedures.

As useful as POC assays are, they may be inappropriate in certain clinical situations. An example is the use of a POC assay to determine glycosylated hemoglobin (HbA_{1c}) for the diagnosis of diabetes mellitus. HbA_{1c} is a measure of blood glucose over the life span of the red blood cell, which is approximately 120 days. While it may be appropriate to use POC HbA_{1c} assays to guide outpatient treatment of patients with diabetes, the analytic performance of these tests—that is, their accuracy relative to a reference laboratory's standard and precision—is such that patients who have true HbA_{1c} values close to the diagnostic cut-point may be misdiagnosed. A cut-point is a value at which subjects are classified as having or not having a condition. The World Health Organization (WHO) recommends an HbA_{1c} cut-point of 6.5% for the diagnosis of diabetes. A value of less than 6.5% does not exclude a diabetes diagnosis and further clinical investigation may be required.[13] Even in the same institution, there is often a difference between the results of an assay performed in an outpatient/clinic setting by one methodology and an assay for the same analyte performed by the reference method in the main hospital laboratory. When such differences are clinically important, such as in diagnosis of a disease, the main laboratory should append a comment to the results to indicate that such discrepancies exist and that correction factors have been applied to make the results compatible.

The American Dental Association (ADA) advocates for POCT of patient blood glucose levels on an ongoing basis or immediately prior to dental treatment as an appropriate activity for persons at risk for diabetes. In support of this recommendation, the ADA has established a billing code (D0142) for this test (Box 28-1).

Box 28-1 CDT Code for Point-of-Care Blood Glucose Testing

D0412 blood glucose level test—in-office using a glucose meter. This procedure provides an immediate finding of a patient's blood glucose level at the time of sample collection for the point of service analysis.

Box 28-2 CDT Code for Point-of-Care HbA1c testing
D0411 HbA_{1c} in-office point of service testing

Additionally, the ADA has established a billing code for testing for $HbA1_c$ (Box 28-2).

Further information on ADA recommendations for POC testing can be found on the ADA website.[14]

Laboratory Analysis

Laboratory analysis is based upon the idea that the material sampled will be collected in a standardized fashion to reduce the likelihood of undue variability of results. Since patients are not standardized, their physical status can significantly affect their hematologic profile and laboratory results. The patient's degree of hydration, level of anxiety, activity, medications, history of tobacco use, sex, and race may impact upon hematologic profile results. Additionally, the presence of certain medical conditions may impact laboratory test results. For example, $HbA1_c$ values are elevated in iron-deficiency anemia patients and decrease after the patients are treated with iron.[15]

Descriptive information regarding the patient is required when submitting a sample for laboratory analysis. This descriptive information may include pertinent medical history, sex, age, race, fasting status, and time of collection. Correctly labeling specimens that have been obtained is of the utmost importance. Samples must be labeled with appropriate identification to ensure the test results will be related back to the patient. The use of $\geq$1 unique patient identifiers such as medical record numbers or birthdate along with bar codes generated to identify that a sample was obtained from a specific known patient has become standard practice in clinics and hospitals. The barcode and unique identifiers are placed on the specimen container and attached to the laboratory requisition form.

In collecting blood for determination of specific analytes, there are different types of collection tubes whose purpose is generally indicated by the color of the top of the tube. Table 28-2 gives a representative sample of the common blood collection tubes and their uses.[16,17] However, the laboratory to which you send samples should provide a list of the blood collection tubes, specimen requirements, and any directions for use. If you are unsure about any of this information, you should contact the laboratory directly.

In order to aid in the draw of blood into the container, most of these tubes contain a vacuum. The tubes should be filled with a certain amount of blood with at least the minimum specimen volume designated by the laboratory. The tops of the tubes should not be removed to completely fill the container. In tubes that contain additives, under- or overfilling can yield in false results. Many of the collection tubes with additives should be inverted several times to allow complete mixing of the blood and/or any additive. Order of draw, when obtaining multiple samples for testing, is important, with the following sequence being recommended: sterile tubes for blood culture; tube for coagulation testing (light blue); gel separator tube (red); tube with heparin additive (green tube); tube with EDTA additive (purple/lavender tube); tube with oxalate/fluoride additive (gray tube).

Falsely high or low results for assays can occur due to materials that interfere with the accurate and precise measurement of the analyte in question. As many laboratory results are determined by spectrophotometric methods, any substance that colors the plasma and serum can interfere with the results. The three major interferences due to abnormal colors in a liquid are lipemia, causing a milky-white color; hemolysis, resulting in a red color; and increased bilirubin, turning plasma/serum orange, green, or brown. Besides altering the color of serum/plasma, many drugs produce significant interference by other means. Therefore, it is important to include medication information on a laboratory requisition slip when requested.

For most tests, blood can be drawn at any time during the day. However, there are exceptions to this statement. For therapeutic monitoring of drugs such as antibiotics, the medical professional needs to know if the drug concentration is within a certain therapeutic range. It is easier to draw a trough level, the lowest level of a drug before administration of the next dose, than a peak level for a drug. A peak level is the highest level of drug in the serum and is usually obtained 1 to several hours after the drug is administered. For an intravenously administered drug, blood is drawn for trough levels just prior ($\leq$30 minutes ideally) to administration of the next dose. Some biochemical assay results are biased by diurnal variations. Time of collection must be considered when interpreting these values in the clinical setting. For example, sampling of blood for distinction of pseudo-Cushing states from Cushing syndrome gives 96% accuracy. In Cushing's syndrome the loss of normal cortisol circadian rhythm and absence of a late-night cortisol nadir is typical. Midnight serum cortisol levels have been used to distinguish patients with Cushing's syndrome from those with pseudo-Cushing's syndrome. However, drawing blood at midnight is inconvenient for an ambulatory patient, so obtaining saliva for cortisol determination at bedtime or midnight is more convenient and just as accurate. For those readers who wish more information about laboratory medicine, including laboratory reference ranges, we recommend the third edition of *Laposata's Laboratory Medicine Diagnosis of Disease in the Clinical Laboratory*.[16]

Table 28-2 Selected examples of blood collection tubes.

Cap Color	Content(s)	Comments and Uses
Red	None	Clotted blood or serum Most routine chemistries, blood bank, serology
Light blue	Sodium citrate	Acts as anticoagulant, plasma coagulation testing
Purple (lavender)	EDTA	Acts as anticoagulant Unclotted blood for hematology, genetic testing, immunosuppressants, red blood cell folate, HbA_{1c}
Green	Sodium/lithium heparin	Acts as anticoagulant heparinized plasma, whole blood, and bone marrow specimens
Gold with gel	Clot activator	Gel for serum separation after centrifugation; shorter clot time Most routine chemistries Do not use for toxicology or drug testing
Gray	Sodium fluoride ± EDTA or potassium oxalate	Fluoride inhibits glycolysis, allowing optimum glucose measurements EDTA and oxalate are anticoagulants
Yellow	Acid-citrate dextrose solution Blood bank studies, human	Anticoagulates blood and preserves cells during processing leukocyte antigen phenotyping
Dark blue	EDTA or none	Trace element determination

New York: McGraw-Hill, 2019; Bakerman S, Bakerman P, Strausbauch P. *Bakerman's ABC's of Interpretive Laboratory Data*, 5th edn. Scottsdale, AZ: Interpretive Laboratory Data, 2014.

Although oral infections are common, bacterial cultures are of limited value in dentistry. Often, all that is needed is a direct smear of the infected tissue of interest, such as fluid from a vesicle, abscess aspirate, or scraping from tongue or mucosal sites. Microbiologic cultures of soft tissue infections of the head and neck are frequently not performed because there is a mixed aerobic/anaerobic flora that is difficult to sample and to culture. For these infections in which a culture has been submitted, most laboratories will either give a diagnosis of mixed aerobic/anaerobic flora and/or list the three most predominant organisms. However, for severe infections such as osteomyelitis, acute parotitis, and cellulitis, culture and sensitivity should be performed. If cultures are to be submitted to a diagnostic laboratory, pus or tissue is the best choice of sample materials. Microbiologic swabs are convenient, but inferior to tissue and fluid. Tissue and fluid are essential for fungal and mycobacterial cultures. Moreover, if there is a possibility that an anaerobic organism is the causative organism, materials for culture should be submitted in anaerobic transport containers. Unless the antibiotic susceptibility of a bacterium can be predicted from its identity, a standardized battery of antibiotic susceptibilities is performed as part of the culture.

However, unless fungal and mycobacterial cultures are sent to a large reference laboratory, often susceptibilities will only be performed with specific antifungal or antimycobacterial drugs upon specific request.

In the clinical pathology area, molecular methods have probably made their greatest inroads in the microbiology laboratory. In many virology reference laboratories, molecular methods with their greater sensitivity have replaced viral cultures. Many companies are marketing polymerase chain reaction (PCR) tests that can be performed in small laboratories. Many of these kits can detect multiple organisms (multiplex) from one sample. However, there is a growing awareness that detecting several organisms in one sample means that the clinical significance of these results is often hard to determine. In quantitative PCR assays, used most frequently for determination of viral loads in blood or tissue, the variability is such that a $\log_{10}$ difference between two different samples is necessary before it can be assumed that there is a true difference between results. In addition, the results of two different quantitative PCR tests performed in different laboratories cannot be compared.

Infectious diseases are one area in which correlation of laboratory results—that is, those from the microbiology laboratory with those from tissue biopsies of the same site—is absolutely essential. With increasing degrees of immunosuppression and more powerful drugs, it is now recognized that organisms that were formerly considered colonizers or of low virulence can invade tissues and be pathogenic. This is especially true of the majority of fungi, which are considered opportunistic pathogens. For example, sinus material from patients with chronic sinusitis often grows *Aspergillus spp*. In immunosuppressed patients the finding of *Aspergillus spp*. does not help the clinician determine if the diagnosis is chronic fungal sinusitis or invasive fungal sinusitis with the accompanying possibility of dissemination to other sites. Only a tissue biopsy will provide definitive evidence of sinus fungal invasion. There are other situations in which culture will provide a definitive identification of an organism, but tissue is necessary for determination of the clinical significance of the organism. Examples include active *Candida spp*. infection from a smear of involved epithelium demonstrating the presence of hyphae; the presence of characteristic viral inclusions in tissues for diagnosis of viral invasion; and the presence of the agents of endemic mycoses in histologic/cytologic material, as cultures may take weeks to grow or fail to grow.

For those organisms that cannot be detected by the methods we have previously discussed, serologic methods are often valuable. These methods detect the presence of a specific antigen in a body fluid or the presence of specific antibodies directed against the organism. Unfortunately, for many exotic pathogens, serologic diagnosis depends on assays available only in large, reference laboratories or at facilities such as the Centers for Disease Control and Prevention (CDC).

Theoretically, the most specific methods for measuring antibody production detected against a particular pathogen depend on the detection of immunoglobulin (Ig) M for documentation of an acute infection or measurement of an antibody, usually IgG, at two different time intervals, weeks apart. In many cases, these measures are not practical: either the peak of IgM has passed, or it is unlikely that the patient will return for a second visit to the laboratory for a blood draw weeks distant for the initial clinic visit. In such cases, the clinician must depend on an assay that detects the absolute magnitude of the antibody response at the time of the clinic visit.

Healthcare providers may order laboratory tests by completing an appropriate medical order for the test. Many of the major laboratories have online systems to request testing and to view the results. In order to use these online systems, the clinician must register with these laboratories. In the United States, the cost of laboratory tests may be billed to medical insurance and this billing process may make the process of ordering tests cumbersome for dental providers. For instance, the ordering dental healthcare worker may not be a preferred provider with the medical insurance company. The definition of a preferred provider is a provider who has a contract with the patient's health insurer or plan to provide services at a discount. For nonpreferred providers, the fees charged for laboratory tests ordered may be costlier and the patient may be responsible for a larger portion of the charges than if the provider had been a preferred provider (in the network). The laboratory charges to the patient in a situation such as this may be prohibitive, and the patient may not proceed with recommended dental treatment secondary to the laboratory costs, or may be upset with the dental team when the bill from the diagnostic laboratory is received. In such cases, it may be more efficient and less costly for a patient with medical insurance to have the necessary laboratory tests ordered by their primary care physician. The dental healthcare worker should communicate with the physician when requesting labs and discuss the planned dental procedure and need for the test. Similarly, the physician will need to update the patient's medical records with the reasons the tests were ordered and share those results with the dental healthcare worker.

POSTANALYTIC PHASE OF LABORATORY TESTING

Laboratory results are reported with reference intervals, which are more commonly known as reference ranges. Reference ranges aid in the interpretation of laboratory

results. Reference ranges for each test are determined using the demographics of the presumed healthy population from which specimens were obtained and the specific methods and/or instruments used to assay these specimens. The use of population reference ranges is an inexact science, and factors such as age, sex, and ethnicity are generally not considered. Reference ranges are usually defined as the set of values that 95% of the normal population falls within (also known as a 95% confidence interval). Reference ranges can be influenced by many factors.

Laboratory values that are within the reference range do not assure health. Likewise, laboratory values that fall outside of the reference range may not confirm disease or indicate a problem. When multiple tests on an individual are performed, there is an increased likelihood that an abnormal value may be due to chance. Lab values outside of the reference range should be investigated when clinically or statistically significant. Reference range values may differ among laboratories. Laboratories that are accredited by the College of American Pathologists (CAP) are required to establish and/or validate their own reference values at least annually.[18] Variance in reference ranges from laboratory to laboratory may occur for a variety of reasons, such as the equipment used in the analysis, reagents used, site humidity, temperature differences, and other conditions.

Blood

Formed elements of the blood arise from a common pluripotent hematopoietic progenitor cell, which matures and differentiates to form the various cellular elements. These cells include erythrocytes (red blood cells, RBCs), leukocytes (white blood cells, WBCs), and platelets.

Of these elements, RBCs are the most numerous. RBCs are required for the delivery of oxygen to tissues and use the iron-containing protein hemoglobin to transport oxygen and carbon dioxide. RBCs, unlike WBCs, have no nuclei (anucleate).

Analysis of RBCs includes the volume of packed red cells (hematocrit), concentration of hemoglobin (Hb), and concentration of red cells per unit volume (RBC count; see Table 28-3). Additionally, three indices are used to describe the quality of the red cells sampled. These indices are the mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC).

Table 28-3 Red blood cell count.

Specimen	Traditional Reference Interval	SI Reference Interval
Female whole blood	3.9–5.5 $\times 10^6$ µL	3.9–5.5 $\times 10^{12}$/L
Male whole blood	4.6–6.0 $\times 10^6$ µL	4.6–6.0 $\times 10^{12}$/L

Hemoglobin Concentration

Hb is measured through spectrophotometric methods secondary to its intensely colored nature. Its main function is to serve as an oxygen carrier and it is found in a variety of forms within the blood. These forms include methemoglobin, oxyhemoglobin, carboxyhemoglobin, and other minor components. In order to measure Hb, whole blood is mixed with Drabkin's solution. Drabkin's solution contains sodium bicarbonate, potassium ferricyanide, and potassium cyanide, which causes a conversion of the Hb forms to cyanmethemoglobin. The light absorbance of cyanmethemoglobin is then measured using a spectrophotometer at 540 nm and the concentration of Hb is determined in grams per deciliter of blood (g/dL) (see Table 28-4). Whole blood samples are collected in a purple/lavender-top tube using EDTA (see Table 28-2) as the anticoagulant and may be rejected by the laboratory if the sample has hemolyzed or clotted. Hemolysis (hemolyzed samples) is defined as a pathologic breakdown process in blood of the RBCs. Hemolysis is typically accompanied by varying degrees of a red-colored tinge in serum or plasma once the whole blood specimen has been centrifuged.

As discussed previously, a subfraction of normal Hb is glycosylated hemoglobin or HbA_{1c}, which is formed during the maturation of the RBC. HbA_{1c} is normally about 4.0% of all hemoglobin in adults, but may be elevated to two or three times normal level in individuals with diabetes mellitus. During the maturation process of RBCs, a glucose molecule is attached to the Hb β-polypeptide chains through a nonenzymatic reaction. The rate of synthesis of HbA_{1c} is dependent on blood glucose levels and therefore monitoring HbA_{1c} levels gives a good indication of average blood glucose levels of the preceding 2–3-month time period. As such, these values have become useful in evaluating long-term blood glucose levels in patients with diabetes mellitus (Table 28-5).

Table 28-6 Reference ranges for hematocrit.

Specimen	Traditional Reference Interval	SI Reference Interval
Male whole blood	41%–50%	0.41–0.50
Female whole blood	35%–45%	0.35–0.45

Hematocrit

The hematocrit (Hct) may be measured either using an automated counter or manually. Manual measurement entails centrifugation of anticoagulated whole blood and this is generally an accurate measure of red cell status. Generally, the anticoagulant EDTA is used and a sample is drawn into a purple/lavender-top tube (see Table 28-2). There are certain inherent technique errors in manual determination, though, that may affect the results. Specifically, manual determination measures red cell concentration and not red cell mass. This factor may be important when dealing with a patient who is hemoconcentrated as a result of shock or volume depletion. In these patients, red blood cell volume may be normal or high, but red cell mass would actually be decreased.

Automated measurement of Hct usually does not depend on centrifugation and the automated values closely parallel the manual values. The automated technique directly calculates the Hct through determining the red cell number and red cell volume. In this technique, red cell number multiplied by red cell volume equals Hct (Table 28-6).

Hct values are used in calculating the MCV and the MCHC.

As the amount of RBCs contained within the body is volume dependent, there are differing reference ranges for ages and sexes. Specimens may be rejected from the laboratory if they do not contain enough of a sample or if the sample has coagulated or hemolyzed before analysis.

Red Cell Indices

Red cell indices are useful when evaluating patients for anemias. MCV evaluates for the size of the average RBC, MCH evaluates for the weight of Hb, and MCHC evaluates for the amount of Hb present compared to size.

Mean Corpuscular Volume

The average volume of the RBC is measured through MCV (Table 28-7). This index is used in the classification of anemias. MCV may be calculated using the following formula:

$$\text{MCV}\left(\text{fL}\right) = \text{Hct}\left(\text{proportion or}\%\right) / \text{Number of RBCs}\left(10^{12} / \text{L}\right)$$

where fL = femtoliter and 1 fL = 1×10^{-15} L.

Table 28-7 Reference ranges for mean corpuscular volume.

Specimen	Traditional Reference Interval	SI Reference Interval
Whole blood	80–100 μm^3	80–100 fL

Many condition can increase the volume of the red cells, including folic acid deficiency, vitamin B_{12} deficiency, cirrhosis, and chronic alcoholism. Certain medications may also induce an increase in red cell volume, including phenytoin and some cytotoxic drugs. RBC volume may be decreased with chronic iron-deficiency anemia, thalassemia minor, and other anemias associated with chronic diseases, such as uremia and collagen-vascular diseases.

Mean Corpuscular Hemoglobin

MCH is the measurement of the average weight of Hb per RBC (Table 28-8). MCH is proportional to the size of the RBC and amount of Hb. MCH can be calculated using the following formula:

$$\text{MCH}\left(\text{pg}\right) = \text{Hb}\left(\text{g / dL}\right) / \text{RBC count}\left(10^{12} / \text{L}\right)$$

where pg is picogram and 1 pg = 1×10^{-12} g.

MCH is also used in classifying anemias. MCH is usually increased in macrocytosis and decreased in microcytosis and hypochromia.

Mean Corpuscular Hemoglobin Concentration

The average concentration of Hb in the average RBC is estimated through MCHC (Table 28-9). Thus, this value is dependent upon the amount of hemoglobin to the volume of RBC. MCHC is affected by conditions that affect the Hb or Hct values. The formula is:

$$\text{MCHC}\left(\text{g / dL}\right) = \text{Hemoglobin}\left(\text{g / dL}\right) / \text{Hematocrit}\left(\%\right)$$

Table 28-8 Reference ranges for mean corpuscular hemoglobin (Mass Concentration).

33–37 g Hb/dL	330–370 g Hb/L

Peripheral Smear

Evaluation of blood smears is important in determining whether hematologic disease is present. Alterations in the size, shape, and structure of individual cells can be noted. Peripheral smears have limitations, though, and cannot be used to diagnose anemias, but rather can be suggestive of anemias or other disease processes. Diagnosis of anemia must be made on Hb, Hct, or RBC counts. Additionally, visualization of sufficient quantities of normal platelets may help rule out certain disease states, such as myeloproliferative disease.

The cover-slip or wedge method may be used to prepare a uniform dispersion of blood for microscopic analysis. The blood smears are then stained with either Wright's or May–Grunwald–Giemsa stain. A properly stained slide will have a pink tint, with red cells showing orange and white cells showing purplish blue. The stained sample is then viewed under a light microscope under intermediate power.

Hypochromia or an increase in the central clear area of the RBC is due to poor hemoglobinization. Hypochromia is seen commonly in patients with chronic iron-deficiency anemia.

Polychromatophilia, caused by immature bluish cytoplasmic material and hemoglobin, is noted when there is an increase in the number of circulating RBCs. This activity is seen in patients with severe anemia secondary to blood loss, hemolysis, leukemia, myeloproliferative disease, and other diseases that cause immature forms of RBCs to be released into the systemic circulation. The presence of elevated numbers of macrocytes may suggest the presence of megaloblastic anemia or reticulocytosis—a release of immature forms of RBCs from the bone marrow.

Visualization of reticulocytes (Table 28-10) is not possible with Wright's or Giemsa staining and requires special staining techniques. Schistocytes, or broken RBCs, may also be seen in a peripheral blood smear of individuals with hemolytic anemias, malignancy, hypothyroidism, or alcoholism. Sickle cells are found in patients with homozygous sickle cell anemia.

RBC sedimentation rate and C-reactive protein (CRP) levels are useful in the presence or absence of inflammation. In inflammatory states, the concentration of certain plasma proteins, collectively known as acute-phase reactants, increases. CRP, a member of the pentraxin group of proteins, was the original acute-phase reactant. RBC sedimentation rate is useful in assessing certain patients. The erythrocyte sedimentation rate (ESR) is determined by measuring the rate of RBC sedimentation through a calibrated tube in a specified period of time, usually 1 hour (Table 28-11). The presence of certain acute-phase reactants, such as fibrinogen and haptoglobin, slows the sedimentation of the RBCs. Acute and chronic infections, malignancy, infarction, rheumatoid and collagen diseases, and physiologic stress cause increases in ESR and CRP. Although these tests are nonspecific, they are useful in the detection and/or monitoring of inflammatory conditions or to confirm the presence of organic disease.

Platelets

Platelets assist in hemostasis through the release of serotonin and other vasoconstrictors and through the formation of a thrombus or temporary platelet plug. Abnormal number of platelets in circulation may result from chiefly productive or destructive forces.

Platelet counts are determined from whole blood (Table 28-12).

Thrombocytosis refers to a state of abnormally increased levels of platelets in circulation, usually above 400 $\times 10^3/\mu L$. Causes of thrombocytosis can be primary, reactive, or transitory. In primary thrombocytosis, platelet production may be increased up to 15 times normal and is due to the increased size and mass of megakaryocytes. Other cell lines may be involved and, when this occurs, the disease is characterized by clinical characteristics and the predominant cell line involved. An increase in predominantly megakaryocytes leads to essential thrombocythemia, with an increase in platelets but normal RBCs and normal to slightly increased WBCs.

Reactive thrombocytosis may involve increases in platelet production and release, and may be chronic or acute in nature. Acute reactive thrombocytosis may occur as a result of surgery, acute inflammation, or acute hemorrhage.

Transitory thrombocytosis occurs as a result of movement of platelets from the extravascular platelet pool. These

Table 28-12 Reference values for platelet count.

Traditional Reference Interval	SI Reference Interval
150–450 $\times 10^3/\mu L$	150–450 $\times 10^9/L$

extravascular pools include platelets from the spleen and lung.

The clinical findings in thrombocytosis are related to the underlying disorder and therefore patients are not predisposed to hemorrhage or thrombotic complications.

In patients with an acute recent reason for thrombocytosis, no treatment is generally necessary other than follow-up and observation. In patients with documented thrombocytosis of longer standing, an underlying disorder should be ruled out and the patient should be referred for an appropriate workup.

Thrombocytopenia is characterized by a decrease in the number of circulating platelets, usually below 100 $\times 10^3/\mu L$. Bleeding is the principal characteristic of this state, with patients having minimal symptoms with platelet counts of 50 $\times 10^3/\mu L$. Spontaneous bleeding can be observed in individuals with platelets at or below 20 $\times 10^3/\mu L$.

Thrombocytopenia may be caused by a decreased production of platelets, increased destruction, abnormal distribution, or through massive dilution.

Decreased production may be secondary to decreased megakaryocytes or ineffective erythropoiesis. Drugs, such as chemotherapeutic drugs, may also cause a decrease in platelet production. Diseases affecting bone marrow may also cause a decreased production of platelets. These diseases include leukemia and other malignancies, myelofibrosis, and viruses. Ineffective erythropoiesis may occur from suboptimal nutritional states, especially deficiencies of vitamins B_{12} and folate. Changes in other blood cell lines can also be seen when nutritional deficiencies are severe.

Increased destruction of platelets may occur from immune-related mechanisms. Typically, increased levels of immunoglobulin or complement can be found on these platelet membranes. These platelets are then removed by the reticuloendothelial system, largely the spleen. In certain cases, splenectomy is the treatment for immune-related destruction of platelets.

Abnormal distribution of platelets can occur when a significant portion of the circulating platelets are sequestered to the spleen. An enlarged spleen (hypersplenism) can be noted clinically. Lastly, thrombocytopenia may occur as a result of infusion of large quantities of whole blood in trauma or surgery patients. Additional platelet infusions are the treatment of choice in transfusion-related thrombocytopenia.

Analysis of White Blood Cells

WBCs defend the body against bacterial, viral, protozoal, and fungal invasion. WBCs are less numerous in blood and require less dilution to count after the predominant RBCs are lysed from the sample obtained. WBC counts may be falsely elevated in the presence of cryoglobins, aggregated platelets, and nucleated blood cells, or when there is incomplete lysis of RBCs. According to physiologic function, WBCs can be divided into granulocytic, monocytic, and lymphocytic categories. After WBCs have been counted, they are routinely analyzed to determine the percentages of individual cell categories (Table 28-13).

Granulocytes

Granulocyte production is influenced by a variety of factors, including interleukins, colony-stimulating factors, and growth factors. They arise from a progenitor cell line colony-forming units granulocyte/macrophage (CFU-GM), which differentiates into granulocyte (CFU-G) or monocyte (CFU-M) lines. Granulocytes are commonly differentiated according to staining techniques into three categories: neutrophils, eosinophils, and basophils.

Granulocytes undergo various stages of development within the bone marrow until they reach the metamyelocyte stage. In neutrophil maturation, the metamyelocyte nucleus forms a curved rod and this stage is called a "band" or "stab" neutrophil. Band neutrophils mature into segmented neutrophils, with a 4–8-day supply of segmented neutrophils called the marrow reserve. Metamyelocytes comprise approximately 45% of the maturation storage compartment of the bone marrow, while band neutrophils comprise 35% and segmented neutrophils comprise 20%. Eosinophils comprise 0%–5% and basophils comprise 0%–1%.

Table 28-13 Reference values for differential white blood cell count.

Traditional Reference Interval		SI Reference Interval
Differential count (absolute)		
Neutrophils	1800–7800/μL	1.8–7.8 $\times 10^9$/L
Bands	0–700/μL	0.00–0.70 $\times 10^9$/L
Lymphocytes	1000–4800/μL	1.0–4.8 $\times 10^9$/L
Monocytes	0–800/μL	0.00–0.80 $\times 10^9$/L
Eosinophils	0–450/μL	0.00–0.45 $\times 10^9$/L
Basophils	0–200/μL	0.00–0.20 $\times 10^9$/L
Differential count (number fraction)		
Neutrophils	56%	0.56
Bands	3%	0.03
Lymphocytes	34%	0.34
Monocytes	4%	0.04
Eosinophils	2.7%	0.027
Basophils	0.3%	0.003

Mature cells are released from the bone marrow sinusoids into the peripheral blood system. The blood system consists of equally large circulating and marginating pools. The marginating granulocytes adhere to the endothelial-lined walls of the blood vessels. Granulocyte reserves are also found in the spleen. Circulating granulocytes are in transit to a potential site of action within the tissues and travel from the circulatory system to the tissues through the process known as diapedesis. Both band and segmented (segs) neutrophil forms are found circulating in blood. Bands usually comprise approximately 3%–5% of total WBC count and segs comprise approximately 50%–70% of the WBC count. Although the presence of bands has been taken to mean the presence of infection, increased number of these cells are found in a variety of pathologic conditions. Moreover, there are a large number of technical problems associated with a precise determination of a band count. For these reasons, among others, many clinical laboratories no longer report band counts.

Segmented neutrophils are chiefly responsible for fighting bacterial infection.

Additionally, an increase in the number of neutrophils may be found associated with inflammation, myeloproliferative disorders, neoplasms, or hemolysis. Certain medications can also affect the number of neutrophils found in circulation and these medications include corticosteroids and lithium.

A decrease in the normal number of neutrophils may be associated with diseases of the bone marrow such as aplasia or hypoplasia. Medications such as antineoplastic agents or radiation therapy can also cause a decrease in the normal number of neutrophils. Sequestration of neutrophils can be caused by hypersplenism, while destruction of neutrophils may be caused by antigen–antibody reactions, antibody-mediated destruction, certain medications, and viral and bacterial infections.

When a larger number of immature neutrophils is found in the circulating blood (greater than 20% of normal value) it is termed a “shift to the left.” Immature neutrophil release may be indicative of a bacterial infection, toxemia, or hemorrhage. When a large number of mature neutrophils are present in the circulating blood, it is known as a "shift to the right" and may be indicative of megaloblastic anemia, liver disease, or iron-deficiency anemia. Once granulocytes and especially neutrophils reach affected peripheral tissues, they can begin the process of phagocytosis and trigger the immune system reaction. Eosinophils are granule-containing cells. The granules are of two types: azurophilic granules, which are nonspecific and found in all granulocytes, and specific granules. The specific granules are characteristically bright red when stained with eosin dyes. These granules, which contain major basic protein, eosinophilic cationic protein, and eosinophil-derived neurotoxin, have been implicated in the tissue damage observed in asthma and other allergic conditions. Elevation in the number of eosinophils is seen with allergic reactions, infections with roundworms and other parasites, and certain chronic mucocutaneous diseases such as pemphigus.

Basophils are also granule-containing cells. Their equivalent in tissue is the mast cell. Basophil granules have a high proportion of histamine and heparin. Loss of these granules (degranulation) occurs during antigen–antibody-mediated reactions. As a result of degranulation there is increased vascular permeability, vasodilatation, and smooth muscle spasm. Anaphylaxis is a severe life-threatening reaction associated with massive basophil degranulation. Leukotrienes mediate this degranulation process.

Monocytes

Mononuclear phagocytic cells are composed of monocytes, macrophages, and their progenitor cells. These cells all arise from CFU-GM, and CFU-GM cells then develop into either CFU-G or CFU-M cells.

Monocytes typically have a large indented or oval nucleus that is centrally located within the cell. When visualized utilizing Wright’s stain and a microscope, a monocyte will contain a large area of light-blue–gray cytoplasm and many fine granules. These granules contain peroxidase. Monocytes are found in the bone marrow and the peripheral blood. Peripheral monocyte cells have a circulatory half-life of 8.5 hours. Monocytes in the blood and connective tissue are capable of differentiating into macrophages. These macrophages are normally nonmotile, but may become activated as a result of the inflammatory process. When this occurs, these motile macrophages are known as free macrophages and they move to the area of inflammation through a process of chemotaxis. These macrophages then phagocytize particulate matter. This ability to become mobile and phagocytize particulate matter makes macrophages an important part of the cellular defense mechanism. They differ from neutrophilic granulocytes, the first line of defense against infections, in that monocytes and macrophages are seen as a second line of defense.

Lymphocytes

In addition to the nonspecific activities of monocytes, macrophages, and granulocytes, lymphocytes also play a role in defending the body. The lymphocytic defense system differs, though, in that it is specific; that is, it is acquired and involves the formation of specific antibodies and lymphocytes, which in turn attack specific invaders. Active immunity occurs when an individual recovers from a natural infection and

Table 28-14 Reference values for immunoglobulin (Adult).

	Traditional Reference Interval	SI Reference Interval
Immunoglobulin A	50–350 mg/dL	0.5–3.5 g/L
Immunoglobulin D	0.5–3 mg/dL	5–30 mg/L
Immunoglobulin E	10–179 IU/mL	24–430 μg/L
Immunoglobulin G	600–1560 mg/dL	6.0–15.6 g/L
Immunoglobulin M	54–222 mg/dL	0.5–2.2 g/L

has a reduced susceptibility to acquiring the disease again. Active immunity can also occur through vaccination, in which the body's immune system is stimulated into producing protective antibodies against the specific disease targeted. Passive immunity occurs when sensitized cells called lymphocytes or antibodies to the specific target disease are injected into a host.

In understanding specific immunity, it is necessary to review the humoral and cell-mediated branches of specific immunity.

Humoral Branch

Humoral immunity involves the development of circulating antibodies to a specific corresponding antigen, which is a substance that is capable of invoking an immune response. These antibodies are known as immunoglobin and consist of five subtypes (Table 28-14). IgG is the most predominant in the serum and is able to cross the placenta. As such, it is important in conferring passive immunity from mother to child. IgE is important in allergic reactions. Other immunoglobins are IgM, IgA, and IgD.

Antibodies combine with a specific antigen causing a specific reaction to occur, such as cell lysis, agglutination of the invading cells, or triggering of complement formation. These antibodies may also activate anaphylaxis, causing mast cells and basophils to release their contents in an effort to immobilize the invading cells. Most antibodies are produced by the plasma cells. Plasma cells may reside in the lymph nodes or spleen or may be found in lymphoid tissue in the gut. Plasma cells originate from B lymphocytes. B lymphocytes arise from cells in the bone marrow and undergo maturation in an unknown location in mammals, possibly the bone marrow itself. The maturing B lymphocytes are known as B lymphoblasts, and these cells may develop into either plasma cells or memory B lymphocytes. The memory B lymphocytes are involved in a stronger secondary immune response, which occurs when the antigen interacts with the host at a later date.

Cell-Mediated Branch

T lymphocytes are responsible for the cell-mediated branch of the immune system. T lymphocytes arise from a stem cell in the bone marrow and migrate to the thymus, where they mature. During this maturation process, T lymphocytes develop surface receptors, which makes them capable of reacting to a specific antigen.

T lymphocytes constitute about 80% of the lymphocytes found in circulating blood and have a long survival. Generally, these lymphocytes are found in the lymph nodes and spleen and recirculate between these areas and the blood. Approximately 5% of total lymphocyte mass can be found in circulating blood.

T lymphocytes are further classified into functional subgroups through the use of monoclonal antibodies against specific T lymphocyte–associated antigens. Two of the most commonly used markers for functional categorization are CD4 (cluster of differentiation) and CD8 markers.

CD4 cells have an inducer function and signal B lymphocytes to produce antibodies. CD4 cells also are the primary cells infected by the human immunodeficiency virus (HIV). During the course of HIV disease there is an absolute decrease and dysfunction in the number of CD4 lymphocytes. As such, CD4 cell count is widely used to assess disease management, prognosis, and staging of HIV. Certain opportunistic infections, including opportunistic infections of the oral cavity, are correlated with decreased CD4 cell counts.

CD8 lymphocytes have a cytotoxic function, which may suppress CD4 cells or may inhibit B-cell differentiation. Both these activities may inhibit antibody production.

A normal CD4:CD8 ratio is approximately 2:1 and may be reversed due to certain diseases.

The absolute lymphocyte value is the total number of lymphocytes over the total number of WBCs. The relative number of lymphocytes is determined from a blood smear and is reported as a percentage, with a normal range of 22%–40%.

Lymphocytopenia occurs when there is a decrease below the normal range in the number of lymphocytes. Typically, bacterial and viral diseases may cause lymphocytopenia.

Lymphocytosis occurs when the blood lymphocyte count increases above the normal reference range. This condition is also associated with viral, bacterial, and some parasitic infections. Additionally, it may occur as a result of drug reactions or tertiary or congenital syphilis. Malignant conditions such as lymphocytic leukemia, lymphoma, Waldenström's macroglobulinemia, and other neoplasms may also cause lymphocytosis.

DIAGNOSTIC ORAL PATHOLOGY

Lesion Description

When suspicious lesions are noted during a clinical examination and clinical diagnosis is not possible, diagnostic pathology is the gold standard for diagnosis. For soft tissue lesions, the specific location and distribution

(i.e., tongue—dorsal, lateral, ventral, gingiva, buccal mucosa, floor of mouth, keratinized vs. nonkeratinized mucosa), size and number of lesion(s) (greatest dimension of length, width, and surface elevation measured in centimeters), morphology (elevated, depressed, flat), color (red, white, pigmentation), texture (velvety, smooth), and consistency (soft, fluid-filled, firm) are documented. A clinical photo provided along with the description is beneficial for lesion documentation and also of use in evaluating lesion activity or the response to treatment. Each clinical photo is a snapshot in time and the lesion can change (regress, mature, elevate, or ulcerate). Photographs taken at recall or follow-up appointments afford the opportunity to monitor changes in the lesion or response to therapy. Soft tissue morphology, such as fluid-filled (vesicle, bulla, and pustule), elevated mass (papule, nodule, and tumor in order from small to large in size), and surface consistency (plaque, erosion, ulcer, and macule) should be included as lesion descriptors. Vesicles are small blebs or sacs with clear or amber-tinged fluid like serum. Bullae are larger, blister-like sacs that may contain fluid that is serosanguinous or tinged with blood.

Clinical Adjuncts to Diagnosis

To facilitate early diagnosis of malignant and potentially malignant oral mucosal lesions, a number of techniques and devices have become available. Exfoliative cytology, full-thickness (transepithelial) cytology, liquid cytology (taking advantage of the discohesive nature of epithelial malignancy and subsequent molecular diagnostics), lights of varied spectra (from blue to amber green to bright white) to assess either a better visualization, tissue reflectance, or light absorption, and autofluorescence techniques now exist.

Liquid-based cytology is a relatively new method of cytology. It has chiefly been used for the Papanicolaou (Pap) test, but is also used for detecting oral cancer. Typically, a collecting device or cytobrush is directed over suspicious oral mucosal sites. The collecting device is placed in a preservative and sent to the pathology laboratory. The benefits of using liquid-based cytology are that cellular debris such as mucous, blood, and other debris can be discarded more easily. Liquid-based techniques also reduce the proportion of unsatisfactory samples through carefully producing thin layers of the cell on the microscope slide. This reduces the number of false negative results.

Chemiluminescence is the emission of light of varying degrees of intensity and time from a chemical reaction. These properties of light are used to aid clinicians in detecting early asymptomatic precancerous and cancerous lesions in the oral cavity. ViziLite Plus with TBlue is a commercially available diagnostic tool that uses chemiluminescence to aid in detecting oral cancer. Patients rinse with an acetic acid solution before the clinician examines the mucosa for abnormalities using a special disposable mirror light device. MicroLux DL manufactures a similar system and also markets OraBlue Oral Lesion Marking System, a toluidine blue dye kit.

Autofluorescence occurs when certain biofluorophores found within tissue fluoresce upon exposure to a light source with a wavelength between 400 and 460 nm. Diseased tissue does not fluoresce and appears darker in color than nondiseased tissue. The VELscope Vx Enhanced Oral Assessment System is a commercially available device to visualize tissue autofluorescence in the oral cavity. OralID markets a similar light source device. OralID's fluorescence technology uses a blue light with a wavelength of 435–460 nm.

These adjunctive techniques, while designed primarily for early detection, have encouraged practitioners to look closely at suspicious lesions, and may convince the patient and often the clinician that a biopsy is appropriate or that the patient should be referred for biopsy. These techniques do not substitute for biopsy diagnosis. However, those adjuncts that employ molecular diagnostics are promising in assisting in early diagnosis. Loss of tissue autofluorescence in narrow-band imaging can indicate the full extent of a malignant mucosal lesion when planning the surgical biopsy.

In a report published in the *Journal of the American Dental Association*, an ADA expert panel suggests that adult patients with seemingly innocuous or nonsuspicious oral mucosal lesions of unknown diagnosis should be followed up on periodically to determine the need for further evaluation. Lesions that do not resolve should be biopsied or the patient should be referred to a specialist. Furthermore, the panel does not recommend cytologic adjuncts for seemingly innocuous or suspicious lesions. Clinicians may use adjunctive cytology for additional lesion assessment should a patient decline a biopsy, or they may refer to a specialist. The panel did not recommend autofluorescence, tissue reflectance, or vital staining adjuncts for the evaluation of potentially malignant disorders among adult patients with clinically evident, seemingly innocuous, or suspicious lesions.[19]

Patton and coworkers performed a systemic review of adjunctive techniques for oral cancer examination and lesion diagnosis. They concluded that, due the lack of data on the effectiveness of adjunctive cancer-detection techniques in general dental practice settings, clinicians must rely on a thorough oral mucosal examination, supported by specialty referral and/or tissue biopsy for oral premalignant and malignant lesion diagnosis.[20]

Clinical Assessment

Tissue biopsy is recommended when there is a concern for malignancy. It is also recommended when pigmented lesions are noted or these pigmented lesions have irregular borders. In some cases, the lesional characteristics of appearance, anatomic location, duration, and distribution, when coupled

with patient history, may be sufficient for clinical diagnosis. Examples of lesions that can be diagnosed and treated without a biopsy include pericoronitis, gingivitis, or periodontal abscesses. The response to therapy (or lack of response) is also informative as a lesional feature. There is the risk of modifying key diagnostic clues when therapy is rendered without a biopsy. If the lesion does not heal, and a subsequent biopsy is performed, histologic diagnosis can be more challenging due to the change in diagnostic features caused by the treatment. For example, a lesion that has inflammation as a critical diagnostic feature will be modified by a corticosteroid, but not necessarily adequately treated. There is value to the adage that you should be certain of what you are treating. However, benign-appearing lesions can share the clinical characteristics of other, more ominous entities. The persistence and change in size, color, or texture of a clinical abnormality warrant close follow-up and biopsy.

Ulceration (tissue loss that extends into the lamina propria of mucosa or dermis of the skin) and erosion (a superficial loss of epithelium) are quite common findings in the oral mucosa. Assessment of duration and distribution (keratinized attached mucosa versus nonkeratinized loose mucosa) of the ulcer has diagnostic implications. Clinical provocation that elicits a positive Nikolsky sign (the tissue slides laterally with sheer pressure applied to normal-looking mucosa adjacent to an erosion) characteristic of vesiculobullous disease requires a special biopsy technique. The biopsied tissue should be submitted in appropriate tissue fixative that preserves antigenicity (phosphate-buffered saline—Michel's/Zeus fixative) in addition to sampled tissue submission in 10% neutral buffered formalin. If tissue slippage/blade drag is noted during scalpel biopsy, use of a traction/stabilizing suture can assist in keeping tissue intact.

Areas of atrophic red mucosa and a white pseudomembranous covering on mucosa often represent variants of oral candidiasis, a diagnosis that should be considered in immunocompromise, diabetes mellitus, history of corticosteroid and other immunosuppressant use, broad-spectrum antibiotic use, xerostomia, and poor nutrition.

By informing/alerting the pathologist to the medical condition of the patient, fungal stains can be ordered at the same time as the standard hematoxylin and eosin (H&E).

Mucosal ulcers with rolled or umbilicated margins may represent entities as varied as squamous cell carcinoma, deep fungal infection (histoplasmosis, mucor/phycomycosis), syphilis, tuberculosis, or traumatic ulcerative granulomas. Any supporting history aids the pathologist in the selection of histochemical stains to highlight organisms when granulomatous inflammation is observed. Various polishing agents utilized in dentistry can be embedded in gingival tissue and the resulting granulomas will reveal polarizable material under polarized microscopy.

Anatomic Pathology Laboratory

The anatomic pathology laboratory provides consultative assistance when oral cytology and biopsy are required for diagnosis. The biopsy requisition form is the formal consult for a pathologic diagnosis. As such, as much supporting patient information (habits, medication/nutraceutical, family and medical history, imaging, and blood laboratory analyses when appropriate) should be included or accompany the requisition. Good-quality clinical photos are a plus when showing the anatomic location and lesion characteristics.

Oral cytology is commonly used to identify suspected fungal infections and herpetic infections. For exfoliative cytology, a moistened tongue blade, cytobrush, or moistened cotton-tipped applicator are scraped or rubbed over a leukoplakic, erythroblastic, or normal-appearing tissue (if burning mouth is evident). The collected material is placed on a microscopic slide and fixed with cytospray (or simply hairspray as an inexpensive alternative) and forwarded to the laboratory with a request for periodic acid–Schiff (PAS) staining for suspected fungal infection. Mark or label the surface where the specimen is placed with the frosted side up when placing the patient's name and oral site. Pencil marks are preferred for labeling, as they will not be dissolved (like ink) by lab preparation. PAS will stain viable organisms and Grocott–Gomori's methenamine silver (GMS) will stain nonviable organisms. The lab will report cell presence and fungal yeast and hyphal form presence if noted on microscopic examination.

A Tzanck prep or smear is used for suspected herpetic lesions when vesicles are noted clinically. For the smear, the vesicle is burst with a sterile anesthetic needle and the vesicle fluid and constituent cells are dispersed in the middle of an oriented microscopic slide. Cytospray is used to fix the fluid and cellular content. The slide is sent to the lab in a sleeve or carrier designed for slide transport to prevent breakage. A request for a Pap or Diff-Quik stain for a suspected viral lesion should accompany the slide on the requisition form. These stains will highlight ballooning degeneration and molded nuclei characteristic of herpetic viral infection. Tzanck smears will not distinguish between infections due to *Herpes simplex* and those due to *Varicella zoster*.

Biopsy

A biopsy is a surgical procedure undertaken to definitively diagnose abnormality or disease within a tissue. Biopsy is required when the clinical appearance and patient history are insufficient for clinical diagnosis. Biopsy involves sampling live tissue by scalpel, punch, or fine needle aspiration in an area of perceived deviation from normal. Accurate

diagnosis is dependent upon being able to discern a site that is outside of that considered normal, rather than random sampling of apparently normal-looking tissue. Normal-appearing oral mucosa is sometimes biopsied to diagnose minor salivary gland inflammation in Sjögren's disease and amyloid deposition around blood vessels in suspected amyloidosis. The surgical procedure involves prudent choice of anesthetic placement and careful manipulation of the sampled tissue to minimize introduction of anesthetic or surgical artifact (such as edema, crush, or clamp artifact by tissue forceps, or tissue cautery by electrosurgical and laser units). Traction or stabilization sutures minimize clamp and crush artifact. A suture is placed in the lesional tissue and tugged to facilitate the scalpel or sharp scissor biopsy. Stabilization sutures assist in keeping epithelium and connective tissue adherent in vesiculo- or immunobullous disease when the tissue slides (positive Nikolsky sign) during the scalpel biopsy (blade drag).

Tissue fixation is a means of preservation of the constituent cells in a "life-like" state for subsequent embedding and thin sectioning. Fixation limits autolytic processes and tissue necrosis that would alter the normal morphologic architecture of the cells. Fixation stabilizes the tissue for transport or storage. Many fixatives are available, but for routine H&E stained slides, 10% neutral buffered formalin is most commonly used. When antigen preservation is necessary in presumed immuno-bullous diseases (pemphigus, pemphigoid, erosive lichen planus), then phosphate-buffered saline fixatives such as Michel's or Zeus solutions are used to avoid antigen degradation by formalin. Optimal cutting temperature (OCT) fixative is utilized in frozen section preparation, as it limits freeze artifact that would be created by snap-freezing tissue. Frozen section is used in hospital settings and dermatology labs when a rapid diagnosis and margin adequacy are required in cases of suspected malignancy. The volume of the chosen fixative and specimen thickness are critical considerations in insuring adequate fixation pressure for appropriate tissue penetration. The volume of fixative should be at least 10 times that of the tissue specimen and the specimen thickness the size of a nickel coin (~2.0 mm).

Decalcification of hard tissue specimens (bone, teeth) is accomplished in the lab receiving the tissue. Hard tissue specimens require additional processing time because of the necessary decalcification. Oral and maxillofacial pathology laboratories and hospital laboratories have this capability.

Embedding in paraffin (hard wax) is done in the chosen lab. This will further preserve tissue and provide sufficient rigidity for ease of cutting thin tissue specimens on a microtome for subsequent staining and use of light microscopy.

H&E can be the singular stain or the initial scout stain. H&E will elucidate basophilic organelles (hematoxylin) and acidophilic (eosin) organelles within the cell. Abnormalities noted on H&E staining in collagen content, surface organisms, cytoplasmic content, and mucin production would necessitate additional special staining to highlight or decorate those abnormalities. The additional stains necessary for diagnosis take time and the diagnosis may be delayed a short while.

Biopsy Technique

A biopsy can be performed on soft tissue or hard tissue and is excisional or incisional, depending upon whether all or a portion of the lesion is removed. The biopsy technique will employ a scalpel, shave, punch, needle aspiration, or scissors when a pedunculated lesion is encountered.

The excisional biopsy is the technique for total removal of the lesion and is most often used when the lesion is less than 1.0 cm in size (see Figure 28-3A), while the incisional biopsy is a sampling of a portion of a lesion greater than 1.0 cm in size for diagnosis prior to more extensive surgery (see Figure 28-3B). These parameters are altered based on the skill of the clinician and the anatomic location of the lesion.

In the shave biopsy, a sharp instrument shaves the surface lesion. Shave biopsies are often performed on skin or mucosa as a "scout" procedure used to plan completion surgery.

The punch biopsy is akin to a "cookie cutter" technique done on broad, flat surfaces. The punch instrument was designed for small skin and mucosal biopsies, but is often used to uncover dental implant fixtures. The punch biopsy technique is effective for removal of small lesions for excisional biopsy. A core or needle biopsy can be used for tissue core cell collection (like a large-bore needle, or the biopsy gun used for breast and testicular lesions) and fine needle aspiration can be used for fluid content assessment and flow dynamics evaluation of vascular lesions. Fine needle biopsy is beneficial in diagnosing salivary gland and thyroid masses. The cells collected by the minimally invasive technique are assessed much like a cytologic smear. The fine needle insertion into the lesion can be guided by ultrasound or other imaging modalities.

Needle aspiration is required in radiolucent bone lesions in suspected vascular processes to assess whether the lesion is high flow or low flow, prior to attempting extractions or bone biopsy. Bone biopsies require surgical handpieces and burs, or Rongeur forceps and osteotomes for the removal of hard tissue.

The following description will focus on the soft tissue scalpel biopsy, as the principles are similar to many of the other sampling techniques.

After administration of anesthesia—block anesthesia is preferred—a gauze screen (like a hockey net at the back of the throat) is placed to prevent aspiration of the specimen. An elliptical incision is made with a #15 (small curved cutting

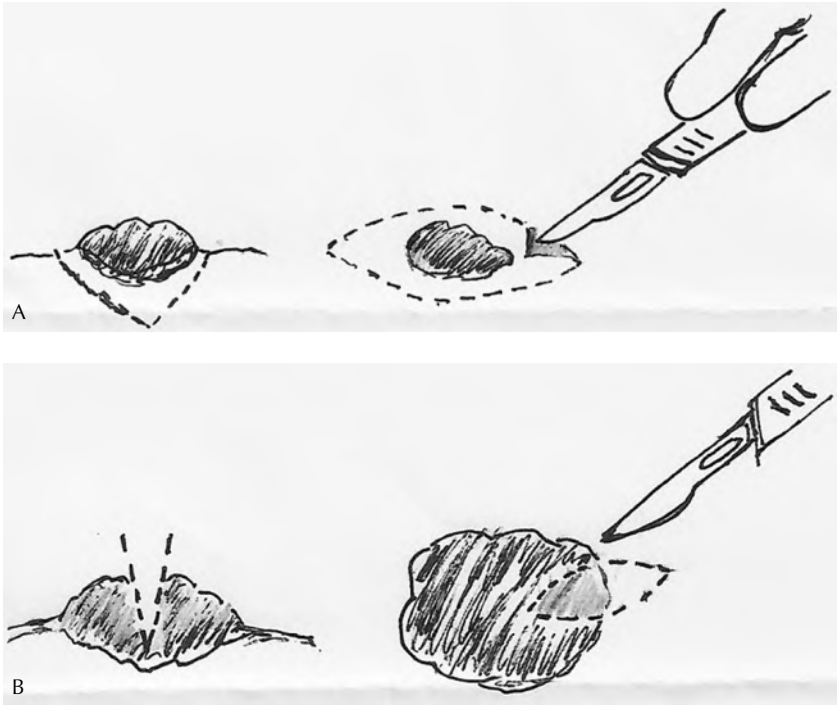

Figure 28-3 A. Excisional biopsy. B. Incisional biopsy.

edge) or #11 (elongated, triangular cutting edge) scalpel blade with tissue tension provided by tissue forceps, or to minimize crush artifact, a traction suture. The dimension of the incision is three times the length of the lesion and the same as the width of the lesion angled in toward the base like a "V." This helps facilitate wound closure. Curved Iris scissors can be used to free the tissue at the base. Hemorrhage control, wound cleansing, and suture closure completes the surgery. Silk suture is supple and less irritating than chromic gut, which is stiff and easily toyed with and often "untied" by tongue movement. Silk sutures do not resorb like chromic gut sutures and must be removed at a subsequent appointment.

The biopsy specimen can be placed on a surgical tray and anatomically oriented with a suture to the sterile card the suture was wrapped around, or it may be oriented with India ink. The specimen is placed in the formalin container, labeled with the patient name, biopsy location, and date taken. The container will have a volume of 10% neutral buffered formalin at least 10 times the volume of the biopsy specimen. This insures adequate fixation pressure. A thick specimen may require dimensional reduction, following appropriate orientation for the same fixation volume requirement. Sometimes several containers are necessary to avoid confusion about lesion location, especially when multiple sites are sampled.

A specimen that has characteristics of an immunobullous (vesiculobullous) disease should also have a portion of the fresh specimen placed in a container of phosphate-buffered saline (Michel's or Zeus solution) for antigen preservation, as the lab will need to do immunofluorescence testing. The special fixative permits the immunofluorescent stains to highlight or decorate where autoimmune attack has occurred in the tissue.

Thorough completion of the biopsy requisition form will eliminate delay of specimen processing by the referral lab.

Salivary Diagnostics

Once viewed solely as a quantitative and qualitative measure of salivary output from the exocrine tubuloalveolar intraoral minor glands and the paired extraoral major salivary glands, salivary diagnostics now encompasses a varied array of tests of infectious, autoimmune, hormonal, and malignant diseases.

For salivary output, tests would report whether salivary flow was stimulated or unstimulated and whole versus gland specific (typically parotid). Sialometry was the term for the assessment of this salivary output. In the normal state, rigorous chewing produced more saliva as necessary to improve oral mucosal lubrication and for food bolus formation. Enzymatic content of saliva began the digestive process and hormonal activity facilitated subsequent digestion activity in the gut.

In the interest of rapid, POC testing, the ease of collecting oral fluids has resulted in a myriad of noninvasive diagnostic

tests. Specific biomarkers have become available to examine the components of saliva in health and disease states.

The biocomponents of oral fluids (i.e., saliva, gingival crevicular fluid, mucosal transudates) include microbial agents (viruses, bacteria, fungi), hormones, antibodies, cytokines, proteins, growth factors, drugs, electrolytes, metabolites, and various tumor markers. Nucleic acid derivatives are present from human and microbial sources. The significance of the oral biomarker findings can only be determined when paired with other clinical and laboratory data.

CONCLUSION

Laboratory medicine will continue to play a major role in the fluid, ever-changing environment of medical diagnosis. Salivary, serologic, and tissue assessments biochemically, molecularly, and microscopically provide insight into overall patient health. As genetic research-driven technology advances, and new, efficient, and cost-effective diagnostic methods continue to evolve, the complex healthcare environment demands up-to-date methods in high-quality patient management. Complete patient information linked with laboratory testing in a timely and economically feasible fashion will facilitate that management. Informed and appropriately requested diagnostic tests from complete and specialized diagnostic laboratories will serve the provision of healthcare delivery by enhanced capability in diagnosing, treating, and preventing disease. Dental healthcare workers can achieve the recommendations of the 2015 Institute of Medicine on improving diagnosis in healthcare through effective teamwork in the diagnostic process, and through enhancement of healthcare professional education and training in diagnosis.

More than ever, we are inundated with biomedical and other scientific information from varied and sundry sources. Such material is readily available and can today be retrieved by anyone with access to the internet. However, this type of access comes with a certain responsibility. The traditional publishing landscape is rapidly changing, with an increasing number of journals and websites purportedly providing trustworthy and reliable information.

There has been a rapid rise in the number of predatory journals—journals that will publish any article for a fee without proper peer review, claim to be indexed on different publishing databases, and assert that they have a system of measurement that implies scientific rigor, for example high impact factors, which turn out to be of their own creation or from dubious sources—and books that offer miracle cures and recommend strange and often dangerous medical practices and interventions. Many individuals get much of their medical information from health apps and social media postings, where pseudoscientific beliefs can gain a large following and be reinforced, which generates a culture of suspicion and distrust of recognized medical norms and healthcare professionals.

In order to provide faster exchange of research ideas and research findings, several websites have emerged where articles can be posted prior to being accepted or even prior to being peer reviewed (medRχiv: www.medrxiv.org; bioRχiv:

Burket's Oral Medicine, Thirteenth Edition. Edited by Michael Glick, Martin S. Greenberg, Peter B. Lockhart, and Stephen J. Challacombe.

www.biorxiv.org; Preprints: www.preprints.org). Information found on these websites must be evaluated, like all non-peer-reviewed materials. There obviously also exists access to trustworthy and reliable biomedical information, much of which can be retrieved for free (see below).

This changing publishing landscape puts the onus on the users of biomedical information, including oral healthcare professionals, to be able to formulate focused and precise clinical queries, utilize good and efficient search strategies to find pertinent information, and, last, be able to assess and synthesize the retrieved information in order to acquaint themselves with the best available evidence and put it into practice.

DEFINING AND ASKING THE RIGHT QUESTION

There are two facets to addressing the "right question": one when articulating a research question in order to identify an existing knowledge gap and generate research that can bridge this gap; and the other when searching for an answer to a clinical query in order to inform practice. This chapter will address the second aspect: how to formulate a clinical query to perform a thorough literature search and assess the trustworthiness and reliability of the available evidence to enhance patient care.

PICO Questions

A focused question should be relevant to a particular clinical scenario and articulated in a manner that can inform an appropriate search strategy. One approach, often utilized when performing a systematic review, is to parse a question into four different parts:

- The **p**atient, population, or health problem being addressed.
- The **i**ntervention or exposure being considered.
- The **c**omparison intervention or exposure.
- The clinical **o**utcome(s) of interest.

Framing a question in this manner is often abbreviated as a "PICO" question, where the "P" represents a patient, a population, or a health condition; "I" represents an intervention or an indicator; "C" represents a comparison or control; and "O" represents an outcome. Sometimes a "T" is added—PICO(T)—representing a **t**ime element or even a **t**ype of study.

A simple example that illustrates a PICO(T) question is assessing the outcome of treating patients with aphthous ulcers with systemic glucocorticosteroids (GCS). Patients with major aphthous ulcers (Patient) that are treated with systemic GCS (Intervention) are compared to patients not receiving systemic GCS (Comparison) to assess the healing of the aphthous ulcers (Outcome) during a time period ranging from 10 to 14 days (Time). This question can be made even more granular by, for example, including only male patients, who receive only a specific dose of systemic GCS, and comparing these patients with patients who receive oral mouth rinses containing GCS (Table 29-1).

PICO and similar frameworks need to be tweaked according to the type of question being asked. For example, clinical questions concerning therapy, prevention, diagnosis, prognosis, or etiology may have to be framed differently (Table 29-2). Utilizing a PICO(T) framework is also helpful when treating patients in order to formulate differential diagnoses.

Table 29-1 Example of PICO(T) questions and framework.

PICO(T) Item	Specifics	Example
P— patient, population, or problem being addressed	Patients' demographics, such as age, gender, and ethnicity, and overall health status Possible subcategory of the problem	Presence of major aphthous ulcers
I—intervention or exposure	What type of intervention is being considered? In case of medication, what is the dosage? How is the medication being dispensed and used (systemically or a mouth rinse)?	Treatment of major aphthous ulcers with systemic glucocorticosteroids
C— comparison intervention or control	The comparison may be no intervention, or an intervention with the same medication but with a different dosage	No medication
O— clinical outcome(s) of interest	What is the desired outcome? Are there undesired outcomes? Who will assess the outcome (the patient or the clinician)?	Healing of the major aphthous ulcer
T—time frame	Time from dispensing the medication to clinical examination	Patient is being examined by a calibrated examiner every 3 days

Table 29-2 Changes in the PICO framework depending on the type of query.

Question Type	P patient, population, or problem	I intervention or exposure	C comparison intervention or control	O clinical outcome(s) of interest
Diagnosis— discriminate patients with a disease or conditions from those without the disorder	Specific disease or condition	Diagnostic test or procedure, diagnosis by exclusion	Accepted reference standard for that disease or condition	Sensitivity, specificity, predictive values, accuracy, odds ratio, proportion of true positives, true negatives, false positives, and false negatives, likelihood ratio
Therapy—determining the effects (desirable and undesirable effects) of an intervention on relevant outcomes	Patient's disease or condition	Therapeutic intervention	Active intervention, standard of care, no intervention, or placebo	Resolution of the disease or condition, impact on quality of life, disease frequency and incidence rate
Harm and prevention— determining the effects of an intervention or exposure considered potentially harmful on outcomes relevant to patients (e.g., downsides or adverse effects)	Patient's general health condition and risk factors	Preventive measure, e.g., minimize drinking sugar-sweetened beverages	Another preventive measure, no intervention	Disease frequency and incidence rate, harmful effects
Prognosis— predicting the future course of a patient's recovery or aggravation from a disease	Patients with a disease or health condition	Presence of one or multiple prognostic factors	Absence of one or multiple prognostic factors	Survival rates, mortality rates, rates of disease progression
Etiology or causation— determining the origin of a disease or condition	Patients at risk of a disease or condition, or comorbidities	Presence of risk factors and the duration of exposure	Absence of risk factors or shorter duration of exposure	Disease frequency and incidence rate, rates of disease progression

PICO questions are often referred to as foreground questions, as these are more specific than background questions that address more general knowledge. Differentiating between foreground and background questions facilitates formulating a search strategy.

SEARCHING THE LITERATURE

When answering clinical inquiries, it is necessary to conduct an evidence-based literature search. Below is an outline of search strategies that will help the oral medicine practitioner retrieve the most useful information, as well as descriptions of the commonly used evidence-based resources.

The practice of evidence-based oral medicine begins with articulating a clinical question (see above), and then moves to conducting a literature search for relevant information, evaluating the evidence, and using that evidence to answer the clinical question in order to make a decision in a clinical setting.

The exponential growth of complex health information is why it is essential not only to learn how to search for the best evidence-based literature in effective and efficient ways, but to be able to evaluate that literature as well. In order to conduct complex literature searches (such as the literature searches required to conduct systematic reviews), it can help to work with a librarian or other information professional.

Search Strategies

Begin with a broad search, using only a few terms, and do not apply any search filters. There are several databases and resources available that are populated with clinical practice guidelines, synopses, systematic reviews, primary studies, and other information (Table 29-3). (Tip: Use nouns as search terms rather than adjectives to retrieve literature that contains quantifiable results.) If researching a clinical question, the PICO framework (see above) components of population and intervention are useful in determining initial search terms. To narrow results, add additional terms using Boolean logic (Figure 29-1). Next, employ search filters to limit results to relevant material—useful search filters include limits such as language, publication date, and study design type. If the search is retrieving too many results or too many irrelevant results, narrow the search by searching a specific field (e.g., title or abstract). Finally, if the results of the initial search are not relevant, try using Boolean logic to include synonyms (e.g., "pregnancy" for "pregnant women")

Table 29-3 Databases and other resources for searching the literature.

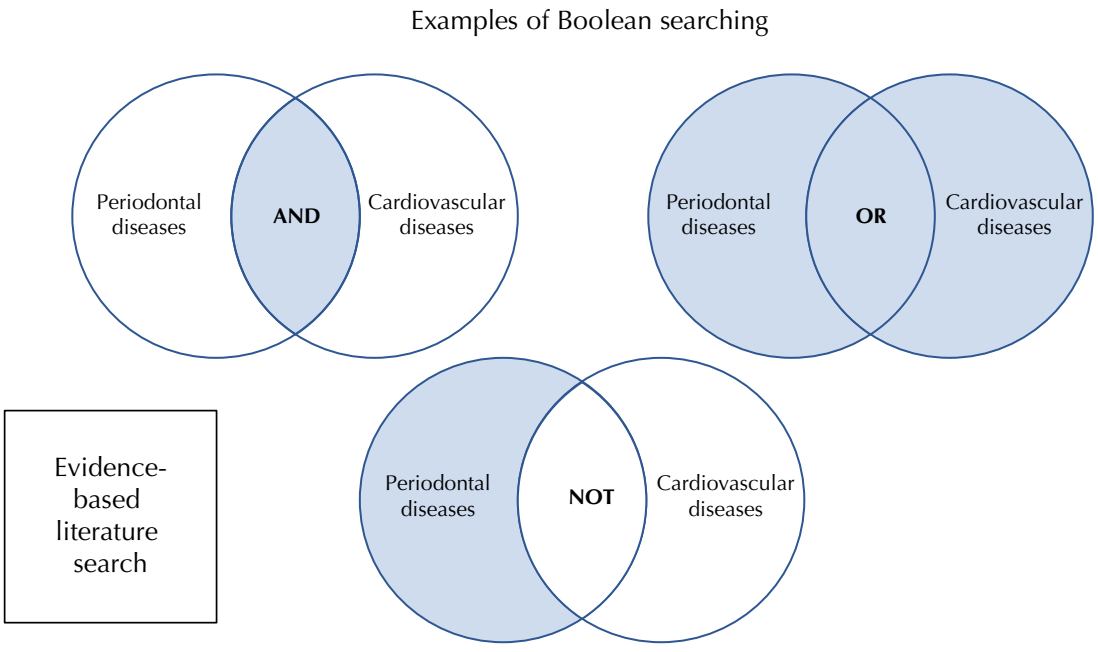

Figure 29-1 Boolean search.

and alternative spellings (e.g., UK and US spellings) for search terms.

Many medical databases use controlled vocabulary—the preferred terminology used within a particular database to describe and index materials. When conducting extensive searching, examine the databases' thesauri to identify synonyms for search terms. (Note: most medical databases will correct common misspellings, recognize abbreviations, and automatically search plurals.)

Databases and Other Resources

In order to conduct a thorough search for relevant information, search a combination of databases. Although the determination of which databases to search depends on the topic/question at hand, at a minimum search Cochrane (the gold standard for evidence-based information), Trip (the best "preappraised" resource), and PubMed (the most comprehensive medical literature search engine; see below for database descriptions and individual search tips). Search all three of these major databases in order to avoid missing relevant material; there is less overlap among these resources than one would assume, because they cover different types of materials and the material in each is updated on different cycles. Each of these databases has a unique underlying architecture, vocabulary, and results algorithm, and therefore will return different results.

A search strategy for evidence in order to decide a course of action within a clinical setting or answer a clinical question will differ from a search strategy for conducting a literature review or a systematic review. The latter are comprehensive, the former is not. If a search is being conducted to answer a clinical question, include high levels of evidence (e.g., guidelines or systematic reviews).

If an initial search results in too many irrelevant items, the following strategies may be useful:

- Limit the search to the title and abstract.
- Limit the results to secondary, preappraised literature such as clinical practice guidelines, summaries, critical summaries, and systematic reviews.
- If the search does not result in secondary literature, one strategy to narrow down the result of primary studies is to limit the search to randomized controlled trials (RCTs).
- If a search retrieves too many irrelevant results, searching using subject headings (rather than keywords) might prove to be a more efficient search strategy. Searching by subject headings will narrow the result of the search to only those items for which the subject heading in question has been considered (indexed) as the main topic of the item. Most of the databases listed here include specialized thesauri that list the subject headings used to index articles contained in the databases.
- At least preliminarily, set aside results published a decade or more ago.
- Add additional PICO components to your search terms, beginning with the outcome category.

Table 29-4 contains a list of databases that contain oral medicine–related information. An effective search strategy would begin with a search in Cochrane, followed by a search of Trip (particularly if Cochrane does not return relevant results), and then a search of PubMed to cover any potential gaps in results. Cochrane contains materials with high levels of evidence, such as systematic reviews, and is therefore an effective starting place. Because Cochrane only includes secondary materials, however, it is a smaller database than many of the others listed, and therefore may not contain all the information relevant to the topic being searched (including the most recent information). PubMed, by contrast, is the largest database listed, and will always retrieve the most results.

Begin with a search using a combination of keywords and subject headings in order to gather a sense of the results and to capture results that might be so new that they have not been assigned subject headings at the time of the search. Cochrane and PubMed share a thesauri of index terms—both databases use MeSH (Medical Subject Headings) for subject headings (see below for a detailed explanation of MeSH). Trip does not use a specialized thesaurus. After conducting the initial search, note any useful related terms and synonyms, and revise the search using all relevant search terms.

SELECTING THE RIGHT ARTICLE

Type of Clinical Information

Clinicians informing their practice using scientific literature are interested in answering questions directly related to their day-to-day activities. As mentioned before, such questions are classified according to their nature in four clinical areas:[1,2]

- *Diagnosis*: establishing the ability of a test to discriminate patients with a disease or conditions from those without the disorder.
- *Therapy or prevention*: determining the effect (desirable and undesirable) of an intervention on relevant outcomes (e.g., patient-centered outcomes).
- *Harm/etiology*: determining the effects of an intervention or exposure considered potentially harmful on outcomes relevant to patients (e.g., downsides or adverse effects).
- *Prognosis*: predicting the future course of a patient's recovery or aggravation from a disease.

Table 29-4 Workflow for searching for evidence.

Type of Question/Situation	Resources to Consult	Level of Evidence Available
Consider first: Does a guideline for the question/situation exist?	1) Epistemonikos 2) Trip 3) ECRI Guidelines Trust 4) Point-of-care resources	Guidelines, guideline summaries
Therapy/prevention question (general)	1) Cochrane Database of Systematic Reviews 2) Trip 3) PubMed	Critical summaries, meta-analyses, systematic reviews, randomized controlled trials (RCTs)
Therapy/prevention question (drug therapy)	1) Cochrane 2) Trip 3) Embase 4) PubMed	Critical summaries, meta-analyses, systematic reviews, RCTs
Harm/etiology question	1) Cochrane 2) Trip 3) PubMed	Critical summaries, meta-analyses, systematic reviews, observational studies
Diagnosis question	1) Cochrane 2) Trip 3) PubMed	Critical summaries,* meta-analyses,* systematic reviews,* cross-sectional studies, case report/series
Prognosis question	1) Cochrane 2) Trip 3) PubMed	Critical summaries,* meta-analyses,* systematic reviews,* observational studies, case report/series

* Indicates that this type of evidence may not be available for this type of question.

Table 29-5 Type of clinical questions and preferable type of study design.

Type of Question	Example	When Feasible, Preferable Study Design	Preferable Source of Information for Clinicians
Harm or etiology	What is the association between receiving dental radiographs and the occurrence of any type of meningioma?	Cohort *or* case–control studies	Systematic review including the appropriate type of study design for a clinical question
Diagnostic	What is the diagnostic test accuracy of autofluorescence devices when triaging a seemingly innocuous oral mucosa lesion for biopsy?	Cross-sectional diagnostic test accuracy studies	*or*
Prognostic	What is the impact of different radiation dose exposures of the parotid and submandibular glands in salivary flow 3 months post radiation?	Cohort studies	Evidence-based clinical practice guideline informed by systematic reviews, including the appropriate type of study design
Therapy or prevention	What is the effect of using a hyperbaric chamber for preventing osteonecrosis of the jaw in a patient's head and neck cancer undergoing radiation therapy?	Randomized controlled trials	

It is recommended that users of the literature correctly determine the type of question to address, as achieving this step will allow the question to be linked to the most appropriate study design (Table 29-5). When addressing therapeutic questions, experimental designs using chance (analogous to tossing a coin) rather than convenience to allocate participants to a treatment of interest that is compared with another active intervention, placebo, or no treatment are preferable (RCTs). In the absence of such experimental types of study, clinicians can also use nonexperimental or observational types of design. In this type of study, not chance but clinicians, patients and their preferences, or simply the circumstances determine the allocation of participants to treatment arms or an exposure.

In theory, one can also answer harm questions using RCTs; however, when a potential hazard is apparent (e.g., a serious, initially unintended adverse event), the intentional assignment of participants to the potential harmful intervention is not ethical. In this case, observational studies (cohort and case–control studies) are helpful to learn about the eventual harmful effect of an exposure or intervention that has occurred or will occur, without the need for the investigator to assign participants to the study arms.

As no diagnostic test is perfect, clinicians who want to learn about the performance or accuracy of diagnostic strategies for replacing a preexisting test because it is cheaper or less invasive, for triaging subsequent test applications (e.g., a positive result warrants further investigation to confirm diagnosis, while a negative result rules out the disease), or for adding on a new test to a preexisting diagnostic workout will choose a particular type of study design. Diagnostic test accuracy studies recruit participants with a suspicion of having the condition of interest and undergo an index test or new test, while also receiving a reference test or gold standard. Then, investigators report how often the index test is in agreement and disagreement with the reference test.[3]

Questions of prognosis examine the presence of factors that can positively or negatively influence the future course of action of a disease or condition, with the purpose of increasing the chance of achieving better outcomes. These studies include patients with and without a particular feature or prognostic factor (e.g., age, comorbidity, educational status, etc.) and examine the extent to which this factor influences a particular outcome in the future.

It can be inferred from the variety of clinical questions and study design indications presented here that the idea of a single "evidence pyramid" placing RCTs at the top of the hierarchy as the most suitable study to inform all clinical decisions is an oversimplification, as such a depiction ignores the idea that study design on its own is not a fair indicator of trustworthiness.[4] The traditional evidence pyramid is more appropriate for being applied to questions about therapy. Thus, it is strongly recommended to abandon the use of this evidence pyramid and replace it with a broader perspective, in which not a single primary study but rather a body of evidence (i.e., the group of studies informing the effect of an intervention of exposure on a particular outcome) is considered for decision-making. The certainty that clinicians can place in this evidence then not only focuses on the risk of bias of the studies at hand, but also the consistency across their findings (i.e., studies showing similar results), the precision of their estimates (i.e., width of confidence intervals), the relevance or directness of the study to the question at hand (i.e., appropriate generalizability or applicability), and the possibility for publication bias (i.e., the extent to which all studies conducted are made available irrespective of their results).[1,5,6] (For more details on study design, see Chapter 1: Overview of Clinical Research).

It is not uncommon that a new and somewhat controversial primary study attracts clinicians' and patients' attention, including presentations of the findings in media channels. However, clinicians should favor systematic reviews and evidence-based clinical practice guidelines over a single study, as systematic reviews and evidence-based clinical practice guidelines provide the full picture of all available evidence regarding a clinical question, making them more informative for the busy practitioner. In the same way that "one swallow doesn't make a summer," a single study outcome must be put in the context of the totality of the evidence before it is decided that a change in practice is warranted.

Causation, Association, and Correlation

Causation is important for clinical practice. Any practitioner trying to determine what is the best therapeutic strategy to treat a condition or disease, or looking for risk factors and studying their influence in the occurrence of a future event, is framing a causal question. Despite seeming simple, causal inferences are complex. In a hypothetical world where anything is possible, an investigator interested in studying the effect of the human papilloma virus (HPV) vaccine on the incidence of oropharyngeal squamous cell carcinoma (OSCC) will administer the vaccine to a group of participants, preferably a few thousand of them, and then perform follow-up assessments to determine how many did and did not develop OSCC. In this hypothetical world, the investigators would now time-travel back to the time before the vaccine was initially administered and enroll the same people who, in the first scenario, were vaccinated against the HPV virus and this time not administer the vaccine. The investigators would again perform follow-up assessments and determine how many did and did not develop OSCC. Thus, in these hypothetical scenarios, the same people were both vaccinated and not vaccinated and were essentially acting as their own control group. However, in the real world where one only has access to one side of the story at a time and the alternative scenario is missing and unobserved, this is called the "counterfactual dilemma."[7]

Since time-traveling remains possible only in theory, researchers will try all sorts of methodologic strategies to access that inaccessible alternative scenario. One strategy is to have a control group that could stand in for the second (unobserved) scenario. As inferred from the time-traveling idea, it is necessary to have a second observation—a control group—that is as similar as possible to the group receiving the experimental intervention. Hence, any time that two groups under comparison differ, the trustworthiness of an

association or causality claim weakens. Additional information on causality and its frameworks can be found elsewhere.[8]

The terms "causation" and "association" are often used interchangeably, but while causation implies association, the opposite is not true. For example, people who consume four or more cups of coffee a day have a lower risk of presenting with actinic cheilitis (AC). This does not mean that consuming coffee provides a protective effect from suffering from AC; rather, an alternative explanation would be that those consuming a larger amount of coffee a day usually work in indoor environments, such as an office, which dramatically reduces their exposure to direct sunlight, a known risk for AC. In this scenario, sunlight exposure is a confounder—that is, an alternative explanation for both the exposure (sunlight) and the outcome (AC)—for the association between coffee consumption and AC. Thus, a causal connection cannot be claimed, and the hypothesized association is spurious.

Nor can the terms "association" and "correlation" be used interchangeably. An association refers to one variable or clinical feature providing information about another variable or clinical feature. A correlation refers to one variable or clinical feature increasing or decreasing a fixed amount for a unit of increase or decrease of the other variable or clinical feature (Figure 29.2). Thus, "correlation implies association, but not causation. Conversely, causation implies association, but not correlation."[9]

A question for this section remains: Why do causation-related issues matter at the moment of selecting an article? When answering a question of therapy, for example, clinicians would prefer RCTs over analytic observational studies (e.g., cohort and case–control designs), and those analytic designs over case series, case reports, and other forms of anecdotal information. Thus, the ranking offered above (i.e., the traditional evidence pyramid) relates to the strength of those types of study design to establish causality. Study design by itself, however, is not sufficient as an indicator of validity or trustworthiness. It is necessary to determine the extent to which the authors appropriately implemented the methodologic measures required to minimize the effect of bias and confounding, while obtaining results with sufficient precision to draw meaningful conclusions.

BIAS, CONFOUNDING, AND RANDOM ERROR

Science is used to understand the world around us and attempts to predict outcomes or consequences of people's actions. To achieve these goals, answers from the literature must reflect an underlying reality or truth: a truth that can never be completely known, but one that can be surmised and approximated by using estimates and inferences. There are two main issues that deviate estimates from clinical studies from the truth: (1) bias and confounding; and (2) random error.

Bias and Confounding

Both bias and confounding result from systematic errors. Bias is the term used to describe reasons for studies deviating from the underlying truth (i.e., misguided estimation of the true effect of an intervention or exposure in an outcome) due to limitations in their planning and design, participant recruitment, conduct, data gathering, and analysis. The ways in which suboptimal methods distort clinical study results are numerous.[10] For example, in 1979 Sackett described more than 35 types of bias that may affect RCTs and 56 potential biases affecting analytic observational study designs (e.g., cohort and case–control studies).[11]

The presence of bias in the different study designs cannot be disregarded. For example, in studies answering questions of therapeutic or preventive interventions, one may claim

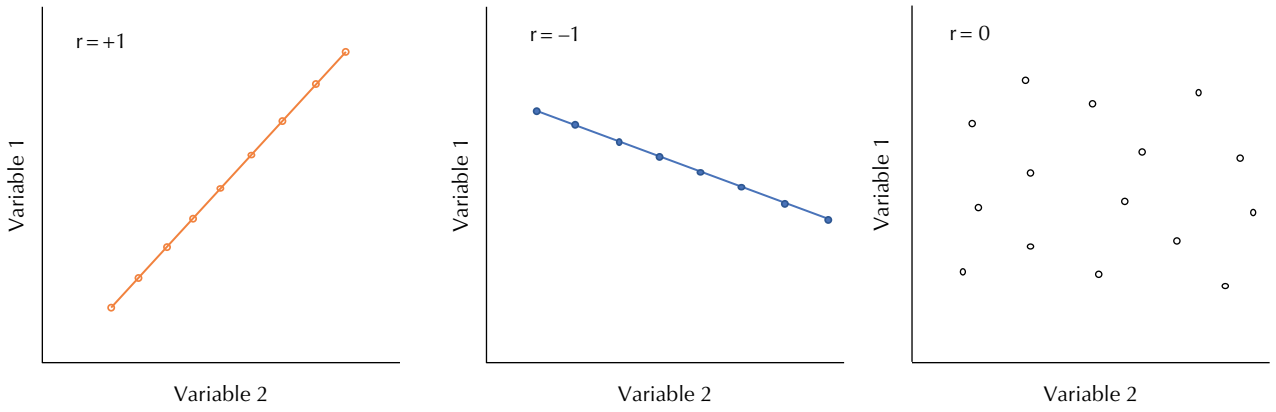

Figure 29-2 Illustration of correlations.

that a specific therapy is effective for managing or preventing a certain condition and implementing it. In reality, imbalances in prognostic factors at the moment of recruitment (e.g., the control group has more severe cases of the disease compared to the experimental intervention arm), while the study progresses (e.g., lack of blinding), or even at the end of the study (e.g., participants in the intervention arm lost to follow-up due to an adverse effect of the experimental intervention) can result in an overestimation of the treatment effect. In studies answering questions of prognosis, the presence of bias and confounding can lead to misguided predictions, which may induce either an overly optimistic or overly pessimistic assessment of a patient's fate. In the presence of a high risk of bias, studies answering questions of harm can conduce to an overestimation or, even more concerning, an underestimation of the adverse effects of an intervention or exposure causing deleterious consequences. Finally, studies implementing poor methodologic strategies and answering questions of diagnosis often report an overestimation of their accuracy.

These misleading estimates can cause two main problems in practice. The first problem is when test results define the patient as sick, while in reality they are not, exposing the patient to all the additional undesirable and unnecessary consequences associated with the cascade of clinical strategies resulting from establishing a definitive diagnosis and further treatment. The second problem is when the test results suggest that a patient does not have a disease, when in fact they do have it, delaying urgent treatment, allowing the disease to naturally progress, severely affecting prognosis, and in the case of an infectious disease resulting in not using strategies to mitigate contagion. (See Chapter 1: Overview of Clinical Research to learn more about the methodologic strategies implemented to reduce bias and confounding.)

Random Error

Even a study conducted with high methodologic rigor to minimize the influence of bias and confounding can still suffer from the play of chance, or random error. In previous sections of this chapter it has been mentioned that irrespective of how well-designed or powerful (i.e., large sample size and number of events, high signal-to-noise ratio) a study is, one will never be able to fully access the true effect of an intervention or exposure. This is the case because "chance is directionless, and it is equally likely, for instance, to overestimate or underestimate treatment effects."[2] In practical terms, this means that when two treatments or two exposure statuses are compared, any difference that the researchers find may simply be a reflection of the play of chance (e.g., by chance that day most patients recruited in the study were sicker than those recruited on other days, or they tended to report more adverse outcomes when asked about their health status). Investigators minimize the probability of being misled by random error by increasing the number of events and the sample size. Issues related to precision and random error will be covered in subsequent sections in this chapter.

INTERPRETING STUDY RESULTS

Outcome Measures in Clinical Research

According to Relevance

Patient-Important and Patient-Reported Outcome Measures

Conference speakers, investigators, and clinicians often refer to research findings as "clinically relevant" to distinguish them from "statistically significant" but "clinically irrelevant" results.[1] The term "clinically relevant," however, remains ambiguous. Does the use of the word "clinical" mean that such an outcome is important to the clinician or to the patient? The daily activities of a clinical practitioner can help us to better understand whose perspective may be of more value. Clinicians treat patients to achieve three broad goals: (1) increase longevity (at both person and tooth level); (2) decrease symptoms and the impact of a disease in people's life; and (3) to prevent future disease.[2] When evaluating whether clinicians have achieved these three goals, one may consider measuring outcomes that effectively reflect the degree of clinician success.[12]

Outcomes like mortality, survival, and the presence and absence of morbidities are of high relevance for both patients and clinicians, and likely as well as to society as a whole. These "patient-important outcomes" are often linked to diagnostic means and measures that make them fairly reliable, and also objective. This type of outcome is usually measured when defining success for goals 1 and 3 (i.e., increase longevity and prevent future morbidity). However, when trying to measure success for goal number 2 (i.e., decrease symptoms and impact of a disease), the patient perspective becomes particularly relevant.

One proposal to define such success is by using a type of "patient-important outcome" called a "patient-reported outcome measure" (PROM). PROMs are defined as "any report of the status of a patient's health condition that comes directly from the patient without interpretation of the patient's response by a clinician or anyone else."[13] In other words, PROMs are a specific type of outcome that attempts to reflect the patient experience, and the patients' perspective is a construct or attribute to which only they can have access, and therefore only they can report. The evidence suggests that PROMs exhibit poor correlations with biomarkers,

clinician-reported outcomes, physiologic parameters, and laboratory tests.[12] The relevance of PROMs becomes more apparent when studying the latest definition of oral health by the FDI World Dental Federation: "Oral health is multifaceted and includes the ability to speak, smile, smell, taste, touch, chew, swallow, and convey a range of emotions through facial expressions with confidence and without pain, discomfort, and disease of the craniofacial complex."[14] Many components in this definition reflect abilities and functions that can only be understood and measured by directly accessing the patient experience and the impact that oral health has in their daily life (e.g., ability to speak, smile, smell, taste, touch, chew, swallowing, experiencing pain and discomfort).

Circling back to the initial question in this section, outcomes that are important to inform practice should be patient important, and the expression "clinically relevant" should reflect outcomes that are relevant to patients.[15] Thus, note the importance of moving from the use of clinician-centered terminology in favor of a patient- or person-centered perspective.[16]

Surrogate Outcomes Surrogate outcomes are indirect measures observed sooner than the definitive or patient-important endpoint. Researchers often use surrogate measures to make extrapolations about the impact of an intervention or exposure on a clinically meaningful endpoint.[17] For example, a significant reduction in plaque among patients using oscillating powered compared to side-to-side powered toothbrushes could be used by researchers to conclude that oscillating brushes may be more effective in reducing a patient-important outcome, such as periodontal disease. Measuring surrogate endpoints can be advantageous for researchers as they are typically observed quicker and are easier to measure than the patient-important outcomes. Thus, researchers can conduct shorter, smaller, and less expensive studies.[17,18]

Although measuring surrogate endpoints can be advantageous from an investigator perspective, there are some drawbacks associated with using them in clinical research. Many statistical methods have been developed to help researchers make extrapolations from surrogate outcomes; however, the impact of these extrapolations is still unknown.[17,19] Surrogate outcomes are typically measured in Phase II or proof-of-concept clinical trials, in an attempt to assess whether an intervention is biologically active, making them useless for day-to-day clinical decision-making. By contrast, Phase III trials are designed to provide definitive assessments of the effectiveness of an intervention. If Phase III trialists want to use surrogate endpoints as a valid substitute for patient-important outcomes, there must be evidence that the effects of an intervention on the surrogate outcome can reliably predict clinically meaningful effects on the final patient-important endpoint.[20]

Composite Outcomes Composite outcomes are a single measure of effect that combines two or more outcomes. Investigators may find these measures useful to avoid making an arbitrary choice among several available primary outcomes.[21] Additionally, the use of composite outcomes allows for increasing statistical power and precision owing to more events (i.e., increasing the occurrences of the outcome) and increased trial efficiency (e.g., smaller sample size, fewer resources). Another application of composite endpoints is in the presence of competing risks.[22] Last, from a clinical point of view, composite outcomes may be easier for patients to understand when participating in shared decision-making, by considering many relevant outcomes at the same time.[22]

The use of composite outcomes also comes with limitations. This is verified when the result from the composite outcome (i.e., overall result across outcomes) tells a different story than its individual components (i.e., suboutcomes contributing to the composite result).[21] Imagine a trial assessing the effectiveness of a chemotherapeutic drug compared to placebo for managing oral cancer. The researchers report a significant decrease in the composite outcome of "death and tumor shrinkage" in those receiving the drug compared to the placebo group. However, when examining each individual component of this composite outcome, it is clear that there is a reduction in tumor shrinkage, but no impact on death. The presentation of the research findings in a composite manner could be misguided, as it would imply that the drug had a significant impact on both tumor shrinkage and death, when in fact it showed no impact on death at all. Thus, clinicians using composite outcomes to inform practice need to take into consideration not only the aggregated composite outcome, but also each component.[23]

According to Type of Data

The data collected and used for research purposes can come in many forms, with binary, ordinal, continuous, counts and rates, and time-to-event data being the most common types. The study design and research question(s) defined by the investigators will usually dictate the type of outcome data that they will collect (Table 29-6).

Measures of Association Measures of association or effect are calculated using the different types of data listed above. Their purpose is to provide a quantitative estimation of the effect or association between an intervention or exposure and an outcome. Measures of association are usually expressed in relative and absolute terms.

Table 29-6 Type of outcome data.

Type of Data	Definition	Example
Dichotomous	Dichotomous or binary data is a type of categorical (grouped) data in which responses can take on one of two possible states.	Mucositis: yes or no Xerostomia: yes or no
Ordinal	Ordinal data is a type of categorical (grouped) data in which the categories have an inherent order.	Cancer grade (grade 1, grade 2, grade 3, grade 4) Caries lesion status (sound, initial, moderate, advanced)
Continuous	Continuous data is a measurement of numeric quantity and can take on any value in a specified range. The number can take on any value and be reported with any number of decimal places.	Weight Age Blood pressure
Counts and rates	Counts are the collective number of times that an event or outcome occurs in a population. Rates are a way of relating these counts to the amount of time that the population was at risk for the event. A rate is calculated by dividing the count by the total amount of time the people at risk for an event contributed to the study.	In a study of a novel surgical technique for treating oral cancer, the count or number of hospitalizations post surgery in patients who underwent the novel surgery was 20. The patients in this group contributed a total of 430 years of follow-up to the study (i.e., person-years).The rate of post-surgery hospitalizations among these patients was 20/430 = .047 per person-year or 4.7 per 100 person-years.
Time-to-event (TTE)	Time-to-event data captures the time it takes for an outcome to occur in a population.For each patient in a study, the event-free time is recorded. If that person experiences the event, this time is also recorded.	Time to infection with human papillomavirus among patients who received the human papillomavirus vaccine Cancer-free survival among patients treated for oropharyngeal cancer

- *Relative effects* (e.g., Risk Ratio [RR], relative risk difference (i.e., relative risk reduction [RRR] or relative risk increase [RRI]), odds ratio, hazard ratio), or the proportional effect of an intervention compared to another intervention or exposure and the lack of it on a health outcome, tend to remain consistent across populations and outcomes (Table 29-7).[26] For example, a recent systematic review evaluated the effect of corticosteroids for treating patients with symptoms of oral lichen planus.[27] In relative terms, their findings suggest that using topical corticosteroids in an adhesive base compared to a placebo may increase the risk of resolving pain complaints by 91% (RR 1.91, 95% confidence interval [CI] 1.08–3.36). This can also be presented as a twofold increased chance to resolve pain complaints when corticosteroids are compared to placebo. Topical corticosteroids offer this benefit to any patient presenting with lichen planus irrespective of the country of origin or setting around the world. Does the same hold true, however, when applied to more versus less severe cases? This is when the concept of absolute measure of an effect becomes relevant.
- *Absolute effects*, in a way, help clinicians to better contextualize the relative treatment effect to their practice, which makes them more relevant and, at the same time, less universal and yet more context specific (Table 29-8). Following the previous example in patients with lichen planus, it is known that 306 out of 1000 (or 30.6% baseline risk for reporting spontaneous pain resolution) of patients not treated with corticosteroids will experience spontaneous pain resolution. When applying the relative effect (RR 1.91) to that 30.6% baseline risk, a new risk is obtained, reflecting the potential benefit of using corticosteroids (30.6% multiplied by 1.91= 58.4%). Thus, we know that 584 out of 1000 patients receiving corticosteroids will also experience pain resolution. In absolute terms, the intervention would allow 278 more patients out of 1000 to achieve pain resolution compared to placebo after 8–9 weeks follow-up.[27]

Using relative and absolute estimates allows patients and clinicians to better inform care-related decision by providing the magnitude of the potential benefits and harms. The extent to which the magnitude of desirable or undesirable effects means something to a patient, to a point where an intervention or test is considered worthwhile or useless, is a matter of interpretation of that magnitude in the face of patients' values and preferences. In the next section, some of the strategies proposed to assist in the interpretation of the significance of research findings are discussed.

Clinical versus Statistical Significance

In an initial hypothetical study, researchers attempted to determine the rate of potentially malignant disorders (PMDs) in the oral cavity in two communities: community A and community B. They obtained statistically significant

Table 29-7 Relative measures of association.

Measure	Definition	Dental Example
Relative risk or risk ratio (RR)	The relative risk or risk ratio provides participants with an exposure or receiving a therapy with a measure of risk for developing a preidentified outcome. It does this by quantifying the proportion of participants who develop the outcome in the intervention group over all at risk in this group in comparison to, or divided by, the proportion of participants who develop the outcome in the comparison group over all at risk in this group. Risk ratios are presented in clinical trials and cohort studies, where the intervention is exchanged for an exposure. Relative risks cannot be presented in case–control studies because, in addition to other factors, there are no participants that are truly at risk in case–control studies and therefore the formula's denominator cannot be built.	When using therapeutic application of aloe vera (28 out of 31 total patients improved) versus placebo (21 out of 24 total patients improved), the relative risk of patients with lichen planus experiencing clinical improvement is RR = 1.03. This means that patients with lichen planus receiving aloe vera have 1.03 times the risk of experiencing a clinical improvement compared to patients not receiving aloe vera. Alternatively, this can also be presented as a relative risk difference (RRD), in this case, a relative risk increase (RRI) in the chance of experiencing clinical improvement. This means that patients with lichen planus receiving aloe vera can experience a 3% increase in the risk of having a clinical improvement compared to the patients not receiving aloe vera as an intervention.[24]
Odds ratio (OR)	Odds ratios are presented in clinical trials and observational studies, including both cohort and case–control studies. In clinical trials and cohort studies, the odds ratio quantifies the proportion of participants with the odds of experiencing a preidentified outcome in an exposed or intervention group over the odds of the outcome in an unexposed or comparator group. In case–control studies, the odds ratio is a proportion of the odds of participants with the outcome having an exposure compared to or divided by the odds of participants with no outcome, the comparison group, having the exposure.	When using therapeutic application of aloe vera versus placebo, the odds of patients with lichen planus experiencing clinical improvement is OR = 1.33. This means that there is 1.33 increased odds of clinical improvement in lichen planus using aloe vera as compared to placebo.[24]
Preventive Fraction (PF)	The preventive fraction corresponds to the proportion of the disease or other undesirable outcome that would be prevented or avoided if an entire population receives an intervention or exposure of interest. The preventive fraction is obtained by subtracting the incidence (or event rate) of the disease or undesirable outcome of interest in the population (I_p) from the incidence (or event rate) if the entire population were exposed or received the intervention of interest (I_e). Then this difference is divided by the incidence (or event rate) of the disease or undesirable outcome of interest in the population (I_p). Thus, the preventive fraction is expressed as follows: (I_p-I_e/I_p).	In a study assessing the effect of topical aloe vera compared to placebo for resolving lichen planus lesions, PF = 3%. In other words, 3% of lichen planus lesions that would have remained unresolved were resolved by applying topical aloe vera instead of applying the placebo.[24]
Hazard Ratio (HR)	A hazard is the event rate at an instant in time. A hazard ratio quantifies the proportion, at any point in time during the follow-up period, of participants experiencing an event in the intervention group compared to those experiencing an event in the control group.	Patients receiving placebo experienced 74% 3-year oral cancer-free survival compared to patients receiving erlotinib, who experienced 70% 3-year oral cancer-free survival. This corresponds to HR = 1.27, meaning that patients in the placebo group are 27% more likely to experience oral cancer-free survival over 3 years when compared to patients in the erlotinib group.[25]

results showing that the PMD rate in community A is higher than in community B—50% of people in community A have PMDs, but in community B 48% of people have PMDs. Clinically, one could say that these are comparable rates, and a 2% difference may not lead to further inquiry. In a second hypothetical study, researchers found results that were not statistically significant, in which the data suggested that 75% of people in community A had PMDs, while only 25% of people in community B presented with PMDs. This difference should trigger additional questions, and possibly further studies to ascertain the reason for it. People in community B might be doing something that has improved the rate of PMDs, or maybe they are less exposed to a carcinogenic substance, or the lack of statistical significance is

Table 29-8 Absolute measures of association.

Measure	Definition	Example
Risk difference (RD) [absolute risk reduction (ARR) or absolute risk increase (ARI)]	Risk differences or [absolute risk reduction (ARR) or absolute risk increase (ARI)] are absolute measures, as compared to relative measures, which are proportions. They are calculated using the absolute risk (i.e., the risk of patients developing an outcome in each group of a study) expressed as a number or a percentage. The RD is the difference between the absolute risk between two groups.	When using therapeutic application of aloe vera versus a placebo, the relative risk of patients with lichen planus experiencing clinical improvement is RR = 1.03. Via the data used to calculate the relative risk, we can estimate the effect as an absolute risk. 28 patients in the aloe vera arm (total N = 31) experienced clinical improvement. The absolute risk of improving with aloe vera can be presented as 900 out of 1000 patients receiving aloe vera improved, or 90% of patients receiving aloe vera improved. Similarly, 21 patients in the placebo arm (total N = 24) experienced clinical improvement. Therefore, the absolute risk for improving using placebo can be presented as 880 out of 1000 patients improved, or 88% of patients receiving placebo improved. The RD can also be calculated by subtracting the absolute risk of the control group from the intervention group, for an RD/ARR = 2%. This means that patients receiving aloe vera gel were 2% more likely to experience clinical improvement compared to the placebo group. Or, aloe vera gel will improve clinical appearance in 20 additional patients out of 1000 compared to the placebo group.[24]
Number needed to treat for an additional benefit (NNTB)	In a randomized controlled trial (RCT) comparing an intervention to placebo, the NNTB is the number of patients that need to receive the intervention rather than placebo for one person to experience a beneficial outcome in a given time frame.[28] This measure is calculated by taking the inverse of the risk difference (i.e., 1/RD). Small NNTBs are indicative of a favorable intervention.	In a study assessing the effect of topical aloe vera compared to placebo for resolving lichen planus lesions, 28 out of 31 patients in the aloe vera group experience clinical improvement compared to 21 out of 24 patients in the placebo group, resulting in an NNTB of 35. This means that 1 person will experience resolution of their lichen planus for every 35 people treated with aloe vera after 12 weeks.[24]
Number needed to treat for an additional harmful outcome (NNTH)	In an RCT comparing an intervention to placebo, the NNTH is the number of patients that need to receive the intervention rather than placebo for one person to experience a harmful outcome in a given time frame. This measure is calculated by taking the inverse of the risk difference (i.e., 1/RD). Large NNTHs are indicative of a favorable intervention.	In an RCT comparing the effectiveness of pimecrolimus cream with vehicle cream for the treatment of erosive lichen planus, investigators measured the incidence of adverse events in each group. After 60 days, 5 out of 10 patients who received pimecrolimus cream experienced an adverse event compared to 1 out of 10 patients in the vehicle cream group. This corresponds to an NNTH of 3, meaning for every 3 people treated with the pimecrolimus cream, 1 person will experience an adverse event throughout 60 days of follow-up.[29]
Mean difference (MD)	The mean difference is a measure that quantifies the difference in the mean value or average of a continuous outcome between the two groups. When there is no difference in the treatment effect between the two groups, MD = 0. When conducting additional statistical analysis such as a meta-analysis, it may also be necessary to standardize measures of association by calculating a standardized mean difference. This summary statistic will not be discussed in depth here.	A study assessed the effect of systemic prednisone compared to a placebo drug in patients with recurrent aphthous stomatitis. The mean days to resolution of the ulcer was measured in both groups. The mean days to resolution was 4.55 and 10.85 in the prednisone and placebo groups, respectively. MD = –6.3 days (4.55 – 10.85 = –6.3). On average, the patients who took prednisone experienced resolution of their ulcer 6.3 days earlier than patients who took the placebo pill.[30]

simply a matter of study power (i.e., sample size and number of people with PMDs). Thus, whether results are or are not statistically significant have no bearing on the clinical significance of the findings.

There is a large consensus in the research community advocating for discontinuing the use of statistical significance (e.g., emphasis on significant P-values) as a measure of relevance for study findings. Their concerns are backed by evidence, suggesting that research is more likely to get published if it demonstrates statistically significant results.[31] In order to improve their chance of publication, investigators might be tempted to manipulate the data, for example by implementing something called P hacking.[32] This practice is a form of data manipulation that results in statistically

significant P-values. With significant P-values, researchers may be more likely to get published, get awarded a grant, or enjoy other positive outcomes in the research community. A recent article summarized data manipulation strategies as follows: "These practices are akin to the Texas sharpshooter fallacy, in which an incompetent shooter sprays the side of a barn with bullets and then draws a target around the bullet holes to show how accurate of a shot he was."[33] For the novice practitioner of evidence-based clinical practice, it is not always possible to identify when manipulation of data is occurring. At the very least, when using evidence to inform practice it is important to maintain vigilant skepticism and avoid being persuaded by every "almost too good to be true" positive outcome that one encounters in the literature or presentations by gurus at prestigious conferences.

What Is the Null Hypothesis?

When conducting a scientific study, it is very difficult to prove that an observation is true and deserves attention. For example, it would be difficult to prove the following: "All people in the community who smoke get oral cancer." The likelihood that one could examine every single person in the community would be extremely difficult, if not impossible. Even if 99% of the community who smoked are examined and all had cancer, there is still a remaining 1% of the community who smoked whose cancer status remains uncertain. As is commonly noted in research, an absence of evidence is not evidence of absence.[34] In other words, just because something is not seen does not mean it does not exist. In research, rather than stating that something is the case (referred to as the "alternative"), researchers instead present the "null" and then try to find evidence to refute it or not refute it: "All the people in the community who smoke do not have oral cancer." This statement is easier to refute, as it will be sufficient to find just one person in the community who smokes and has oral cancer to reject such a statement. While it is not the primary goal of investigators to conduct research to report something to be false, by principle and philosophy, research methodology makes disproving/refuting easier than proving. And this is where the null hypothesis comes in. Researchers' goal when designing a project is to provide evidence as to what extent an observation of the world is compatible with a preconceived statement (i.e., assuming that the null hypothesis is correct).

P-Values, What They Are, and What They Are Not

Probably one of the most cited statistics and the one upon which most journal reviewers focus when considering an article for publication is the P-value. Researchers will often aim to reach that critical value of $P \leq 0.05$; this accomplishment leads them feeling validated for their research with findings that can be considered statistically significant. Yet there are times when the illustrious P-value gets more credit than is due. Given that critically appraising the research literature requires a broad understanding of statistics, it is necessary to have a solid understanding of science's most ubiquitous statistic. A broader and valid understanding of P-values contextualizes them as one piece in a "statistical model." A model is the group of assumptions, methods, and steps (e.g., definition of selection criteria, study recruitment process, implementation of allocation concealment, blinding for outcome adjudicators, analysis planning, null hypothesis formulation statistical test of choice, selection of data to report) that investigators plan and execute when trying to get an understanding of a phenomenon.[35]

A P-value is defined as "a statistical summary of the compatibility between the observed data and what we would predict or expect to see if we knew the entire statistical model (all the assumptions used to compute the P-value) were correct."[35] Thus, the role of statistical tests is to provide a numeric value that reflects the distance or degree of compatibility between the data observed in the study and a predefined statistical model. As mentioned above, such a model includes all the assumptions, decisions, and steps for the execution of a study from which a phenomenon was observed, and not merely the comparison of the P-value against a predetermined level of significance or "alpha level"—by convention set at 0.05. A small P-value, equal to or lower than the alpha level, can be attributed to a number of potential explanations. One possible explanation is that the observed data are not close to or not compatible with the predefined statistical model (i.e., all aspects of the research, including the null hypothesis), warranting a rejection of the null hypothesis, under the condition that all assumptions to obtain the P-value were correct. Another explanation can be that methodologic issues, confounding, residual bias, or reporting issues contributed to the computation of a small P-value, making the data look "unusual" with regard to the model. Unfortunately, hypothesis testing is incapable of differentiating between these two scenarios: "$P \leq 0.05$ only means that a discrepancy from the hypothesis prediction (e.g., no difference between treatment groups) would be as large or larger than that observed no more than 5% of the time if only chance were creating the discrepancy (as opposed to a violation of the test hypothesis or a mistaken assumption)."[35]

Clinicians must be careful not to put emphasis on the P-value out of proportion to what it represents. For instance, it offers no insight into the magnitude of the effect of the observed phenomenon: a P-value of 0.04 is no weaker than a P-value of 0.02. A smaller P-value does not automatically imply more statistically significant results, nor more

substantial outcomes. In addition, P-values do not represent the extent to which the observed differences in a study are due to chance alone, nor do they reflect the probability of the null hypothesis being true (the computation of P-values assumes that the null hypothesis is true).

Interpreting Confidence Intervals

CIs have emerged as an alternative to P-values for examining the relevance and implications of study results for practice. They provide a range of plausible results in the same units as the outcome measure of interest (including direction and magnitude), and represent progress toward making research findings more accessible and understandable for decision-making. A CI has upper and lower boundaries, as well as a point estimate representing the best estimate that reflects the observed data.[1] When researchers present 90%, 95%, or 99% CIs obtained from a single study, they are always representing a range of results, which may or may not contain the true value, irrespective of the percentage of confidence. The "confidence" aspect of the interval refers to a coverage probability that is applicable to a long sequence of repeated calculations of CIs.[35] For example, if an investigator computes many 95% CIs repeatedly for the phenomenon of interest, on average 95% of them will contain the true effect size, and, by extension, 5% of the CIs will not contain the true value. As the concept of confidence is applicable to the series of CIs and not to a single observation, one would never know whether the single CI reported in a clinical study belongs to the 95% that contains the true value or the 5% that does not contain the true value. This observation emphasizes the need for replication of study results in scientific research, an aspect often ignored by the research community, which frequently prioritizes novelty and uncommon findings over replication of initial results that were "too good to be true."

The width or precision of a CI is determined by sample size and the number of observed events of interest, and has important implications for its ability to inform practice and policy decisions. Picture, for example, a study testing a new surgical technique that promises to reduce the incidence of dental implant failures (Table 29-9). If the same study is repeated over time, increasing the sample size and number of events for both experimental and control groups (implant failure) while keeping the absolute risk constant across both arms in increments that double the risk, it can be verified that a 20% relative risk reduction (RRR) is present across all scenarios (people who received the new surgical technique experienced a 20% reduction in implant failure compared to those who received the conventional technique). However, the width of the 95% CI and the ability to inform the effect of the new surgical technique on implant failure varies. In the second to last scenario in Table 29-9, the lower boundary of the 95% CI only suggests a 5% reduction in the risk of experiencing implant failure, an effect in implant failure that many can consider negligible, especially if the new technique requires the adoption of different equipment, additional training, and other expenses. In other words, changing practice and adopting the new technique in the face of a 5% RRR in the outcome may not be worthwhile. On the other hand, the upper boundary of the CI suggests a 33% reduction in implant failure, a treatment effect that many clinicians would consider large enough to change practice and adopt the new technique. When in the presence of a CI whose boundaries provide evidence that would determine different clinical actions (e.g., adopting the new technique would not be worthwhile vs. adopting the new technique seems to be appropriate), one can claim that such a CI is imprecise or

Table 29-9 Sample size, absolute risk reduction, relative risk reduction, and width of a confidence interval *Sample size and width of a confidence interval (CI).*

Experimental group			Control group					
Implant failures	Total number of implants	Absolute risk	Implant failures	Total number of implants	Absolute risk	Absolute risk reduction (ARR)	Relative risk reduction (RRR)	RRR; 95% CI
8	20	0.40	10	20	0.50	0.10	0.20	0.20; –60 to 60%
16	40	0.40	20	40	0.50	0.10	0.20	0.20; –31 to 51%
32	80	0.40	40	80	0.50	0.10	0.20	0.20; –13 to 43%
128	320	0.40	160	320	0.50	0.10	0.20	0.20; 5 to 33%
320	800	0.40	400	800	0.50	0.10	0.20	0.20; 11 to 28%

The five different studies illustrate that an increase in sample size will result in a narrower confidence interval constructed around the relative risk reduction (RRR); that is, it will provide more confidence that the "true" RRR for the implant failure rate is close to the observed 10% ARR and 20% RRR.

has a width that is not narrow enough to effectively inform practice. Let's focus now on the last scenario presented in Table 28-9. Here, the 95% CI suggests an 11% increase in the incidence of implant failure (lower boundary) as well as a 28% increase in the same outcome. With both boundaries suggesting an increase in implant failure by using the new technique, and the lower boundary still reflecting a reduction that many clinicians would consider relevant enough to warrant a change in practice (i.e., the adoption of the new surgical technique), one can claim that this CI is precise and narrow enough to inform practice.[1]

After being presented with these scenarios, one question remains unanswered: How can patients and clinicians define thresholds to evaluate the extent to which a treatment effect can be judged as important? What is the smallest magnitude of a treatment effect that patients can identify as a meaningful improvement or deterioration in a particular outcome?

Use of Thresholds to Interpret Evidence: The Minimal Important Difference

A concept called minimal important difference (MID) addresses the challenges in interpreting outcomes (including PROMs), and in particular the need to establish a threshold between an unimportant versus a small but important impact. An MID corresponds to the smallest change in score of an outcome of interest, either beneficial or harmful, that patients would perceive as important.[36,37] Since it was first described, there has been an exponential growth in the number of publications in the medical literature referring to the concept. There are two main approaches in the literature for estimating an MID: (1) distribution-based and (2) anchor-based methods. Distribution-based methods evaluate a change in a PROM by estimating statistical parameters (e.g., pared t-statistic, effect size, standard error of measurement, standard deviation of 0.5, etc.).[38–40] These methods have been questioned as they rely on the statistical characteristics of the PROM, and do not reflect the patient perspective, highly desired when interpreting the impact of healthcare interventions.

In anchor-based methods, PROM results are compared against an external independent criterion—the anchor—that is in itself understandable and relevant for patients and exhibits at least a moderate correlation with the PROM.[41,42] Examples of anchors are healthcare utilization, response to treatment, disease severity, and presence of symptoms. Investigators establish the MID by relating the results of the anchor to those of the target PROM.

Investigators can apply anchor-based methods in a longitudinal or cross-sectional fashion.[39] The global rating of a change or transition item is one of the most frequently used longitudinal anchor-based methods (e.g., "Are you feeling better or worse, and if so, what is the extent of the change?").[41] Other examples of anchor-based methods use a comparison to disease-related criteria, preference ratings, and comparison to a known population.[39] The main advantage of anchor-based methods over distribution-based methods is the inclusion of criteria that are relevant for patients.

APPLYING THE RESULTS TO PRACTICE AND POLICY

After identifying the best available evidence to inform practice, assessing its validity (i.e., risk of bias or the extent to which methodologic strategies were appropriately implemented to minimize effect bias and confounding), and examining the study results, including the magnitude of a treatment effect and the strength of an association between an exposure and an outcome, clinicians and policy-makers still need to answer a subsequent question: "Is this evidence relevant for my decision-making needs?"

Consideration of All Patient/Person-Centered Outcomes

One of the hallmarks of any study, systematic review, or clinical practice guideline is that all patient/person-centered (or important to patients or people) outcomes should be defined, measured, and included for analysis, regardless of whether the evidence-collection process resulted in no studies reporting these outcomes. In fact, when defining the basis for decision-making, it should be clinical judgment and patient input that inform the set of desirable and undesirable outcomes needing to be documented, not their availability in the research literature. What this tells clinicians and policy-makers is that the authors looked for all relevant studies and outcome data relevant for decision-making, irrespective of the data actually reported in the literature, which represents an approach to basing healthcare decisions in "what matters from a patient's point of view" rather than "what it is reported in the literature" with no discretion of relevance. Though there is inherent uncertainty in the evidence-based decision-making process in the absence of data, the presentation of all patient-important outcomes allows users to be confident that decisions are being made using the best available evidence. The fact that for many relevant clinical questions more definitive patient/person-centered outcomes are not available is in itself a valuable piece of information for those facing a choice. In contrast to surrogate outcomes, patient/person-centered outcomes will best inform decisions in the clinic and in policy-making, as they directly relate to how patients and, in turn, clinicians perceive the benefits and harms of a therapy or diagnostic test.

Additionally, it is an integral part of the evidence-based decision-making process to consider patients' values and preferences. A patient's and, sometimes, caregiver's preferences may dictate whether the undesirable effects associated with an intervention outweigh the potential benefits or vice versa, a contrast that is commonly seen in value-sensitive decisions.[43]

Balancing Benefits and Harms (Magnitude of Desirable and Undesirable Effects)

In addition to a therapy's desirable effects, or benefits, clinicians and policy-makers should weight those against the undesirable effects or harms, and associated costs and burden. In the context of implementing shared decision-making, it is important to present all desirable and undesirable effects to the patient when considering a clinical decision, as the relative importance of these outcomes and the appreciation for their magnitude may vary from patient to patient, particularly in highly value-sensitive decisions (Figure 29-3).

Shared decision-making involves patients and clinicians working together to articulate patients' values and preferences, which ultimately should inform the clinical decision. Patients need information to work with their clinician to make an informed decision that is best for them. This is a conversational, bi-directional approach, not a clinician to patient–directional approach.[44]

When conducting evidence-based clinical practice guidelines, a guideline panel solicits feedback about the scope and recommendations from the public and stakeholders as an essential methodologic step in the development of quality clinical practice guidelines. This step ensures that all considerations from the general public or society, patients, and key stakeholder organizations or agencies are included in the panel's final recommendations. It is expected that guideline panels define the relative importance of outcomes based on patients' values rather than their own. This process also provides guideline developers additional information on how patients perceive the therapy and its alternatives. That informs users on how the typical patient may perceive the benefits and harms of a therapy, providing further information to the patients in the context of shared decision-making. Defining to what extent the use of an intervention produces "more good than harm" is a challenging activity that clinicians nevertheless must perform on a daily basis. Informing such a balance with trustworthy data that contextualizes the magnitude of the desirable and undesirable consequences makes a decision truly evidence based.

Patients Similar to the Ones in My Practice

Clinical studies often focus on generating—by using strategies like randomization, allocation concealment, blinded adjudication of outcomes in the groups, or with the application of the intention-to-treat principle—two groups that are comparable. However, these strategies frequently fail to address the extent to which the characteristics of the patients recruited reflect the general population or the typical patient suffering from the condition under investigation. Applicability or generalizability represents "the degree to which the results of a study can be generalized [or applied] to settings or samples other than the ones studied."[2] The National Institutes of Health (NIH) released policy guidelines in 1994 (updated in 2017) that ensure NIH-funded research includes subjects of all genders, sexes, ages, and racial or ethnic groups.[45] But not all research is NIH funded, so it is important to be prudent when evaluating the literature before applying the findings to practices. There are three key questions when assessing the extent to which the results of a study conducted in certain sample can be applied to another setting:[2]

- Have biologic factors that might modify the treatment response been excluded? Biologic factors including sex, age, race, presence of comorbidities, and specific features of the disease can modify the effects observed from studies

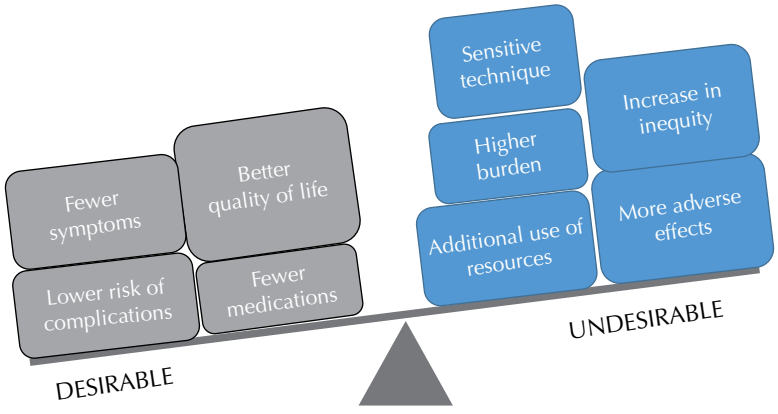

Figure 29-3 Balancing benefits and harms.

when compared to an individual patient in the community. Experienced clinicians will be able to identify the role that these factors may play in modulating the disease process and defining whether a given therapy would be an unsuccessful treatment in an individual patient with any of these modulating factors.

- Can the patients adhere to treatment requirements? Investigators often attempt to recruit participants who have demonstrated a high level of adherence and commitment to the study and the therapy under testing. On the one hand, this is a desirable feature of clinical studies to minimize the effect of missing participant data, making sure that all patient outcomes are accounted for in the analysis, and therefore minimizing risk of bias. On the other hand, these over-adhering participants may well not represent the ability of people in the community or the general population to effectively stick to the treatment, especially in the face of high burden, costs, significant adverse events, and so on. It is reasonable to assume that real patients outside a research setting would exhibit lower levels of adherence, negatively affecting the observed treatment effect in the study informing a decision. Interventions that carry little burden would suffer less from adherence issues compared to highly intense and demanding therapies.
- Can the clinicians adhere to treatment requirements? Clinicians' ability to appropriately diagnose, ask relevant questions during the medical history recollection, apply their technical skills, and use supportive equipment according to specifications are essential considerations when determining to what extent a practitioner would be able to replicate the therapy from the study in their practice. This point is of particular importance in dentistry as a profession that relies heavily on surgical procedures. The more sensitive an intervention in a clinical study is to technique and experience, the less likely it is that a regular general practitioner in the community will be able to obtain treatment results close to the ones reported in the research literature. In the presence of large discrepancies between clinicians' expertise in a trial compared to another clinician attempting to apply the evidence from that trial, the more serious the issues of applicability or generalizability that would emerge.

In summary, when assessing the applicability of a study to clinical practice, valuable information can be found in the methods section of the article; definition of selection criteria (inclusion and exclusion criteria) should be critically appraised and assessed for similarity between the research subjects and the clinical patients of interest. Should one completely ignore the evidence when patients in the setting of interest do not match the study subjects? The answer is probably no, as in many cases the only available information is coming from a study with issues of applicability. A clinician with a deep understanding of applicability will be cautious when a study reporting a highly effective therapy is outside their level of surgical or technical expertise, too distant from the patients of interest, or too burdensome, therefore negatively affecting patients' adherence.

One special point of interest is the determination of whether a particular clinical practice guideline can be truly helpful in the hands of a clinician.

Utilization of Clinical Practice Guidelines and Clinicians' Expertise

The evidence-based practitioner will have reviewed the possible outcomes of a treatment, balanced harms and benefits, and considered whether the patients in a study match the patients in their clinic. The last question a clinician should be prepared to answer is: "Am I prepared to conduct the treatment indicated in the clinical guideline?" For example, the American Academy of Pediatrics has developed guidelines for sedation before, during, after a dental procedure.[46] After reading these guidelines, one will be well informed in the considerations for and practice of sedation for pediatric patients. But the guidelines make clear that practitioners need to be knowledgeable about a variety of areas; for example, they must be trained in advanced pediatric airway management. Therefore, these guidelines cannot be adopted by every clinician, as not every clinician has been trained in this area.

While these guidelines point out the required training to utilize them, others may not be as clear. In these situations, it is important that the clinician be ready to self-assess and follow the ethical principles laid out in dentistry.[47] If a clinician were to implement a guideline without the appropriate training, there is a risk that they would be violating the principle of nonmaleficence, or "do no harm." Without proper training, a clinician may not be prepared for the adverse outcomes of a treatment or procedure. It is up to each clinician to constantly self-assess, and when faced with a lack of training to help patients, appropriately refer or determine that time to retrain is warranted.

Another key question within the implementation discussion is how to resolve contradictions between guidelines and training. For example, recent guidelines regarding antibiotic use recommend antibiotics in a limited number of situations, contradicting the general practice of generous antibiotic prescribing practices.[48–50] Many dentists and physicians may not feel comfortable with these new guidelines, as the latter contradict what they were taught in school or learned in a continuing education course. Some prefer to prescribe an antibiotic under the misguided assumption that doing it

"just in case" is appropriate. Studies examining why guidelines are not implemented cite lack of agreement, lack of training, and lack of skills.[51] Unfortunately, there is no one simple resolution to this issue. Changing attitudes and behaviors is a difficult process. It is therefore important that evidence-based practice continues being taught broadly to those early in their career, as well as those well versed in their fields. Learning how to practice evidence-based dentistry is a skill, just like learning how to do a filling. It takes time and requires repetition.
