Lester W. Burket DDS, MD
1907–1991

Dr. Lester W. Burket, widely considered the father of Oral Medicine, wrote the first edition of this groundbreaking text, Oral Medicine Diagnosis and Treatment, published in 1946.

Dr. Burket was trained in dentistry at the University of Pennsylvania and medicine at Yale. He was one of the first to stress the importance of the knowledge of medicine to the practice of dentistry, the role dentists could play in the diagnosis and management of diseases of the mouth and jaws, and the benefit to patients from close collaboration of dentists and physicians.

In addition to his devotion to teaching, he founded the Department of Oral Medicine at the School of Dental Medicine at the University of Pennsylvania, and served as Department Chair from 1944 to 1972, while also serving as Dean of the dental school from 1951 to 1972.

Dr. Burket would be pleased to see the scope of the present text as well as the international group of authors writing the thirteenth edition of his classic text.

"The good physician treats the disease; the great physician treats the patient who has the disease."

Sir William Osler

We have found Oral Medicine to be an extraordinarily rewarding career, and for this we are grateful to the pioneers of the field for their vision, creativity, and dedication to their work. They established oral medicine as a specialty at the interface of dentistry and medicine, and we owe them a huge debt. It is therefore to Lester Burket and the other leaders of the past in academics, clinical practice, and research who mentored and guided us that we dedicate this book. We also dedicate it to current and future practitioners of Oral Medicine around the world who share our professional fulfillment in this developing specialty, and especially to our families who have supported us throughout the years.

Contents

Preface

It is with great pleasure that we share this thirteenth edition of the classic text *Burket's Oral Medicine* with students, residents, and professional colleagues around the world. This edition reflects the scope of modern oral medicine in both the content and the international nature of many new contributors.

Two experienced editors with international reputations for clinical and academic excellence, Dr. Peter Lockhart and Dr. Stephen Challacombe, have been added as Editors to this new edition, which has contributed to expanding the scope of the text and the diversity of the authors.

As the volume and availability of both basic and clinical biomedical information are growing at an ever-increasing pace, we realize that today's students, teachers, and practitioners of oral medicine must broaden the scope of their knowledge to increase their competence as clinicians, academics, and researchers. The chapters from the 12th edition describing oral mucosal and salivary gland disease, orofacial pain, TMD, and dental management of medically complex patients have been expanded and updated. In addition, the 13th edition contains chapters not found in traditional books in this discipline, including chapters on clinical research, pediatric oral medicine, psychiatry and psychology, geriatric oral medicine, laboratory medicine, and appraising and interpreting the biomedical literature.

With more than 80 authors from across the globe, we have broadened the scope and approach to ensure that this text is highly relevant to teaching and practice in many different countries and clinical settings.

Michael Glick, Martin S. Greenberg, Peter B. Lockhart, and Stephen J. Challacombe

List of Contributors

Alfredo Aguirre, DDS, MS
Professor
Department of Oral Diagnostic Sciences
School of Dental Medicine
University at Buffalo,
The State University of New York
Buffalo, NY, USA

Ivan Alajbeg, DMD, MSc, PHD
Professor
Department of Oral Medicine
School of Dental Medicine
University of Zagreb
University Hospital Center Zagreb
Zagreb, Croatia

Faizan Alawi, DDS
Professor of Pathology
School of Dental Medicine
Professor of Dermatology and Pathology and Laboratory Medicine
Perelman School of Medicine
University of Pennsylvania
Philadelphia, PA, USA

Robert Anolik, MD
President and Founding Partner, Allergy & Asthma Specialists, PC Director of Clinical Research, Allergy & Asthma Specialists, PC Clinical Associate Professor of Pediatrics, Drexel University School of Medicine
Adjunct Associate Professor, Department of Oral Medicine, University of Pennsylvania
Blue Bell, PA, USA

Rafael Benoliel, BDS (Hons)
Professor, Department of Diagnostic Sciences
Rutgers School of Dental Medicine
Rutgers, The State University of New Jersey
Newark, NJ, USA

Austin Booth, MLIS, MA
Dean of the Division of Libraries
New York University
New York, NY, USA

Leah M. Bowers, DMD
Oral and Maxillofacial Radiology
Department of Oral Medicine
School of Dentistry
University of Washington
Seattle, WA, USA

Michael T. Brennan, DDS, MHS, FDS RCSEd
Professor and Chair
Department of Oral Medicine

Introduction to Oral Medicine and Oral Diagnosis: Patient Evaluation

Michael Glick, DMD, FDS RCSEd
Martin S. Greenberg, DDS, FDS RCSEd
Peter B. Lockhart, DDS, FDS RCSEd, FDS RCPS
Stephen J. Challacombe, PhD, FDS RCSEd FRCPath, FDSRCS

Oral medicine, as defined by the American Academy of Oral Medicine, is "the specialty of dentistry responsible for the oral health care of medically complex patients and for the diagnosis and management of medically related disorders or conditions affecting the oral and maxillofacial region." Definitions vary in different parts of the world, but most include the diagnosis and nonsurgical management of oral mucosal and salivary gland disease, orofacial pain, and dental treatment of patients with medical disorders.

The overall goal for all oral healthcare professionals is to deliver and maintain optimal health for their patients. A recent definition was approved by the World Dental Parliament in 2016, which expanded the definition to include three different domains: disease and condition status, psychosocial status, and physiologic function.[1] The inclusion of a psychosocial status and physiologic function deviates from traditional definitions that mainly focused on the presence or absence of disease, and, further, it promotes the inclusion of patient values and preferences, as well as elevates the importance of subjective findings. This approach is more aligned with a person-centered care approach that emphasizes a patient's problem in the context of behavioral, socioeconomic, and environmental aspects, and their impact on the patient and on the care that needs to be delivered.[2–4] This definition has also been the underlying framework to establish outcomes that can be used to measure the oral status of an individual.[5]

Given the nature, complexity, and potential systemic implications for some oral conditions, coupled with an aging population with multimorbidities (multimorbidities do not identify an index disease, while comorbidities focus on an index disease and other diseases) and individuals taking numerous medications, all oral healthcare clinicians are required to enhance their knowledge of many aspects of medicine. Therefore, what previously was considered the purview of oral healthcare professionals with hospital-based

Burket's Oral Medicine, Thirteenth Edition. Edited by Michael Glick, Martin S. Greenberg, Peter B. Lockhart, and Stephen J. Challacombe.

training has become increasingly more important in general and specialty dental practice.

Advances in clinical practice are influencing many aspects of patient care, from our initial contact with a patient, through medical history-taking, diagnosis, and treatment options. For example, electronic health records (EHRs) allow for sharing health information among multiple clinicians caring for the same patient and can provide point-of-care algorithms for eliciting and using health information. Modern imaging techniques, such as computerized tomography scans (CTs) and magnetic resonance imaging (MRI), provide more detailed information and are a means to acquire more sophisticated data, but require enhanced training for accurate interpretation. Nevertheless, one of the most important skills for accurate diagnosis and management remains an experienced clinician with highly developed skills of listening and examination.

The initial encounter with a patient may influence all subsequent care. The skilled, experienced practitioner has learned to elicit the subjective (i.e., history-taking) and objective (e.g., clinical, laboratory) findings and other necessary information required for an accurate diagnosis. This process is an art, as well as a skill. Although mastering a patient evaluation can be assisted by specific clinical protocols, the experienced practitioner will add their own skills and experience to the diagnostic methodology.

A variety of accessible sources of healthcare information are now readily available to patients, and many will use this information to self-diagnose, as well as demand specific treatments. As a person-centered approach is encouraged, where a patient's preferences and values will influence care, the practitioner must listen to the patient to understand their needs, fears, and wishes and address them to arrive at an appropriate treatment plan that results in informed, scientific, and evidence-based choices. Furthermore, part of a shared decision-making approach includes the responsibility of the oral healthcare professional to educate their patient about the implications and consequences of a diagnosis and subsequent treatment. Creating an environment for effective communication between provider and patient has been shown to improve health outcomes.[6]

The process of obtaining, evaluating, and assessing a patient's oral and overall health status can arbitrarily be divided into seven major, sometimes overlapping, parts:

1) History and examination.
2) Establishing a differential diagnosis.
3) Obtaining necessary consultations, as well as appropriate laboratory tests, such as specific blood investigations, a biopsy, and imaging studies, all based upon the initial differential diagnosis.
4) Final diagnosis.
5) Formulating a plan of action.
6) Initiating treatment.
7) Follow-up assessment of response to treatment.

INFORMATION GATHERING

An appropriate interpretation of the information collected through a medical history and patient examination achieves several important objectives. It affords an opportunity for:

- Gathering the information necessary for establishing a diagnosis for the patient's chief complaint.
- Assessing the influence of the patient's systemic health on their oral health.
- Detecting other systemic health conditions of which the patient may not be aware.
- Providing a basis for determining whether dental treatment might impact the patient's systemic health.
- Giving a basis for determining necessary modifications to routine dental care.
- Monitoring medical conditions of relevance to the maxillofacial condition.

Medical History

Obtaining an appropriate and accurate medical history is a critical first step for all patient care. It begins with a systematic review of the patient's chief or primary complaint, a detailed history related to this complaint, information about past and present medical conditions, pertinent social and family histories, and a review of symptoms by organ system. A medical history also includes biographic and demographic data used to identify the patient.

There is no universally agreed method for obtaining a medical history, but a systematic approach will help the practitioner to gather all necessary information without overlooking important facts. The nature of the patient's oral health visit (i.e., initial dental visit, complex diagnostic problem, emergency, elective continuous care, or recall) often dictates how the history is obtained. The two most common means of obtaining initial patient information are a patient self-administered preprinted health questionnaire, or recording information during a systematic health interview without the benefit of having the patient fill out a questionnaire. The use of self-administered screening questionnaires is the most common method in dental settings. This technique can be useful in gathering background medical information, but the accurate diagnosis of a specific oral complaint requires a history of the present illness and other verbal information. While the basic information for a past medical history may be obtained by a questionnaire, a vital

part of the evaluation of a patient with a complex diagnostic problem is the history of the present illness, which is a combination of science and art and should be taken directly by the clinician.

The challenge in any healthcare setting is to use a questionnaire that has enough items to obtain the essential medical information, but is not too long to deter a patient's willingness and ability to fill it out. These questionnaires should be constructed in a manner that allows the clinician to query the patient about the most essential and relevant required information, yet provides a starting point for a dialogue with the patient about other pertinent information not included on the health form. Preprinted self-administered or online health questionnaires are readily available, standardized, and easy to administer and do not require significant "chair time." They give the clinician a starting point for a dialogue to conduct more in-depth medical queries, but are restricted to the questions chosen on the form and are therefore limited in scope. The questions on the form can be misunderstood by the patient, resulting in inaccurate information, and they require a specific level of reading comprehension. Preprinted forms cover broad areas without necessarily focusing on particular problems pertinent to an individual patient's specific medical condition. Therefore, the use of these forms requires that the provider has sufficient background knowledge to understand the reasons for the questions on the forms. Furthermore, the provider needs to realize that a given standard history form necessitates timely and appropriate follow-up questions, especially when positive responses have been elicited. An established routine for performing and recording the history and examination should be followed conscientiously.

The oral healthcare professional has a responsibility to obtain relevant medical and dental health information, yet the patient cannot always be relied upon to know this information or to provide an accurate and comprehensive assessment of their medical or dental status.

All medical information obtained and recorded in an oral healthcare setting is considered confidential and may in many jurisdictions constitute a legal document. Although it is appropriate for the patient to fill out a history form in the waiting room, any discussion of the patient's responses must take place in a private setting. Furthermore, access to the written or electronic (if applicable) record must be limited to personnel who are directly responsible for the patient's care. Any other release of private information should be approved, in writing, by the patient and that approval retained by the dentist as part of the patient's medical record.

Given that medical status and medication regimens often change, a patient's health status or medication regimen should be reviewed at each office visit prior to initiating dental care. The monitoring of patients' compliance with suggested medical treatment guidelines and prescribed medications is part of the oral healthcare professional's responsibilities. The following strategies are common to nearly all methods of history-taking:

- Review available patient information prior to meeting the patient.
- Greet the patient; use the patient's name; ensure privacy; sit rather than stand, preferably at eye level; maintain eye contact as often as possible; listen carefully to the patient's concerns; do not rush the interview process.
- Do not concentrate chiefly on entering the information into an electronic health record, as this may distract you from listening to pertinent information.
- Use the patient's own words (in quotation marks) to describe the primary reason(s) to seek care/consultation; i.e., be absolutely clear about the patient's chief complaint(s).
- Use open-ended questions to encourage open dialogue with the patient. Although all information should be collected in a systematic fashion, the order is not as important as is initiating a dialogue with the patient about their health.
- Create a timeline of the reported patient-related events. An accurate chronology is an extremely important element to establish or deny a causative relationship.

The medical history traditionally consists of the following subcategories:

- *Identification*—name, date and time of the visit, date of birth, gender, ethnicity, occupation, contact information of a primary care provider (physician and, if applicable, dentist), referral source.
- *Chief complaint (CC)*—the main reason for the patient seeking care or consultation and the length of time these symptoms have been present, recorded in the patient's own words.
- *History of present illness (HPI)*—taking an effective HPI takes experience and is often the key to making an accurate differential diagnosis. It includes a chronologic account of events; state of health before the presentation of the present problem; description of the first signs and symptoms and how they may have changed; description of occurrences of amelioration or exacerbation; previous clinicians consulted, prior treatment, and degree of the response to previous treatment. For those who favor mnemonics, the nine dimensions of a medical problem can be easily recalled using OLD CHARTS (Onset, Location/radiation, Duration, Character, Habits, Aggravating factors, Reliving factors, Timing, and Severity).[7]
- *Review of systems (ROS)*—identifies symptoms in different body systems (Table 1-1). The ROS is a comprehensive and systematic review of *subjective* symptoms affecting different bodily systems. It is an essential component for

Table 1-1 Review of Systems (ROS): A systematic approach to ascertain mostly subjective symptoms associated with the different body systems.

General: Weight changes, malaise fatigue, night sweats
Head: Headaches, tenderness, sinus problems
Eyes: Changes in vision, photophobia, blurring, diplopia, spots, discharge
Ears: Hearing changes, tinnitus, pain, discharge, vertigo
Nose: Epistaxis, obstructions
Throat: Hoarseness, soreness
Respiratory: Chest pain, wheezing, dyspnea, cough, hemoptysis
Cardiovascular: Chest pain, dyspnea, orthopnea (number of pillows needed to sleep comfortably), edema, claudication
Dermatologic: Rashes, pruritus, lesions, skin cancer (epidermoid carcinoma, melanoma)
Gastrointestinal: Changes in appetite, dysphagia, nausea, vomiting, hematemesis, indigestion, pain, diarrhea, constipation, melena, hematochezia, bloating, hemorrhoids, jaundice
Genitourinary: Changes in urinary frequency or urgency, dysuria, hematuria, nocturia, incontinence, discharge, impotence
Gynecologic: Menstrual changes (frequency, duration, flow, last menstrual period), dysmenorrhea, menopause
Endocrine: Polyuria, polydipsia, polyphagia, temperature intolerance, pigmentations
Musculoskeletal: Muscle and joint pain, deformities, joint swellings, spasms, changes in range of motion
Hematologic: Easy bruising, epistaxis, spontaneous gingival bleeding, increased bleeding after trauma
Lymphatic: Swollen or enlarged lymph nodes
Neuropsychiatric: Syncope, seizures, weakness (unilateral and bilateral), changes in coordination, sensations, memory, mood, or sleep pattern, emotional disturbances, history of psychiatric therapy

identifying patients with a disease that may affect dental treatment or associated symptoms that will help determine the primary diagnosis. For example, a patient with skin, genital, or conjunctival lesions who also has oral mucosal disease, or a patient with anesthesia, paresthesia, or weakness who also presents with orofacial pain. The clinician records both negative and positive responses. Direct questioning of the patient should be aimed at collecting additional data to assess the severity of a patient's medical conditions, monitor changes in medical conditions, and assist in confirming or ruling out those disease processes that may be associated with patient's symptoms.

- *Past medical history (PMH)* (may not have been revealed in systems review)—general health; immunizations; major adult illnesses; any surgical operations (date, reason, and outcome); medications (prescribed medications, over-the-counter medications, supplements) and home remedies; allergies.
- *Personal and social history (SH)*—birthplace; marital status; children; habits (tobacco use, alcohol use, recreational drug use); occupation; religion (if it may have an impact on therapy); sexual history if relevant to complaint.
- *Family history (FH)*—health or cause of death of parents, siblings, and children. The FH should also include diseases important to the patient's chief compliant, including genetic disorders; and common diseases, such as cardiovascular diseases or diabetes mellitus.

Patient Examination

The examination of the patient represents the second stage of the evaluation and assessment process. An established routine for examination decreases the possibility of missing important findings (signs).

A routine head and neck examination should be carried out at least annually or at each recall visit. This includes a thorough inspection (and when appropriate palpation, auscultation, or percussion) of the exposed surface structures of the head, neck, and face and a detailed examination of the oral cavity, dentition, oropharynx, and adnexal structures. Laboratory studies and additional special examination of other organ systems may be required for the evaluation of patients with orofacial pain, oral mucosal disease, or signs and symptoms suggestive of otorhinologic or salivary gland disorders, or signs or symptoms suggestive of a systemic etiology. A less comprehensive but equally thorough inspection of the face and oral and oropharyngeal mucosae should be carried out at each visit and the tendency to focus on only the tooth or jaw quadrant in question should be strongly resisted.

Each visit should be initiated by a deliberate inspection of the entire face and oral cavity prior to intraoral examination. The importance of this approach in the early detection of head and neck cancer cannot be overstated (see Chapter 7, Oral and Oropharyngeal Cancer).

Examination carried out in the dental office (surgery) is traditionally restricted to that of the superficial tissues of the oral cavity, head, and neck and the exposed parts of the extremities. On occasion, evaluation of an oral lesion logically leads to an inquiry about similar lesions on other skin or mucosal surfaces or about the enlargement of other regional groups of lymph nodes. Although these inquiries can usually be satisfied directly by questioning the patient, the oral health professional may also quite appropriately request permission from the patient to examine axillary nodes or other skin surfaces, provided

that the examination is carried out competently and there is adequate privacy for the patient. A male oral health professional should have a female assistant present in the case of a female patient; a female oral health professional should have a male assistant present in the case of a male patient. Similar precautions should be followed when it is necessary for a patient to remove tight clothing for accurate measurement of blood pressure. A complete physical examination should not be attempted when facilities are lacking or when religious or other customs prohibit it, or when no chaperone is present.

The degree of responsibility accorded to the oral health professional in carrying out a complete physical examination varies among institutions, hospitals, states, and countries.

The examination procedure in a dental office setting may include any or all of the following six areas:

- Registration of vital signs (respiratory rate, temperature, pain level, pulse, and blood pressure).
- Examination of the head, neck, and oral cavity, including salivary glands, temporomandibular joints, and head and neck lymph nodes.
- Lesions of the oral mucosa should have a detailed description including location, size, color, ulceration and induration, and an assessment of the severity made. Detailed descriptions of specific diseases presenting as ulcers, blisters, or white or red lesions can be found in Chapters 3–7.
- Assessment of cranial nerves, particularly when the patient presents with nondental orofacial pain, weakness, anesthesia, or paresthesia.
- Examination of other organ systems, when appropriate.
- Ordering indicated laboratory studies.

Consultations

Requesting Consultations from Other Clinicians

The overall purpose of a consultation is to clarify issues or help with diagnosis or management. Oral medicine clinicians are involved with two major types of consultations: those that they initiate for their own patients as a request from another healthcare professional; and those in response to a request for help with a patient of another healthcare professional.

Consent from the patient is needed before a consultation is initiated. All verbal and written consultation should be documented in the patient's record. A consultation letter should identify the patient and contain a brief overview of the patient's pertinent medical history and a request for relevant and specific information. The written request should be brief and should specify the particular concern and items of information needed from the consultant (Box 1-1).

Patients who may need medical consultation include:

- Those with known medical problems who are scheduled for either inpatient or outpatient dental treatment and cannot adequately describe all of their medical problems.
- Those with abnormalities detected during history-taking, on physical examination, or through laboratory studies.
- Those who have a higher risk for the development of a particular medical problem (e.g., diabetes with increased risk of atherosclerotic cardiovascular disease).
- Those for whom additional medical information is required that may impact the provision of dental care or assist in the diagnosis of an orofacial problem.
- Those with an orofacial disorder, which may also affect other parts of the body. For example, oral lesions may also involve the skin and conjunctiva.
- Those who are being considered for a medication that may have an adverse effect on another medical problem, such as diabetes or hypertension, or drug interactions.

Requests for consultation should include the problem and the specific questions to be answered and should be transmitted to the consultant in writing. Adequate details of the planned oral or dental procedure, include, as appropriate:

- Estimated risk of clinically significant bleeding.
- Assessment of time and stress to the patient.
- Expected period of post-treatment disability.
- Details of the particular symptom, sign, or laboratory abnormality that gave rise to the consultation.

Medically complex patients may have a medical condition that suggests the need for an opinion from the patient's physician as to risks involved in an invasive or stressful dental procedure, too often referred to as "clearing the patient for dental care."[8] In many cases, the physician is provided with too little information about the nature of the proposed dental treatment (type of treatment, amount of local anesthetics, anticipated bleeding, etc.) to help in this regard. Physicians cannot be expected to understand the nature of dental procedures and they should not be asked to "clear" patients for dental treatment. They should be contacted for pertinent medical information that will help the oral healthcare provider make the decision as to the appropriateness of the dental treatment plan. The response of a given patient to specific dental interventions may be unpredictable, particularly patients with comorbidities and those taking one or more medications. A physician's advice and recommendation may be helpful in managing a patient, but the responsibility to provide safe and appropriate care lies ultimately with the clinician performing the procedure.[9] Another health professional cannot from a legal standpoint "clear" a patient for any dental procedure and thus a request for "medical clearance" should be avoided.[8]

Box 1-1 Oral Medicine Inpatient Consultation

Patient: BRADLEY, BOB **MRN:** 0002222222
Age: 36 years **Sex:** Male **DOB:** 5/4/1983
Oral Medicine Resident: Dr. Alexandra Howell

Requesting Service: Hematology **Attending Physician:** INPATIENT HEMATOLOGY
Reason for Admission: LEUKOCYTOSIS; THROMBOCYTOPENIA
Date of Admission: 01/24/2020 **Hospital Day:** 2

Reason for Consult: Hospital dentistry consult requested by Dr. Green for oral evaluation and to rule out oral infection prior to immunosuppressive chemotherapy.
Source of History: Patient and medical record.

Chief Complaint: Patient not aware of any problems with his mouth in the past 6 months. He denies active dental pain but says that his "enamel keeps chipping off."

History of Present Illness:
Patient is a 36 y/o male with past medical history of chronic acid reflux who presented to our Emergency Room on January 24 with right-sided abdominal & flank pain and decreased urine output. He was found to have an acute kidney injury with hyperkalemia. CT of his abdomen/pelvis showed hydronephrosis/hydroureter and splenomegaly. CBC revealed white blood cell count of 53.9, hemoglobin of 10, and platelets 29,000. He was transferred to the inpatient hematology service for further evaluation and management of acute T-cell ALL and tumor lysis.

Health Status
Allergies: None known
Current Medications:
allopurinol 300mg per 1 tablet ORAL daily
hydroxyurea (Hydrea) 1,000 mg per 2 capsules ORAL q8h
sevelamer (sevelamer carbonate 800 mg oral tablet) 800 mg per 1 tablet ORAL TIDWM (3 times a day with meals)
Labs from 01/25/2020: ANC = 3150; INR=1.2; aPTT = 32.8; ALT/AST = 26/28.

Past Medical History: No active or resolved past medical history items have been selected or recorded. Patient states he has not seen a dentist in 10+ years.

Family History: Cancer—mother. Diabetes mellitus—father.

Extraoral examination: No trismus or swelling noted. Significant lymphadenopathy in postauricular area bilaterally.

Intraoral examination: Very poor oral hygiene with heavy plaque and calculus. Rampant dental caries with several retained root tips and fractured teeth. Noted a draining sinus tract/fistula on the buccal gingiva of lower left first molar (root tip) with moderate swelling and erythema. Also noted possible sinus tract above tooth #8.

Review/Management: Reviewed soft tissue neck CT. Relevant dental findings include numerous dental caries and extensive periodontal disease with periapical lucencies involving the mandibular left second molar, mandibular left first molar, mandibular right first molar, and multiple maxillary and mandibular incisors. Multiple root tips, and grossly enlarged and erythematous gingiva.

Impression: Diagnosis: dental caries, root tips, and advanced periodontal disease. Multiple draining sinus tracts/fistulas of the buccal gingiva. Posterior auricular bilateral lymphadenopathy R>L, moderate sized.

Recommendations: Patient does have clear signs of active dental infection. Recommend patient be transported to the dental clinic by wheelchair for a comprehensive clinical examination, full mouth series of radiographs and a Panorex for full treatment planning. We have tentatively scheduled him for the dental clinic on Monday morning, 1/27/20 at 10:00 am, pending medical stability. Treatment recommendations will be available following our department case conference on Tues 1/28/20.

Responding to Consult Requests from Other Clinicians

There are three major categories of oral medicine consultations:

- Diagnosis and nonsurgical treatment of orofacial disorders, including oral mucosal disease, temporomandibular and myofascial dysfunction, chronic lesions involving the maxilla and the mandible, orofacial pain, dental anomalies, maxillary and mandibular bone lesions, salivary gland disorders, and disorders of oral sensation, such as dysgeusia, dysesthesia, and glossodynia.
- Dental treatment of patients with medical problems that affect the oral cavity or for whom modification of standard dental treatment is required to avoid adverse events.
- Opinion on the management of dental disease that does not respond to standard treatment, such as rampant dental caries or periodontal disease in which there is a likelihood of a systemic etiologic cofactor.

In response to a consultation request, the diagnostic procedures outlined in this chapter may be followed, with the referral problem listed as the chief complaint and with supplementary questioning (i.e., history of the present illness) directed to the exact nature, mode of development, prior diagnostic evaluation/treatment, and associated symptomatology of the primary complaint. An examination of the head, neck, and oral cavity is important and should be fully documented, and the ROS should include an exploration of any associated symptoms and including pertinent negatives. When pertinent, existing laboratory, radiographic, and medical records should be reviewed and documented in the consultation record, and any additional testing or specialized examinations should be ordered.

A comprehensive consultation always includes a written report of the consultant's examination, usually preceded by a history of the problem under investigation and any items from the medical or dental history that may be relevant to the problem. A formal diagnostic summary follows, together with the consultant's opinion on appropriate treatment and management of the issue. Other previously unrecognized abnormalities or significant health disorders should also be communicated to the referring clinician. When a biopsy or initial treatment is required before a definitive diagnosis is possible, and when the terms of the consultation request are not clear, a discussion of the initial findings with the referring clinician is appropriate before proceeding. Likewise, the consultant usually discusses the details of their report with the patient, unless the referring dentist specifies otherwise. In community practice, patients are sometimes referred for consultation by telephone or are simply directed to arrange an appointment with a consultant and acquaint them with the details of the problem at that time; a written report is still necessary to clearly identify the consultant's recommendations, which otherwise may not be transmitted accurately by the patient. The details of an oral consultation must be documented on the patient's chart.

An important responsibility for hospital-based dentists is responding to consults from medical and surgical services. It is not at all uncommon for hospitalized patients to have routine maxillofacial problems (e.g., toothache) that have nothing to do with their reason for hospitalization. More commonly, patients may have a wide variety of problems that are directly related to their medical condition or its treatment (e.g., mucositis secondary to cancer chemotherapy) or require a dental exam to eliminate a possible source of infection during cancer chemotherapy.[9]

In hospital practice, the dental consultant is always advisory to the patient's attending physician; the recommendations listed at the end of the consultation report are suggestions and not *orders,* and are not implemented unless authorized by the attending physician. For some oral lesions and mucosal abnormalities, a brief history and examination of the lesion will readily identify the problem, and only a short report is required; this accelerated procedure is referred to as a limited consultation (Box 1-2).

Both custom and health insurance reimbursement systems recognize the need of individual practitioners to request the assistance of a colleague who may have more experience with the treatment of a particular clinical problem or who has received advanced training in a medical or dental specialty pertinent to the patient's problem. However, this practice of specialist consultation is usually limited to defined problems, with the expectation that the patient will return to the referring primary care clinician once the nature of the problem has been identified (diagnostic consultation) and appropriate treatment has been prescribed or performed (consultation for diagnosis and treatment).

ESTABLISHING A DIFFERENTIAL AND FINAL DIAGNOSIS

Before establishing a final diagnosis, the clinician often needs to formulate a differential diagnosis based on the history and physical examination findings. The disorders included in the differential diagnosis will determine which laboratory tests, such as biopsies, blood tests, or imaging studies, are required to reach a final diagnosis.

Box 1-2 Outpatient Oral Medicine Consultation

Date: _____

To: John Doe MD

From: Robert Dent DMD

Patient Name and Date of Birth

The patient is a 19-year-old female sent for a consultation for evaluation of recurring oral ulcerations, which have been increasing in severity for the past 5 months.

The patient has a history of occasional oral ulcers since age 10 with 2 to 3 ulcers occurring 3 to 4 times yearly and lasting 8 to 10 days. Five months ago, she began to experience 5 to 10 ulcers each month lasting 2 to 3 weeks. Each episode has been treated with prednisone 30 mg once daily for 5 to 7 days. The lesions heal with this regimen, but recur in 3 to 4 weeks.

The patient denies conjunctival lesions, although on 2 occasions during the past 3 months she had a vaginal ulcer. She has acne-type facial lesions since taking prednisone monthly.

Her past medical history is remarkable for depression. She denies hospitalizations or surgery and has no known drug allergies.

She takes Lexapro for depression, but no medications other than prednisone for oral ulcers.

Her review of systems is remarkable for weekly episodes of intestinal cramping and diarrhea. She denies GI bleeding or black tarry stools. The remainder of the review of systems is noncontributory except for the skin and vaginal lesions noted above.

The family history is significant for her mother and maternal grandmother having a history of recurring oral ulcers during adolescence. Her father is of Japanese descent and her mother is Caucasian.

She is currently a college student and denies smoking or use of recreational drugs.

The examination showed multiple acne-like lesions of the skin of the face.

There was no cervical lymphadenopathy or salivary gland enlargement.

Cranial nerves II–XII were grossly intact.

The oral mucosa had 5 shallow ulcers 5 mm to 8 mm in diameter surrounded by inflammation: two involving the left lateral tongue, one on the dorsal tongue, and one involving the left buccal mucosa. No vesicles or white lesions were present.

Impressions

1) Recurrent aphthous ulcers; increasing in severity during the past 5 months
2) R/O Behçet's disease
3) R/O Lupus
4) R/O celiac disease
5) R/O blood dyscrasia

Plan:

1) Order the following laboratory studies: CBC, CMP, ANA, ESR, tTG-IgA
2) Dermatology consult for evaluation of skin and vaginal lesions, and pathergy test
3) Ophthalmology consult to rule out uveitis or retinal vasculitis suggestive of Behçet's disease
4) GI consultation
5) Biopsies of oral ulcer for routine histology and lupus band test
6) Begin treatment with Clobetasol propionate gel, 0.05% directly to lesions tid
7) If the above laboratory tests and consultations are normal and there is inadequate benefit from topical steroids, consider a trial of pentoxifylline or colchicine

The rapidity and accuracy with which a diagnosis or set of diagnoses can be achieved depend on the history and examination data that have been collected and on the clinician's knowledge and ability to match these clinical data with suspected disease processes. Experienced clinicians with a more extensive knowledge of physiology and maxillofacial disease, and a broader knowledge of the relevant literature, can more rapidly establish a differential and diagnosis. Such "mental models" of disease syndromes also increase the efficiency with which experienced clinicians gather and evaluate clinical data and focus supplemental questioning and testing at all stages of the diagnostic process.

For effective treatment, as well as for health insurance and medicolegal reasons, it is important that a diagnosis (or diagnostic summary) is entered into the patient's record, following the detailed history and physical, radiographic, and laboratory examination findings. This may be a provisional diagnosis dependent on the results of investigation. When more than one health problem is identified, the diagnosis for the primary complaint is usually listed first. Previously diagnosed conditions that remain as actual or potential problems are also included, with the qualification "by history," "previously diagnosed," or "treated" to indicate their status. Problems that were identified but not clearly diagnosed during the current evaluation can also be listed with the comment "to be ruled out." Since oral medicine is concerned with problems that may be modified or linked to concurrent systemic diseases, it is common for the list of diagnoses to include both the oral problem such as a lesion or pain and systemic problems of actual or potential significance in the etiology or management of the oral problem. Items in the medical history that do not relate to the current problem and are not of major health significance usually are not included in the diagnostic summary. For example, for a presenting complaint of pain and swelling in the left side of the face in a 62-year-old female, a diagnosis list might read as follows:

Current:	1)	Alveolar abscess, mandibular left first molar
	2)	Rampant generalized dental caries secondary to radiation-induced salivary hypofunction
	3)	Hyperglycemia; R/O diabetes
Previous	4)	Carcinoma of the tonsillar fossa, by history, excised and treated with 65 Gy 2 years ago
	5)	Cirrhosis and prolonged prothrombin time, by history

A definite diagnosis cannot always be made, despite a careful review of all history, clinical, and laboratory data. In such cases, a descriptive term (rather than a formal diagnosis) may be used for the patient's symptoms or lesion, with the added word "idiopathic," "unexplained," or (in the case of symptoms without apparent physical abnormality) "functional" or "symptomatic." If a note is written prior to a definitive diagnosis, a clinician may list a descriptive term such as chronic oral ulcer with the diseases that must be "ruled out" (R/O) listed, from most to least likely. For example:

oral ulcer from chronic trauma
R/O squamous cell carcinoma
R/O granulomatous disease

The clinician must decide which terminology to use in conversing with the patient and whether to clearly identify this diagnosis as "undetermined." It is important to recognize the undiagnosed nature of the patient's problem and to schedule additional evaluation, by referral to another consultant, additional testing, or placement of the patient on recall for follow-up studies.

Unfortunately, there is no generally accepted system for identifying and classifying diseases, and diagnoses are often written with concerns related to third-party reimbursement and to medicolegal and local peer review, as well as for the purpose of accurately describing and communicating the patient's disease status. Within different specialties, attempts have been made to achieve conformity of professional expressions and language.

Some standardization of diagnoses has been achieved in the United States as a result of the introduction in 1983 of the diagnosis-related group (DRG) system as an obligatory cost-containment measure for the reimbursement of hospitals for inpatient care. However, groupings are mostly based on medical diagnoses, such as the *International Classification of Diseases, Tenth Revision* (ICD-11).[10] The DRG system is designed for fiscal use rather than as a system for the accurate classification of disease. It also emphasizes procedures rather than diseases and has a number of serious flaws in its classification and coding system. The ICD system, by contrast, was developed from attempts at establishing an internationally accepted list of causes of death and has undergone numerous revisions in the past 160 years since it was first suggested by Florence Nightingale; it is maintained by the World Health Organization. It relates to the various emphases placed on clinical, anatomic, biochemical, and perceived etiologic classification of disease at different times and different locations. However, the categories for symptoms, lesions, and procedures applicable to oral cavity conditions are limited and often outdated.

The patient (or, when appropriate, a responsible family member or guardian) should also be informed of the diagnosis, as well as the results of the examinations and tests carried out. Because patients' anxieties frequently emphasize the possibility of a potentially serious diagnosis, it is important to point out (when the facts allow) that the biopsy specimen revealed no evidence of a malignant growth, the blood test revealed no abnormality, and no evidence of

diseases, such as diabetes, anemia, leukemia, or other cancer, was found. Equally important is the necessity to explain to the patient the nature, significance, and treatment of any lesion or disease that has been diagnosed.

FORMULATING A PLAN OF ACTION

Medical Risk Assessment

Medical risk assessment of patients before oral or dental treatment offers the opportunity for greatly improving dental services for patients with complex health conditions. It requires considerable clinical training and understanding of the natural history and clinical features of systemic disease. It is hoped that revisions in dental pre-doctoral training will recognize this need and provide greater emphasis on both the pathophysiology of systemic disease and the practical clinical evaluation and management of medically complex patients.

The information gathering described above is also designed to help the oral health professional:

- Recognize a general health status that may affect dental treatment.
- Make informed judgments on the risk of dental procedures.
- Identify the need for medical consultation to provide assistance in ascertaining the presence of a systemic disease that may be associated with an oral pathology or that may adversely impact on the proposed dental treatment.

Reaching the end point of the diagnostic process and the formulation of a plan of action are usually not a simple process. In order to minimize any adverse events, an assessment of any special risks associated with a patient's compromised medical status that could be triggered by the planned anesthetic, diagnostic, or medical or surgical treatment procedure must be entered in the patient record, usually as an addendum to the plan of treatment. This process of medical risk assessment is the responsibility of all clinicians prior to initiating any treatment or intervention and applies to outpatient as well as inpatient situations.

A routine of initial history-taking and physical examination is essential for all dental patients, as even the apparently healthy individual may, on evaluation, be found to have a history or examination findings of sufficient significance to require a modification to the plan of treatment, a change to a medication, or deferring dental treatment until additional diagnostic data are available. To respect the familiar medical axiom *primum non nocere* (first, do no harm), all procedures carried out and all prescriptions given to a patient should be preceded by conscious consideration of the potential risk of the planned procedure. Establishing a formal medical risk assessment ensures a continuous evaluation process. A summary of the medical risk assessment, delineating potential risks from the proposed plan of action, should be entered in the patient record.

The Medical Complexity Status (MCS) was specifically developed for dental patients and has been used successfully for patients with medical problems ranging from nonsignificant to very complex diseases and conditions.[11] The MCS protocol is based on the premise that complications will rarely arise during provision of routine dental care in an outpatient setting to patients with stable or controlled medical conditions. However, modification of dental care may still be necessary in some circumstances and should be based on the level of the anticipated complication. The MCS classification and protocol, with examples, are described in more detail in Table 1-2.

Modification of Dental Care for Medically Complex Patients

Although there are many different medical conditions that may require modification of dental care, and protocols for a wide variety of situations, the assessment of risk to medically complex patients follows similar guidelines. It is helpful to focus on the following three questions, which will change according to the severity of the underlying disease or condition:

- What is the likelihood that the patient will experience an adverse event due to dental treatment?
- What are the nature and severity of the potential adverse event?
- What is the most appropriate setting in which to treat the patient?

Each of these questions can be subdivided into smaller entities, which will facilitate the assessment of the patient.

The four major concerns that must be addressed when assessing the likelihood of the patient experiencing an adverse event are:

- Potential for impaired hemostasis from medications or disease.
- Potential susceptibility to infection, both maxillofacial and distant to the oral cavity (e.g., infective endocarditis).
- Drug actions and interactions.
- Patient's ability to tolerate the stress and trauma of the dental procedure.

Patients are designated to an MCS category at their initial dental visit, which may be modified during subsequent visits

Table 1-2 Medical complexity status classification and protocol.

Major categories
MCS 0 Patients with no medical problems
MCS 1 Patients with controlled or stable medical conditions
MCS 2 Patients with uncontrolled or unstable medical conditions
MCS 3 Patients with medical conditions associated with acute exacerbation, resulting in high risk of mortality
Subcategories
A No anticipated complications
B Minor complications are anticipated. "Minor complications" are defined as complications that can be successfully addressed in the dental chair
C Major complications are anticipated. "Major complications" are defined as complications that should be addressed by a medical provider and may sometimes require a hospital setting
Examples of different MCS categories
MCS–0
A healthy patient
MCS–1A
A patient with controlled hypertension (No modifications to routine dental care are necessary)
MCS–1B
A patient with epilepsy (petit mal) that is controlled with medications (The patient's epilepsy status is controlled, but if the patient has a seizure, it will pass without any interventions from the oral healthcare practitioner. It would be pertinent to avoid any dental treatment that may bring about a seizure)
MCS–1C
A patient with a penicillin allergy (The allergy will not change a stable condition, but if penicillin is given, a major complication may ensue)
MCS–2A
A patient with hypertension and a blood pressure of 150/95 mm Hg but without any target organ disease (see Chapter 14, "Diseases of the Cardiovascular System") (The patient's hypertension is by definition not controlled, i.e., it is above 140/90 mm Hg. Yet this level of blood pressure, in an otherwise healthy patient, does not justify instituting any dental treatment modifications)
MCS–2B (see Chapter 22, "Disorders of the Endocrine System and of Metabolism")
A patient with diabetes mellitus and a glycosylated hemoglobin of 11% (Because of the patient's poor long-term glycemic control, the patient may be more susceptible to infections and poor wound healing. Dental modifications, such as possible antibiotics before a surgical procedure, may be indicated)
MCS–2C
A patient with uncompensated congestive heart failure (Because of the patient's compromised medical condition, it is important to avoid placing the patient in a supine position in the dental chair as this may induce severe respiratory problems)
MCS–3
A patient with unstable angina

according to the patient's changing medical status. Based on several critical items—MCS category, experience of the oral healthcare professional, the patient's ability to tolerate dental care, adequacy of the dental facility—a determination of where the patient is best treated should be made:

- A non-hospital-based outpatient setting.
- A hospital-based outpatient setting.
- An inpatient short-procedure unit setting.
- An inpatient operating room setting. Most medically complex patients can be safely treated when the factors mentioned earlier have been addressed.

A plan of treatment of this type, which is directed at the causes of the patient's symptoms rather than at the symptoms themselves, is often referred to as rational, scientific, or definitive (in contrast to symptomatic, which denotes a treatment plan directed at the relief of symptoms, irrespective of

their causes). The plan of treatment (similar to the diagnostic summary) should be entered in the patient's record and explained to the patient in detail. This encompasses the procedure, chances for improvement or cure (prognosis), potential complications and side effects, and number of appointments and expense. As initially formulated, the plan of treatment usually lists recommended procedures for the control of current disease as well as preventive measures designed to limit the recurrence or progression of the disease process over time. For medicolegal reasons, the treatment that is most likely to eradicate the disease and preserve as much function as possible (i.e., the ideal treatment) is usually entered in the chart, even if it is clear that compromises may be necessary to obtain the patient's consent to treatment.

It is also unreasonable for the clinician to prejudge a patient's decision as to how much time, energy, and expense should be expended on treating the patient's disease or how much discomfort and pain the patient is willing to tolerate. Patient involvement in decisions regarding the treatment plan—shared decision-making—is necessary to help achieve a satisfactory outcome. Such an approach has been promulgated by the Institute of Medicine as "patient-centered care" and is defined as "Providing care that is respectful of and responsive to individual patient preferences, needs, and values, and ensuring that patient values guide all clinical decisions."[12]

The plan of treatment may be itemized according to the components of the diagnostic summary and is usually written prominently in the patient record to serve as a guide for the scheduling of further treatment visits. If the plan is complex or if there are reasonable treatment alternatives, a copy should also be given to the patient to allow consideration of the various implications of the plan of treatment that they have been asked to agree. Modifications of the ideal plan of treatment, agreed on by patient and clinician, should also be entered in the chart, together with a signed disclaimer from the patient if the modified plan of treatment is likely to be significantly less effective or unlikely to eradicate a major health problem.

Numerous protocols have been proposed to facilitate efficient and accurate preoperative assessment of medical risk. Many of the earlier guides were developed for the assessment of risks associated with general anesthesia or major surgery and focus on mortality as the dependent variable. All too often, these were adopted for risk assessment associated with invasive dental procedures performed under local or regional anesthesia. Of these, the most commonly used is the American Society of Anesthesiologists (ASA) Physical Scoring System (Table 1-3).[13] Although scores such as the ASA classification are commonly included in the preoperative evaluation of patients admitted to hospitals for dental surgery, they use relatively broad risk categories, and their applicability to both inpatient and outpatient dental procedures is limited. Importantly, the ASA score was developed for and is used to assess a patient's ability to tolerate general anesthesia and should therefore not be used to predict complications associated with dental surgery in the outpatient setting.

Table 1-3 American Society of Anesthesiologists (ASA) physical status classification system.

ASA I	A normal healthy person
ASA II	A patient with a mild disease
ASA III	A patient with a severe systemic disease
ASA IV	A patient with a severe systemic disease that is a constant threat to life
ASA VI	A declared brain-dead patient whose organs are being removed for donor purposes

In the event of an emergency, precede the number with an "E."

Monitoring and Evaluating Underlying Medical Conditions

Several major medical conditions can be monitored by oral healthcare personnel.[14] Signs and symptoms of systemic conditions, the types of medications taken, and the patient's compliance with medications can reveal how well a patient's underlying medical condition is being controlled. Signs of medical conditions are elicited by physical examination, which includes measurements of blood pressure and pulse, or laboratory or other diagnostic evaluations. Symptoms are elicited through an ROS, whereby subjective symptoms that may indicate changes in a patient's medical status are ascertained. A list of the patient's present medications, changes in medications and daily doses, and a record of the patient's compliance with medications usually provide a good indicator of how a medical condition is being managed. The combined information on signs, symptoms, and medications is ultimately used to determine the level of control and status of the patient's medical condition.

CLINICAL OUTCOMES AND ORAL DISEASE SEVERITY SCORING

All fields in medicine work toward evidence-based therapy. It is regarded as essential for the advancement of any field, including oral medicine, that there is continuous assessment of the results of treatment, so leading to progress in management. However, it is true that many treatments for oral

diseases are not evidence based, even those regarded as standard therapies. Until the last few years, there had been a lack of any method to routinely assess disease severity and thus to quantify responses to therapies. This led to the obvious need to devise and validate oral disease severity scores for a variety of conditions seen in routine clinical practice, which could also be used for assessing treatment responses. The accepted principle in medicine and surgery is that the response to therapy should be assessed in every single patient seen. This can be performed both from the perspective of the clinician (disease severity scores) and from the patient (patient-reported outcome measures or PROMs).

Disease severity scoring systems are tools that can help clinicians assess both the severity of the objective clinical findings as well as the subjective features of the disease, including its impact on patients' lives. There are three essential aspects that are important in defining the "intensity of the disease": clinical score measuring the level of inflammation, area, and specific clinical features (e.g., ulceration); subjective reporting of pain that the disease is inflicting; and a questionnaire relating to how the condition affects patients' functioning and their lives, known as oral health-related quality of life (OHRQoL).[15] There are now several validated and universally used tools for oral diseases that should be used at every patient visit.

Oral Disease Severity Scoring

The benefits of a scoring system for mucosal disease severity are that (1) they can indicate the severity of disease; (2) they are needed to indicate the efficacy of any treatments; (3) they may distinguish between or reveal subgroups of activity; (4) they may assist in deciding to implement or withhold treatment; and (5) they are a routine clinical audit tool that can also be used for research.

Any such oral disease scoring systems (ODSS) much be objective, must be reproducible, should be easy to use, and should be widely applicable. Fortunately, such ODSSs have been created, validated, and are in use for recurrent aphthous ulceration, oral lichen planus pemphigus, mucous membrane pemphigoid, orofacial granulomatosis, and dry mouth assessment.[15–20] Although additional work is required before these scoring systems are universally accepted and utilized, the principle of assessing disease severity at each clinical consultation is regarded as good clinical practice. See Chapter 4 for more on oral disease severity scoring.

Patient-Reported Outcome Measures and Oral Mucosal Disease

Alongside oral disease severity scoring, it is important to record PROMs. Whereas ODSSs are physician records of disease severity that allow clinical assessment of response to treatment, patient-reported outcomes record outcomes from a patient's perspective and are equally important in overall outcome success. On occasion, the PROMs score will demonstrate satisfaction at the outcome, even though the ODSS may be unchanged or vice versa. There are now simple, validated systems for PROMs[15] and it is appropriate for both to be recorded.

THE DENTAL AND MEDICAL RECORD

The patient's record is customarily organized according to the components of the history, physical examination, diagnostic summary, plan of treatment, and medical risk assessment described previously in this chapter. Test results (diagnostic laboratory tests, radiographic examinations, and consultation and biopsy reports) are filed after this, followed by dated progress notes recorded in sequence. Separate sheets are incorporated into the record for the following: (1) a summary of medications prescribed for or dispensed to the patient; (2) a description of surgical procedures; (3) the anesthetic record; (4) a list of types of radiographic exposures; and (5) a list of the patient's problems and the proposed and actual treatment. This pattern of organization of the patient's record may be modified according to local custom and to varying approaches to patient evaluation and diagnostic methodology taught in different institutions.

In recent years, educators have explored a number of methods for organizing and categorizing clinical data, with the aim of maximizing the matching of the clinical data with the "mental models" of disease syndromes referred to earlier in this chapter. The problem-oriented record (POR) and the condition diagram are two such approaches; both use unique methods for establishing a diagnosis and also involve a reorganization of the clinical record.

Problem-Oriented Record

The POR focuses on problems requiring treatment rather than on traditional diagnoses. It stresses the importance of complete and accurate collecting of clinical data, with the emphasis on recording abnormal findings rather than on compiling the extensive lists of normal and abnormal data that are characteristic of more traditional methods (consisting of narration, checklists, questionnaires, and analysis summaries). Problems can be subjective (symptoms), objective (abnormal clinical signs), or otherwise clinically significant (e.g., psychosocial) and need not be described in prescribed diagnostic categories. Once the patient's problems have been identified, priorities are established for further diagnostic evaluation or treatment of each problem.

These decisions (or assessments) are based on likely causes for each problem, risk analysis of the problem's severity, cost and benefit to the patient as a result of correcting the problem, and the patient's stated desires. The plan of treatment is formulated as a list of possible solutions for each problem. As more information is obtained, the problem list can be updated, and problems can be combined and even reformulated into recognized disease categories.

The POR is helpful in organizing a set of complex clinical data about an individual patient, maintaining an up-to-date record of both acute and chronic problems, ensuring that all of the patient's problems are addressed, and ensuring that preventive as well as active therapy is provided. Furthermore, the POR facilitates interprofessional communication and is a foundation for collaborative practice and teaching.[21,22] It is also adaptable to computerized patient-tracking programs. However, without any scientifically based or accepted nomenclature and operational criteria for the formulation of the problem list, data cannot be compared across patients or clinicians. An additional concern that has been put forward is the reliance on a POR to "automatically" generate a diagnosis.[23] Although the POR will allow for a systematic approach to delineate specific problems, clinicians need to be able to synthesize findings into an appropriate diagnosis.[24]

Despite these shortcomings, two features of the POR have received wide acceptance and are often incorporated into more traditionally organized records: the collection of data and the generation of a problem list. The value of a problem list for individual patient care is generally acknowledged and is considered a necessary component of the hospital record in institutions accredited by the Joint Commission on Accreditation of Healthcare Organizations. Furthermore, the use of a problem-oriented approach may enhance the utilization of and satisfaction with EHRs.[25]

SOAP Note

The SOAP note concept, as well as POR, was initially proposed by Dr. Lawrence ("Larry") Weed in the 1960s and has ever since been a mainstay in teaching and clinical care.[26,27] The purpose of this type of documentation was to provide a clinician with a systematic and structured method—a checklist—to record patient findings. The SOAP note is also used for communication between healthcare professionals and as a teaching aid.

The four components of a problem—Subjective, Objective, Assessment, and Plan—constitute the SOAP mnemonic for organizing progress notes or summarizing an outpatient encounter (see Box 1-3). The components of the mnemonic are as follows:

- *S or Subjective*—the patient's experience, complaint, symptoms, and medical history (a brief review of the chief complaint, HPI, PMH, ROS, current medications, and allergies).
- *O or Objective*—the general clinical examination (physical examination, vital signs); review of laboratory data, imaging results, other diagnostic data; review of documentation from other healthcare providers; and a focused evaluation of the chief complaint or the area of the procedure to be undertaken.

Box 1-3 SOAP Note: Example: A progress note placed in a patient's chart after an oral medicine evaluation

Date _____

S—The patient is a 32-year-old women with a history of multiple sclerosis and recent increasing loss of visual acuity and muscle weakness, with sudden onset of severe but brief episodes of pain involving the left mandibular region. She was admitted by Neurology for evaluation and treatment with intravenous methylprednisone and interferon.

O—Touching lower left lip or gingiva in the region of the mental foramen triggers brief electric shock-like pain.
Extraoral exam reveals no lymphadenopathy, major salivary gland tenderness, or enlargement.
Intraoral exam shows no mucosal lesions or masses in the area of the left mandible. Teeth are not tender to percussion and no dental caries, fractured teeth, or removable prosthesis noted.
Panoramic radiography of the left mandible showed no dental or bony pathology.
A recent MRI of the brain, reviewed with radiology, demonstrated a demyelinating plaque involving the left trigeminal nerve root.

A—Trigeminal neuralgia secondary to multiple sclerosis, no evidence of an oral source for her pain.

P—Current plan includes a trial of carbamazepine or oxcarbazepine.

*Signature*_____

- *A or Assessment*—a synthesis of the subjective and objective findings to arrive at a diagnosis (problem list and differential diagnosis) for the specific problem being addressed.
- *P or Plan*—the need for additional information (e.g., laboratory tests, consultations); referrals; treatment recommendation; patient education for the purpose of shared decision-making.

The SOAP note is a useful tool for organizing progress notes in the patient record for routine office procedures and follow-up appointments. It is also quite useful in a hospital record when a limited oral medicine consultation must be documented. However, in order for other healthcare professionals to more easily retrieve the most relevant information, it might be better to reorganize and document the SOAP note as an ASOP note (Assessment, Plan, Subjective, Objective). One significant drawback with the SOAP framework is the lack of a temporal or time component. This can be remedied by including a time component before consecutive SOAP notes. For example, "The present SOAP note is recorded 14 days following the last SOAP note. During this time the following changes have occurred: ...."

Confidentiality

Patients provide dentists and physicians with confidential dental, medical, and psychosocial information, on the understanding that the information (1) may be necessary for effective diagnosis and treatment; (2) will remain confidential; and (3) will not be released to other individuals without the patient's specific permission. This information may also be entered in the patient's record and shared with other clinical personnel involved in the patient's treatment, unless the patient specifically requests otherwise. Patients are willing to share such information with their dentists and physicians only to the extent that they believe that this contract is being honored.

There are also specific circumstances in which the confidentiality of clinical information is protected by law and may be released to authorized individuals only after compliance with legally defined requirements for informed consent (e.g., psychiatric records and confidential HIV-related information). Conversely, some medical information that is considered to be of public health significance is a matter of public record when reported to the local health authorities (e.g., clinical or laboratory confirmation of reportable infectious diseases such as syphilis, hepatitis, or AIDS). Courts may also have the power to subpoena medical and dental records under defined circumstances, and records of patients participating in clinical research trials may be subject to inspection by a pharmaceutical sponsor or an appropriate drug regulatory authority. Dentists are generally authorized to obtain and record information about a patient to the extent that the information may be pertinent to the diagnosis of oral disease and its effective treatment.

Conversations about patients, discussion with a colleague about a patient's personal problems, and correspondence about a patient should be limited to those occasions when information essential to the patient's treatment has to be transmitted. Lecturers and writers who use clinical cases to illustrate a topic should avoid mention of any item by which a patient might be identified and should omit confidential information. Conversations about patients, however casual, should never be held where they could possibly be overheard by unauthorized individuals, and discussion of patients with nonclinical colleagues, friends, family, and others should always be avoided and should never include confidential patient information.

Informed Consent

Prior consent of the patient is needed for all diagnostic and treatment procedures, with the exception of those considered necessary for treatment of a life-threatening emergency in a comatose patient.[28] In dentistry, such consent is more often implied than formally obtained, although written consent is generally considered necessary for surgical procedures (however minor), for the administration of general anesthetics, and for clinical research.

Consent of the patient is often required before clinical records are transmitted to another dental office or institution. In the United States, security control over electronic transmission of patient records has since 1996 been governed by the Health Insurance Portability and Accountability Act (HIPAA). The creation and transmission of electronic records are an evolving process that is mainly dependent on technological advances and fast movement of the integration of electronic patient information.[29]

There may also be specific laws that discourage discrimination against individuals infected with infectious diseases, such as HIV, by requiring specific written consent from the patient before any HIV-related testing can be carried out and before any HIV-related information can be released to insurance companies, other practitioners, family members, and fellow workers.[30] Oral healthcare professionals treating patients whom they believe may be infected with HIV must therefore be cognizant of local law and custom when they request HIV-related information from a patient's physician, and they must establish procedures in their own offices to protect this information from unauthorized release. In response to requests for the release of psychiatric records or HIV-related information, hospital medical record departments commonly supply the practitioner with the necessary additional forms for the patient to sign before the records are released. Psychiatric information that is released is usually restricted to the patient's diagnoses and medications.

TELEHEALTH/TELEDENTISTRY

Telehealth has been defined as "communication and information technologies [used] to provide or support long-distance clinical health care, patient and professional health-related education, public health, and health administration."[31] Although sometimes used interchangeably, several designations, such as telemedicine, mHealth, and eHealth, have been used to described how to interact and provide care when there is no direct physical contact—remotely—between providers and patients. According to some definitions, telehealth refers to a broad scope of remote healthcare services that may include nonclinical services, while telemedicine specifically refers to remote clinical services.[32] mHealth is usually employed to describe technology used by patients to capture their own health data with the help of apps on devices such as smartphones and tablets, while eHealth mostly refers to utilizing the internet and similar technology.

One of the major drawbacks for the utilization of teledentistry in oral medicine is the inability to perform a clinical examination that includes components such as touch and palpation. In telemedicine there are already armamentaria that aim to overcome these types of limitations. For example, there exist electronic stethoscopes, dermatoscopes, and scales, as well as tele-ophthalmoscopes, video-otoscopes, and digital endoscopes.[33] However, studies have been performed where individuals can take pictures with their smartphones and share these images with a specialist who can make differential diagnoses and determine the need for additional studies, such as biopsies. This technology has enabled early detection of oral cancer, as well as HIV-associated lesions, among individuals in areas without immediate access to specialists.[34,35] Another study using a mobile telemedicine system to diagnose oral mucosal lesions remotely showed a high degree of accuracy, demonstrating the potential for future use of this technology in oral medicine.[36]

The need to develop better, more reliable, and validated technology for oral medicine purposes will enhance our ability to provide care to individuals not only in remote areas, but also during circumstances where person-to-person interactions are being discouraged due to, for example, a pandemic. The Covid-19 pandemic has substantially increased the routine use of telemedicine by many clinicians, including oral medicine specialists. It is expected that as these clinicians become experienced using telemedicine, its use will continue to expand in clinical practice.

Overview of Clinical Research

Dena J. Fischer, DDS, MSD, MS
Darien Weatherspoon, DDS, MPH
Mary A. Cutting, MS, RAC

Evidence-based practice uses current scientific evidence to guide clinical decision-making. In dentistry, this practice integrates the dental professional's clinical expertise, the patient's needs and preferences, and the most current, clinically relevant evidence.[1] Oral health clinical research seeks to improve the evidence base to allow dental professionals and patients to make informed clinical care decisions. The purpose of this chapter is to provide a brief overview of types of research involving human subjects and the features of good clinical research, including ethical and regulatory considerations.

DEFINITIONS OF HUMAN SUBJECTS AND CLINICAL RESEARCH

The US Department of Health and Human Services (Title 45 Code of Federal Regulations (CFR) Part 46)[2] defines a human subject as "a living individual about whom an investigator (whether professional or student) conducting research: obtains information or biospecimens through intervention or interaction with the individual, and uses, studies, or analyzes the information or biospecimens; or obtains, uses, studies, analyzes, or generates identifiable private information or identifiable biospecimens." Research involving human subjects must be reviewed by the overseeing Institutional Review Board (IRB), or an equivalent ethics committee or board in countries outside of the US, to seek approval or determination of exemption prior to enrolling research participants. Human subjects research includes all research in which investigators interact directly with subjects to collect research data, including survey research, and research utilizing existing data/biospecimens from human subjects if at least one member of the research team has the ability to link data/biospecimens to identifiable information.[3] For human subjects research utilizing existing data/biospecimens, an IRB or equivalent ethics committee will make a determination about whether the study would be exempt or non-exempt depending upon the role of the study team member who has access to identifiable information.

Burket's Oral Medicine, Thirteenth Edition. Edited by Michael Glick, Martin S. Greenberg, Peter B. Lockhart, and Stephen J. Challacombe.

Human subjects are also sometimes referred to as "participants," and both terms will be used throughout this chapter.

"Clinical research" can be broadly defined as patient-oriented research. Many types of studies are included under this definition, including studies of human disease mechanisms, natural history studies of disease, epidemiologic studies, prognostic studies, studies of technologies or procedures used to diagnose, prevent, or treat human diseases, outcomes research, and health services research. Clinical research can be broadly categorized as observational or interventional research. In observational studies, participants are identified as belonging to study groups and are assessed for biomedical or health outcomes. Participants may receive diagnostic, preventive, therapeutic, or other types of interventions as "standard of care," but the investigator does not assign the participants to a specific group. Interventional research, or clinical trials, involves prospective assignment of participants to one or more interventions to test the effect of the intervention(s) on the disease or condition. "Intervention" includes anything that can alter the course of a disease, such as a pharmaceutical agent, a medical device, a surgical technique, a behavioral intervention, or a public health program. Clinical research studies, whether observational or interventional, require approval by an IRB or equivalent ethics board/committee and provision of informed consent by the study participants.

STUDY DESIGNS

Several types of designs are available to study diseases and conditions and collect research information. The study designs described below are commonly employed in clinical research.

Case Report and Case Series

A case report (singular) or case series (plural) is a description of one or several individuals with a disease or condition of interest. A case report can offer insights into diagnosis and management of a disease or condition by providing details about the patient's clinical presentation, diagnostic work-up, differential diagnoses, final diagnosis, management, and current disposition. Examples include descriptions of: orofacial manifestations of a patient with a systemic disease and strategies to manage the disease, unusually shaped teeth in a child or children with a genetic syndrome, or an adult presenting with orofacial pain from an unusual source such as a metastatic tumor and the diagnostic approach to determine the pain etiology. The description should be complete enough for use by another clinician who may evaluate a similar case. If the study is a case series, the same diagnostic criteria should be used to group the cases together for a report.

Case series can be very valuable in the description of new diseases or conditions. A good example is the large case series describing 63 cases of osteonecrosis of the jaw (ONJ) associated with the use of bisphosphonates.[4] While the report of this emerging clinical condition suggested a relationship to use of bisphosphonate medication, an obvious limitation of this study design is the lack of a population of individuals without the disease or condition, or a "control" group. Other limits of a case series include the fact that most data are obtained via a retrospective review of existing clinical records. This introduces the potential for recall bias as the researchers are "looking back" at events and extracting record information, which often is a mixture of complete and incomplete facts. Also, the information is recorded for clinical care and not research purposes. Therefore, clinicians will use varying methods to evaluate patient outcomes, such as a non-healing extraction site. If the patients were evaluated as part of a research study, the study team would use a predefined set of criteria to determine study inclusion and judge clinical outcomes and would collect a predefined set of information from the patients such as current and past medications.

Cross-Sectional Studies

Cross-sectional studies are employed frequently in clinical research. Research participants are evaluated at one time point and are not followed over time, creating a dataset that is a "snapshot" of the condition under study. Prevalence studies use cross-sectional designs that describe the population under study, derive a representative sample of that population and define the characteristics under study to establish the prevalence of a disease or condition in a population.[5] For example, the prevalence of oral human papillomavirus (HPV) infection in unvaccinated men and women has been estimated through the National Health and Nutrition Examination Survey (NHANES) 2009–2016.[6] The NHANES study uses a statistically representative sample of the civilian non-institutionalized US population. Many factors must be considered when designing a cross-sectional prevalence study. First, it is not usually feasible to examine an entire population of individuals with a disease or condition. Therefore, the sample being examined should represent the entire population at risk and not only those most severely affected. In the example of ONJ, patients with small non-healing affected sites that healed in two to three months without any intervention should be included as well as those with large lesions that persisted for months, to represent the entire spectrum of the disease. Second, all research participants should be evaluated using the same, standardized methods (read "Outcome Assessment" below). Prevalence studies require very large sample sizes and, therefore, may need to be conducted at more than one

study site (multi-centered) to achieve adequate enrollment. When the number of individuals with the disease of interest is very limited, it may not be possible to conduct a prevalence study.[5]

Cross-sectional studies may also be utilized to assess relationships between an exposure or risk factor and the presence of disease. Because research participants are evaluated at one time point, causal inferences cannot be drawn between the risk factor and disease, representing a major limitation of this study design. Using the example of periodontal disease and cardiovascular disease, some cross-sectional studies have suggested an association between the two conditions. It is important to recognize that the two conditions can occur together in a person because of a common underlying etiology, such as smoking, environmental exposures, and/or limited access to the health care system.[7] Cross-sectional studies linking these conditions do not prove that one causes the other. The temporal relationship, that is, which condition occurs first, cannot be determined from a cross-sectional study. Nevertheless, such cross-sectional designs have value in research, particularly to develop hypotheses for future studies. An initial relationship between a risk factor and presence of disease may be established in a cross-sectional study before consideration of a more resource-intensive study design in which risk factors for disease can be evaluated over time. When establishing initial relationships using a cross-sectional design, the biologic plausibility between the risk factor(s) and disease and potential biases due to data collection at one time point should be described. For example, when exploring the relationship between periodontal disease and cardiovascular disease, study participants may report healthy behaviors such as frequent flossing if they have started to alter their oral health behaviors.

Case-Control Studies

A case-control study is an observational study in which the objective is to evaluate persons with the disease or outcome of interest (cases) and compare them with another group of persons without the disease or outcome (controls) to determine if certain exposures (such as being a current smoker or taking a specific medication) or characteristics are associated with the disease or lack of disease. If the exposure is found more frequently in the cases, it is termed a "risk factor" for having the disease. Sometimes the exposure is found more frequently in the control group, suggesting it might be a "protective factor" that helps protect against a disease. Because this design evaluates individuals with and without the disease or outcome of interest, it may be used to assess the presence or absence of disease, but not development of the disease. There are critical design issues that must be considered in a case-control study.[5] The exposure and disease in both cases and controls should be assessed in the same manner. Patients who have a severe disease may experience recall bias in that they remember more or over-report past exposures or symptoms than generally healthy controls because they are seeking an explanation for why they have a disease. The cases need to represent the entire population of those with the disease, and the controls must be selected from the same population as the cases and should have the same prognostic characteristics. Finally, most experts recommend evaluating at least an equal number of controls as cases and matching cases and controls on variables that may differentially affect the exposure and disease. Selection of controls for a case-control study can be difficult and can introduce bias into the study if not chosen carefully, as discussed at length in the literature.[8–10] A case control study performed across three dental practice-based research networks assessed risk factors for ONJ.[11] ONJ cases were defined as having maxillary or mandibular exposed bone of any size that clinically appeared necrotic, without regard to duration or size. For each case, three controls with no current or previous history of bone necrosis were selected from the same dental practice where a case was diagnosed. Risk factors were ascertained in cases and controls, and the odds of having ONJ in patients who took bisphosphonates was compared to the odds of having ONJ in those who did not take bisphosphonate medication.

Case-control studies are particularly beneficial when studying rare diseases. If the disease of interest is sufficiently rare, such as salivary gland cancers, it may be safe to assume that a sample of cases is representative of the entire population of those with the disease. Findings in case-control studies are typically reported as the odds ratio of the exposure, whereas cohort study (see below) findings are expressed in terms of the relative risk of exposure. Case-control study results cannot be reported as the relative risk, because the investigator determines, and can arbitrarily change, the disease prevalence within the study by setting the number of study participants with and without the disease or outcome of interest. When interpreting the results of case-control studies, limitations in assessing temporality between the exposure and disease and the confidence interval of the association should be considered before making conclusions about the validity (a term used to describe how well the study measures that which it is intended to measure) of the results. A finding of a "dose-response" (in which increasing levels of the exposure such as pack-years of smoking are associated with increasing rates of the disease or condition) increases the strength of the evidence.

Because of criticisms about potential bias arising from control selection in case-control studies, researchers may choose to utilize more than one control population when

designing studies. In a classic example from the medical literature, the relation between estrogen use and endometrial cancer was established using a well-designed case-control study design and two control populations.[12] Cases of endometrial cancer admitted to hospitals (451 cases) were matched to two sets of control populations admitted to hospitals without endometrial cancer, one taken from those seeking gynecological services (442 cases) and another from those who did not seek gynecological services (446 controls). The choice for selection of two hospital control populations was to offset concerns about surveillance bias; that is, that estrogen users may be under greater surveillance for disease development.

Longitudinal Cohort Studies

Longitudinal cohort studies allow the opportunity to collect data over time. The purpose of this study design is to assess associations between an exposure or risk factor and subsequent development of disease or to determine outcomes of standard of care treatment. When performed prospectively to assess associations between an exposure and disease, a representative sample of the population of interest is assessed for an exposure at the beginning of the study, and then new cases of disease accrue during a period of follow-up evaluation. At the end of the study, the differences in exposures between those with and without the disease are evaluated. In some cases, a single population is observed over a period of time to observe the natural incidence of a condition or the natural history of a disease. For example, a study of Swedish adolescents estimated the incidence of temporomandibular disorder (TMD) pain. All individuals aged 12 to 19 years in all Public Dental Service clinics in a Swedish county from 2000 to 2003 were followed over 3 years for development of TMD pain.[13] Research participants with TMD were evaluated for differences that distinguished them from participants without TMD. In this study, TMD incidence was found to be greater in older children and in girls. More frequently, research participants may be selected for a particular exposure, along with a comparable group of controls without the exposure, and both groups are followed over time for development of disease.[14] An example of a longitudinal cohort study examining outcomes of treatment is a study of 372 individuals with head and neck cancer who were enrolled prior to undergoing radiation treatment and followed to determine the rate of oral complications such as oral mucositis, oral pain, and oral health-related quality of life.[15]

Cohort studies may also be retrospective, in which the exposure was captured in a standardized manner in the past, disease status is determined at a point in time before the outcomes of interest developed, and participants are followed over time. This study design assumes that the participant population (exposed and unexposed participants) is representative of the general population, and exposure history is collected accurately. Definitions of disease outcome should be reliable and reproducible and held constant during the study duration. Standard criteria for determining the disease outcome should be applied to exposed and non-exposed participants to avoid bias.

One significant advantage of well-conducted prospective cohort studies over other study designs is that the exposure is collected in a standardized manner, and cases are incident (new cases). This design provides more information about the natural history of the disease, as well as direct estimates of incidence and relative risk.[5] Longitudinal cohort studies have the potential to initially or further establish the temporal relationship between exposure and disease and a dose-response relationship, both of which increase the strength of the study conclusions and may provide evidence about the association (or causality) between an exposure and disease. An important factor in prospective longitudinal cohort studies is the ability to retain the cohort over time. Participants who drop out of research studies may differ from those who remain and may introduce attrition biases into the population sample.

Longitudinal studies by their nature are resource intensive. Large sample sizes for rare diseases and long durations for chronic diseases may be required. Maintaining the use of consistent study methods, such as standardized collection of the exposure, and retaining research participants in the study are continual challenges.

Clinical Trials

The purpose of a clinical trial is to determine whether a particular intervention is associated with a change in a prespecified health-related outcome. A clinical trial involves prospective assignment into one or more intervention groups and assessment of an outcome measure.

Clinical trials can be classified into four phases (Phase I, II, III, or IV) or stages.[16] This step-wise approach reduces the potential for harm from a previously untested intervention and allows investigators to assess safety and determine potential efficacy of a new treatment while minimizing time and costs. A Phase I trial often is the "first-time in human" study, meaning trial participants are the first humans to receive the new drug or treatment. These studies are not randomized or blinded and are typically performed with a small number of participants. The primary goal is to evaluate the safety of the agent and determine a safe dose range for subsequent studies. A Phase II trial tests the new drug in individuals who are randomized to different treatments, with goals of determining potential efficacy and establishing a

more complete safety profile. Feasibility of using the treatment also can be determined. The Phase III trial enrolls hundreds or thousands of participants and is sometimes called a "pivotal study." These trials are designed to test efficacy in a much larger segment of the population with the disease or condition, and results are used to gain drug approval from government agencies. Phase III trials should generate generalizable results. Phase IV trials are post-marketing studies to determine how well a treatment found effective in a Phase III trial works in the community and to assess any side effects associated with its long-term use in the overall population.

A randomized controlled trial (RCT) compares participants receiving the intervention under study to a control group, such as participants receiving another treatment, usual care, placebo treatment, or no treatment. Potential study participants from a well-defined study population are assigned at random to receive or not receive the intervention(s) under study, and then well-defined endpoints are measured at a specific time point. Intervention efficacy is assessed by comparing the outcome measure between the intervention group(s) and the control. RCTs provide the strongest evidence for the causal nature of a modifiable factor (such as inflammation in a periodontal pocket), and the effect that modifying the factor has on disease outcomes (such as reduction in pocket depth).

A key component of RCTs is that research participants are assigned to one of the study arms at random to eliminate the potential for bias in treatment assignment. Random, concealed, or "blinded" allocation of treatment helps ensure that any baseline differences in the treatment groups arise by chance alone. The random allocation process involves generating an unpredictable random sequence and then implementing the sequence in a way that conceals the interventions until participants have been formally assigned to their groups. Both randomization and concealment are necessary to maximize validity in RCTs, and reproducibility of the allocation order and the concealment process are necessary to maintain integrity of the research study. Other important features of high-quality RCTs include independent or "blind" assessment of research endpoints and data analysis based upon the treatment assignment, also known as analysis by "intention to treat." Intention to treat analysis removes artifacts from the study that are caused by unequal attrition in the two study arms, or by treatment crossover.

There are three levels of concealing treatment (blinding) in an RCT: (1) participants are unaware of their study treatment group; (2) the investigators are unaware of the participant's study treatment group; and (3) the statistical analyses are conducted without knowledge of the groups' study treatment. Multiple levels of blinding can occur in an RCT and should be considered when feasible. Recent oral health RCTs that followed the strict principles of clinical trials were two Phase III studies testing periodontal therapy as a treatment to prevent preterm birth[17] and to improve glycemic control.[18]

A limitation of the RCT study design is the concern about external validity, or the extent to which RCT results are applicable beyond the research study. In addition, RCTs are expensive because of the logistics involved in sampling, blinding, treating, and following hundreds of participants; in addition, extremely large sample sizes are required to study rare outcomes. Consequently, some research questions may be more appropriately addressed using other study designs.

Systematic Reviews

A systematic review is a structured process of comprehensively reviewing published research studies focused on a research question in which inclusion and exclusion criteria for study selection are established *a priori*. The purpose of the systematic review is to determine the "state of the science" by objectively identifying, appraising, selecting, and synthesizing high-quality research evidence. Such reviews may also elucidate a paucity of high-quality evidence and, therefore, identify research questions to be addressed in future studies. For more information about systematic reviews, see Chapter 29: How to identify, interpret and apply the scientific literature to practice.

ISSUES IN THE DESIGN, IMPLEMENTATION, AND QUALITY OF CLINICAL RESEARCH

Clinical research, regardless of its type, is a scientific study. Therefore, investigators must take care to conduct studies that minimize bias and maximize reproducibility. Many factors should be considered when designing and implementing clinical studies, including the type of study design, sample size, research participant selection, methods to ascertain exposures and outcomes, ethical and human subjects concerns, and analytical approaches. Below are short descriptions of some of the features of clinical research to consider when designing clinical research studies.

Study Design

Investigators should employ a study design that is suitable and most appropriate for answering the clinical research question of interest. In general, investigators should review the literature on the topic of interest, define the purpose of the study and hypothesis to be tested, and then use the

strongest research design that is acceptable and feasible to address the research question.

Sample Size

When designing clinical research studies, an important consideration is the required number of study participants to draw meaningful statistical conclusions. The sample size depends upon the variability of the data and the effect size, or the difference between values.[25] Analyses should be conducted to determine the sample size needed to accomplish the goals of the study. For longitudinal studies, sample size calculations should take into account study participant attrition over time. Many clinical studies suffer from small sample sizes, and this issue is often a reason why studies are excluded from evidence-based reviews.[26]

Selection of Disease and Control Groups

Another critical factor to consider when designing a study is the definition and selection of the disease and control groups. The disease or case group should be carefully defined to include those individuals with the disease or condition of interest, but without other conditions or variables that may affect the validity of the study results.

Many clinical studies include a control group to compare study outcomes between the case or disease population and those who do not have the outcome of interest or do not receive the intervention being tested. For these studies, the control group should be clearly defined to include those individuals who are similar to the case or test group in many aspects so that there are minimal differing variables between the comparison groups.[8–10] Careful selection of control populations was described in the Case-Control Study section above. To guide control group selection, studies may match cases and controls based upon variables that may contribute to the exposure or disease presentation or severity such as gender, age, current/past smoking history, and setting where participants may be recruited for study participation, such as a tertiary care clinic. Controls should be chosen in the same manner as cases to ensure they have the same likelihood of having the exposure of interest.[8–10] For example, if cases are patients with head and neck cancer being recruited from a radiation oncology clinic, controls should be patients recruited from the same clinic, who are undergoing treatment for another condition.

Potential for Bias

When designing and conducting a research study, there are numerous types of bias that must be considered to maintain the validity of study results. Bias can occur at any phase of research, including decisions related to the study design, implementation of study procedures, methods of data collection, the process of data analysis, and publication of study results.[27] Some bias is inevitable and inherent in certain study designs, and the investigator must show that efforts have been undertaken to lessen the impact of study bias.

Methods to avoid selection bias in observational studies include enrolling consecutive individuals reporting to a clinic who meet inclusion criteria, or recruiting individuals from an existing large population using consistent recruitment criteria for all individuals. RCTs use randomization and allocation procedures for treatment arm assignment to avoid bias.

Other biases can occur during data collection. The use of objective, validated measures for outcome assessment and independent data collectors will reduce these biases (see section Outcome Assessment below). Some biases can be addressed through data analyses, such as accounting for potential confounders and effect modifiers.

Outcome Assessment

Study outcomes or endpoints used in a clinical study or trial must be measurable, reliable (consistent and repeatable), and valid to document disease prevalence and/or progression or determine the efficacy of the intervention being tested. The outcome must be reproducible, and there should be published evidence of its validity. For example, if the goal of a study is to quantify oral cancer pain, the investigator should use a validated instrument to collect pain measures appropriate for the population being studied. In this example, an appropriate instrument would be a pain scale that had been tested previously in a population for whom cancer pain had been assessed and for whom the cultural values related to expression of pain had been similar.

Methods for ascertainment of study outcomes also need to be standardized. Examiners should be calibrated, by having them each examine the same group of patients to measure outcome assessment agreement with each other (inter-rater reliability) and having them examine a set of patients repeatedly to measure their outcome assessment agreement with themselves (intra-rater reliability).[28] Studies that assess caries and periodontal disease over time usually conduct calibration sessions annually or prior to a wave of study visits, during which examiners are calibrated to a gold standard examiner and compared numerically using percentage agreement or kappa scores.[17,29]

Loss to Follow-up and Retention

When planning research studies that intend to follow research participants over time, significant efforts should be

made to retain those participants in the study. Minimizing loss to follow-up is critical to maintaining valid study results. Aside from the concern about missing data, when study participants are lost over time, there is no way to know if they exhibit characteristics that may be different from those who have been retained in the study, such as having more or less severe disease. Both simple and sophisticated analytic methods are available to model missing data, but these cannot protect against bias created by research participant loss. One can look at how participants lost to follow-up differ from those retained and undertake bootstrapping or other rigorous sensitivity analyses to impute missing data and establish a range for the study outcome.[30–32] However, these analytic methods have limitations that should be considered and should not replace the need for rigorous approaches to retain the study population.

Retention strategies should be planned prior to implementing the clinical study and should be tracked carefully throughout the study. If retention efforts are not producing the desired results, strategies should be reassessed and improved during the study's data collection phase.

Retention strategies that can be considered when designing a study include:

- Having a run-in period at the beginning of a study to eliminate those who will be lost or cannot comply.
- Obtaining reliable, complete participant contact information that may include alternate phone numbers, email and physical addresses.
- Obtaining names and contact information for designated family or friends who could be contacted for information on missing participants.
- Sending out communications such as newsletters and educational pieces that inform study participants of new findings in the field or progress of the study, as allowable.
- Sending out reminders such as birthday cards, text messages, phone messages, postcards, or letters.
- Having dedicated and professional study staff with low turnover to establish rapport with study participants.
- Employing outreach workers to find those who may be lost to follow-up.
- Having the data center follow-up individuals via phone or email should they fail to respond to contacts made by the clinic or site. It is possible the participant has a personal reason for not continuing in the study.
- Reviewing death records and registries to account for those missing due to demise.
- Reviewing public media to search for obituaries and accidents.
- Offering study visits during hours that accommodate participants; this may include early mornings, evenings, or weekends.
- Scheduling study visits with other necessary patient care to minimize the number of trips to the study site.
- Creating satellite clinics or sites near where patients are situated so they are not required to travel as much. Venues for data collection may include visits to participants' homes, churches, schools' or worksites to allow study visits to be less disruptive to participants' lives.
- Establishing methods for remote data collection when the study data and outcomes are suitable for such methods.
- Providing incentives that make it easier to participate in the study such as
  - child care
  - paid transportation to the site
  - remuneration as deemed appropriate by the IRB.

Prior to implementing retention strategies in a research study, they should be presented to the IRB for their approval. Further, with the exception of review of public information such as death registries or public media, strategies to obtain follow-up data from participants require participant consent to prevent privacy infringement. An engaged, informed, and interested study population is far more likely to be retained than one who is not.[31]

Analytical Issues

It is impossible in this limited space to discuss all the analytical issues of clinical studies. Important topics include prespecified analysis plans, avoidance of unsupported multiple comparisons, and attention to clinical significance of outcomes. Unless a study is fully hypothesis-generating and exploratory, the principal study hypothesis, sample size, power, and statistical analyses should be prespecified to protect against *ad hoc* analyses that attempt to make provocative conclusions from the data. It is tempting to conduct analyses for which the study was not specifically designed, and it is unusual for convincing, robust conclusions to be drawn from such *a posteriori* analysis. Another threat to the validity of analyses is multiple comparisons, or making too many comparisons for the study sample size. This will quickly undermine study power. Although many statistical corrections are available for multiple comparisons, there is no perfect method and, as such, this approach should be avoided unless necessary. One should also predefine endpoints that will represent clinical significance in the study findings, independent of statistical significance. A common mistake is to conflate statistical significance with clinical significance. For example, an epidemiologic study may result in a caries prevalence difference of 0.1 surfacing between sample groups. Because of a large sample size, the difference may be

statistically significant, but the clinical significance of the finding is questionable. The articulation of planned study analyses can be included in the protocol or in a separate statistical analysis plan depending on the complexity of the planned analyses.[33]

Generalizability and Representativeness

Generalizability of study results and representativeness of the study population are important considerations for any clinical research study. The convenience of conducting a study in a setting such as an academic health center may limit study participant selection and would limit generalizability of study findings to the population with a disease or condition. Similarly, it may be convenient to enroll patients who present to a tertiary clinic, but those study participants may not represent the race, ethnicity, and/or age of individuals in the population with the disease or condition of interest. Consequently, when planning a clinical study, the setting and population from which potential participants will be recruited must be considered as related to representativeness of the study sample and generalizability of study findings.

For example, observational studies of select patient groups often draw conclusions about the condition from small numbers of patients who are in active treatment in one medical center and who have the most severe disease. However, the patients evaluated in the study may not represent all patients in the general population. A single center study does have value in generating new hypotheses for more research, but the studies would need to be replicated in larger, more representative samples to improve generalizability of research results.[25] Studies of rare diseases can be difficult because few patients with the condition of interest are available for study. To overcome this problem, multi-center registries can be established that enroll and follow patients with a particular condition. Examples include the chromosome 22q11.2 deletion syndrome registry that has characterized the highly variable spectrum of the clinical consequences associated with this deletion in over 1400 affected individuals[34] and the international registry to assess safety of denosumab, an antiresorptive drug associated with ONJ.[14]

Concern about representativeness has also occurred in clinical trials with the use of restrictive inclusion/exclusion criteria. To determine if a new drug or technique is effective for treating a disease, potential participants with coexisting conditions may be excluded, or study participation may be limited to a particular age group. This creates a potential for study results to be valid for only a population similar to those enrolled in the trial, which may be a smaller subset of individuals with disease. An example of this problem is clinical trials testing therapies for non-Hodgkins lymphoma (NHL). While the majority of patients with NHL are over the age of 65 years, older adults have been poorly represented in NHL RCTs.[35] Similarly, most RCTs testing caries preventive treatments studied children, though the therapies are recommended for adults.[36]

ETHICAL CONSIDERATIONS AND REGULATORY REQUIREMENTS

Regulatory requirements for research with human participants vary according to the type of study conducted and the region or country in which the research is conducted. In the United States, starting an interventional clinical trial to test the safety and efficacy of an investigational new drug for disease treatment will require an Investigational New Drug (IND) application filed with the United States Food and Drug Administration (FDA) and approval from an Institutional Review Board (IRB). In Canada, a Clinical Trial Application must be filed with Health Canada; an investigator must receive a No Objection Letter from Health Canada and IRB approval to begin a study. In the European Union, the trial of an investigational drug may be started after a Clinical Trial Authorization (CTA) dossier is authorized by a National Competent Authority and an Ethics Committee issues a positive opinion. For a simple observational study intended, for example, to identify risk factors for a disease or condition, regulations for the protection of human subjects must be followed. These may vary with the region or country in which the research is conducted.

For any research study that involves human participants, sponsors and investigators have an obligation to protect the participants, by weighing the foreseeable risks and anticipated benefits before initiating a study and by conducting the study with adequate rigor to produce scientifically valid results. The regulations and guidelines followed by clinical researchers today have their foundations in a variety of codes, resolutions, and guidelines adopted by national and international bodies, including the Nuremberg Code (1947),[37] the Declaration of Helsinki[38] (adopted in 1964 and amended several times through 2013), the Belmont Report prepared by the United States National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research (1979),[39] the International Ethical Guidelines for Biomedical Research Involving Human Subjects published by the Council for International Organizations of Medical Sciences (CIOMS) (released 1993, most recently revised in 2016),[40] and the E6 Guideline for Good Clinical Practice developed by the International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use (ICH).[41]

Beginning in 1990, the ICH brought together representatives of the regulatory bodies and industry representatives from the European Union (EU), Japan, and the US. The mission of the ICH was to promote international harmonization of requirements, to streamline the process of conducting regulated clinical research in different countries. Providing a unified standard for technical requirements and acceptance of clinical data by the regulatory agencies of the participating jurisdictions was intended to facilitate the development and marketing pathway for new medical products. Topics covered by the ICH are categorized as Quality, Safety, Efficacy, and Multidisciplinary Guidelines, based on the criteria for approving new medicinal products. Guidelines in the Efficacy category deal with the design, conduct, safety, and reporting of clinical trials, and include the ICH Guideline for Good Clinical Practice[41] (ICH GCP E6), which was finalized in 1996 and amended in 2016. The Guideline defines Good Clinical Practice as "an international ethical and scientific quality standard for designing, conducting, recording and reporting trials that involve the participation of human subjects" and indicates that "compliance with this standard provides public assurance that the rights, safety and well-being of trial participants are protected, consistent with the principles that have their origin in the Declaration of Helsinki, and that the clinical trial data are credible."

Section 2 of the ICH E6 document lists the 13 principles of ICH GCP (see Table 2-1; also Table 2-2, Table 2-3), which emphasize ethical treatment of human subjects, sound science to justify and support a trial, and scientific rigor and quality in the conduct of the trial. Sections 3, 4, and 5 of the GCP document describe the responsibilities of the following entities involved in the conduct of a clinical trial:

- The IRB or Independent Ethics Committee (IEC) is defined as "an independent body constituted of medical, scientific, and non-scientific members, whose responsibility is to ensure the protection of the rights, safety and well-being of human subjects involved in a trial." The IRB or IEC is expected to review and approve the trial protocol and amendments, the methods and material to be used in obtaining and documenting informed consent of trial participants, qualifications of the investigator, etc., and to conduct continuing review of the trial at least annually.
- The Investigator is defined as "a person responsible for the conduct of the clinical trial at a trial site." Investigator(s) should be "qualified by education, training, and experience to assume responsibility for the proper conduct of the trial, should meet all the qualifications specified by the applicable regulatory requirement(s), and should provide evidence of such qualifications through up-to-date curriculum vitae and/or other relevant documentation requested by the sponsor, the IRB/IEC, and/or the regulatory authority(ies)." The investigator is responsible for supervising any individual or party to whom the investigator delegates trial-related duties and functions conducted at the trial site. A qualified physician or dentist should be responsible for all trial-related

Table 2-1 The principles of good clinical practice.[41]

1	Clinical trials should be conducted in accordance with the ethical principles that have their origin in the Declaration of Helsinki, and that are consistent with GCP and the applicable regulatory requirement(s).
2	Before a trial is initiated, foreseeable risks and inconveniences should be weighed against the anticipated benefit for the individual trial subject and society. A trial should be initiated and continued only if the anticipated benefits justify the risks.
3	The rights, safety, and well-being of the trial subjects are the most important considerations and should prevail over interests of science and society.
4	The available nonclinical and clinical information on an investigational product should be adequate to support the proposed clinical trial.
5	Clinical trials should be scientifically sound, and described in a clear, detailed protocol.
6	A trial should be conducted in compliance with the protocol that has received prior institutional review board (IRB)/independent ethics committee (IEC) approval/ favorable opinion.
7	The medical care given to, and medical decisions made on behalf of, subjects should always be the responsibility of a qualified physician or, when appropriate, of a qualified dentist.
8	Each individual involved in conducting a trial should be qualified by education, training, and experience to perform his or her respective task(s).
9	Freely given informed consent should be obtained from every subject prior to clinical trial participation.
10	All clinical trial information should be recorded, handled, and stored in a way that allows its accurate reporting, interpretation, and verification. This principle applies to all records referenced in this guideline, irrespective of the type of media used.
11	The confidentiality of records that could identify subjects should be protected, respecting the privacy and confidentiality rules in accordance with the applicable regulatory requirement(s).
12	Investigational products should be manufactured, handled, and stored in accordance with applicable good manufacturing practice (GMP). They should be used in accordance with the approved protocol.
13	Systems with procedures that assure the quality of every aspect of the trial should be implemented. Aspects of the trial that are essential to ensure human subject protection and reliability of trial results should be the focus of such systems.

International Council for Harmonisation Integrated Addendum to ICH E6(R1): Guideline for Good Clinical Practice E6(R2), 9 November 2016.

medical or dental decisions. Among the critical duties of the investigator are communication with the IEC/IRB, compliance with the protocol, accountability for the investigational product, proper conduct and documentation of the informed consent process, proper recording and reporting of trial data, and documentation and reporting of safety issues.

- The Sponsor is defined as "an individual, company, institution, or organization which takes responsibility for the initiation, management, and/or financing of a clinical trial." The sponsor is responsible for implementing a risk-based system to manage quality throughout all stages of the trial process, for using qualified individuals to design the trial, develop study documents, conduct the trial, manage the data, and provide safety oversight, for ensuring that adequate data are available to support use of an investigational product in the trial, for ensuring that an investigational product is manufactured in accordance with good manufacturing practice (GMP) standards, labeled appropriately and maintained under appropriate conditions, for submitting applications for investigational product use and information on safety issues to the proper regulatory authorities, and for monitoring the trial to ensure that the rights and well-being of participants are protected, that the trial data are accurate, complete and verifiable, and that the trial is conducted in compliance with the protocol, with GCP and with applicable regulatory requirements. Adherence to GCP is expected of all clinical research monitors and auditors appointed by the sponsor and all staff of contract research organizations to whom a sponsor transfers any study-related functions.

Sections 6 and 7 of the GCP Guidelines outline the critical components of a clinical protocol and an Investigator's Brochure for an investigational product. Section 8 summarizes the minimum essential documents "which individually and collectively permit evaluation of the conduct of a trial and the quality of the data produced." The list includes documents to be generated before the trial begins, during the clinical conduct of the trial and after completion or termination of the trial.

The importance of adhering to the principles of good clinical practice when conducting research with human participants is widely recognized. While the ICH GCP standards

Study Design	Strengths	Weaknesses
Cross-sectional	• Time and resource efficient • Can assess multiple exposures and confounders • Can assess multiple outcomes	• No temporality between exposure and outcome; causality between exposure and outcome cannot be assessed
Case-control	• Time and resource efficient • Can assess multiple exposures and confounders • Good for rare diseases	• Can assess one outcome only • Poor selection of controls can introduce selection bias • Potential to recall bias • No temporality between exposure and outcome
Retrospective and Prospective Cohort	• Can assess causality • Can assess multiple exposures • Can assess multiple outcomes • Ability to control for multiple confounders	• Time and resource intensive • Not ideal for rare diseases
Clinical Trial	• Ability to assess safety and efficacy of an intervention • Prospective assignment into study groups reduces potential bias • Strongest evidence for causality between a modifiable factor and outcome	• Time and resource intensive

were developed as guidelines, the principles have been incorporated into legal requirements in some countries (e.g., Japan, Australia, Canada). In the EU, the ICH GCP is considered a scientific guideline, but legal requirements for following good clinical practice are implemented in Directive 2001/20/EC and then in Regulation (EU) No 536/2014 of the European Parliament and of the Council of 16 April 2014 ("approximation of the laws, regulations and administrative provisions of the Member States relating to the implementation of good clinical practice in the conduct of clinical trials on medicinal products for human use") and Directive 2005/28/EC ("laying down principles and detailed guidelines for good clinical practice as regards investigational medicinal products for human use"). In addition, specific national laws apply within the EU member states (e.g., The Medicines for Human Use [Clinical Trials] Regulations 2004 and its amendments in the United Kingdom). In the US, the FDA endorsed the ICH E6 GCP and published it as a guidance document, with the statement that it "represents the agency's current thinking on good clinical practices." While FDA guidance documents are not legally binding, the principles of good clinical practice and human subjects protection have been incorporated into law in various parts of the U.S. (e.g., 45 CFR part 46 on Protection of Human Subjects, frequently referred to as the "Common Rule," which offers basic protections to human participants involved in biomedical or behavioral research conducted or supported by federal departments and agencies;[2] 21 CFR part 50 on Protection of Human Subjects and 21 CFR part 56 on IRBs; 21 CFR part 312 on Investigational New Drug Applications; 21 CFR part 314 on FDA approval to Market a New Drug; 21 CFR part 812 on Investigational Device Exemptions; 21 CFR part 814 on Premarket Approval of Medical Devices, etc.).

While the GCP guidance was developed for research using regulated investigational products (drugs, biologics, devices) in human participants, the introduction to ICH GCP guidance document states, "the principles established in this guidance may also be applied to other clinical investigations that may have an impact on the safety and well-being of human subjects." Similarly, the World Health Organization (WHO) Handbook for Good Clinical Research Practice, states: "To the extent possible, the principles of GCP should generally apply to all clinical research involving human subjects, and not just research involving pharmaceutical or other medical products ... Although some principles of GCP may not apply to all types of research on human subjects, consideration of these principles is strongly encouraged wherever applicable as a means of ensuring the ethical, methodologically sound and accurate conduct of human subjects research."[2] Following the applicable parts of the GCP guidelines during the conduct of non-interventional studies provides a good starting point for complying with the variety of human subjects protection regulations that exist in countries around the world.

The US Common Rule (45 CFR 46, Subpart A),[2] which stipulates procedural requirements related to IRBs and informed consent, was recently revised for the first time since 1991.[43] The revisions have been adopted by the U.S. Department of Health and Human Services and 19 other Federal Departments and Agencies. These policy changes went into effect on January 21, 2019 in an effort to modernize and simplify the current system of oversight. The revisions are intended to better protect human participants involved in research, while reducing administrative burden placed on investigators. Broad categories for which revisions were adopted include:

- exempt research categories
- requirements for IRB continuing reviews
- informed consent
- single IRB requirements
- requirements for IRB reviews of grant applications and contract proposals.

The EU General Data Protection Regulation (GDPR) became effective on May 25, 2018.[44] The GDPR imposes rules to protect individuals' personal data. Its requirements for the processing of personal data have the potential to impact human participants research activities. While the GDPR applies directly to data controllers and data processors in the EU, it could also apply to data controllers and processors outside of the EU when monitoring data that tracks participants' behavior in the EU. For example, if a clinical study outside of the EU is using personal electronic devices (e.g., wearables or mobile devices) to track participants' health data, these data could be subject to the GDPR if a study participant is visiting the EU and transmits the data to the non-EU study location.

Clinical Trials Registration and Results Reporting

Due to concerns about selective reporting and publication bias resulting in publishing clinical trials with positive findings only and ethical considerations for clinical trial participants who have contributed to clinical trials that have not been published, the practice of clinical trial registration has been required in some circumstances and requested in others. Numerous clinical trials registries exist in many countries to facilitate registration of clinical trials prior to or soon after the first participant has been enrolled. Further, some registries allow for reporting of clinical trial results to offset the concerns about publication bias.

In the US, ClinicalTrials.gov, which is operated by the National Institutes of Health's (NIH) National Library of Medicine, launched in 2000 and provides a publicly accessible

platform for the public to access clinical trial information. The Food and Drug Administration Amendments Act of 2007 (FDAAA Section 801)[45] requires that studies that meet the definition of an "applicable clinical trial" (ACT) that were initiated or ongoing after the law came into effect must be registered on ClinicalTrials.gov. ACTs include the following: controlled clinical investigations (other than phase 1 investigations) of any FDA-regulated drug or biological product for any disease or condition, and certain studies of FDA-regulated medical devices, excluding small clinical trials to determine feasibility and certain clinical trials to test prototype devices, but including FDA-required pediatric postmarket surveillances of a device product. Further, the Final Rule for Clinical Trials Registration and Results Information Submission (42 CFR Part 11)[46] has been in effect since 2017 and clarifies that ACTs generally include interventional studies of FDA-regulated drug, biological, or device products that meet one of the following conditions: The trial has one or more US sites, the trial is conducted under an FDA IND application or IDE, or the trial involves a drug, biological, or device product that is manufactured in the US or its territories and is exported for research. The NIH Policy on Dissemination of NIH-Funded Clinical Trial Information[47] came into effect in January 2017 and requires clinical trials registration and results reporting for all clinical trials funded by NIH, regardless of whether they are subject to the Final Rule. Most NIH-funded trials must be registered and reported on ClinicalTrials.gov, with delayed enforcement of certain clinical trials.[48]

The International Committee of Medical Journal Editors (ICMJE) instituted a policy in 2005 that requires registration of a clinical trial in a public trials registry as a condition of consideration for publication in a journal that follows the ICMJE policy.[49] The ICMJE accepts registration in any registry that is recognized on the WHO International Clinical Trials Registry Platform[50] or in ClinicalTrials.gov.

SAFETY MONITORING

Safety reporting and safety oversight constitute study safety monitoring. Such monitoring must accommodate the nature of the clinical research being conducted. The goal of safety reporting and safety oversight is to protect the human participants from the risks that are intrinsic to participating in the research. It is also important for those reading the literature to know not only the benefits, but also the risks of a new therapy, whether a drug, procedure, or approach. Plans for safety monitoring should be commensurate with the risks and complexity of the study. The plans should include adequate processes to protect those participating in the research while not wasting precious resources collecting and reporting unnecessary or duplicative data. This section includes a brief overview of safety monitoring; references are provided for further reading.

Safety Reporting

The requirements and processes of safety reporting are governed by multiple regulations, guidances, and policies. Currently, clinical research funded by the US government must comply with safety reporting requirements specified by the Common Rule, 45 CFR 46,[2] and associated guidances and policies issued by the Office of Human Research Protections.[51] Studies governed by Food and Drug Law must comply with the requirements of the FDA.[52] There is overlap between some of the requirements as both have their basis in ICH guidance (see above). There are different regulations and guidances pertaining to studies that test biologics or drugs conducted under IND,[53] studies that do not require an IND but include marketed products, and studies that test devices and materials. When designing the study, it is important to determine whether the study requires an IND under 21 CFR 312[53] or Investigational Device Exemption (IDE) under 21 CFR 812.[54] Should an investigator be uncertain whether an IND or IDE is required, the appropriate agency can be contacted to obtain designation.[55–58]

Studies conducted under IND are required to collect "adverse events." Adverse events are any untoward medical occurrences associated with the use of the drug in humans, whether or not considered drug-related (21 CFR 312.32 (a)).[53] An important category of adverse event is a "Serious Adverse Event," which is generally reported to the FDA and IRBs in an expedited manner so that it can be acted upon quickly. Reporting of these events captures information suggesting that a drug poses a significant risk to human participants, and such reports require special scrutiny and attention. Adverse events are considered serious if they result in any of the following outcomes:

- death;
- an immediately life-threatening adverse event;
- an inpatient hospitalization or prolongation of existing hospitalization;
- a persistent or significant incapacity or substantial disruption of the ability to conduct normal life functions;
- a congenital anomaly or birth defect; or
- an important medical event that may not result in the above outcomes may be considered serious when, based upon appropriate medical judgment, it could jeopardize the patient or participant and may require medical or surgical intervention to prevent one of the above outcomes. (21 CFR 312.32(a).[53]

Another important safety definition is "suspected adverse reaction," which means any adverse event for which there is

a "reasonable possibility" of a causal relationship between the drug and the adverse event (21 CFR 312.32(a)).[53] "Unexpected" is another term applied to adverse events. For regulatory purposes, unexpected means that the event has not been observed with drug use previously; that is, it is not listed in the investigator brochure or is not listed at the specificity or severity that has been observed, or it is not described in the general investigational plan or elsewhere in the IND application (21 CFR 312.32(a)). IND sponsors and investigators working under IND are required to have specific knowledge of any adverse events, including their type and severity, that have occurred with previous drug use so that they may recognize those events that require special focus, more detailed information, and expedited reported to the FDA and governing IRB.

The aforementioned safety reporting requirements are specific to drug and biologic studies under IND. For any federally funded study subject to the Common Rule, there is a requirement to capture and report "unanticipated problems involving risks to subjects or others," following specific requirements and time frames. An Unanticipated Problem meets all the following criteria:

- "unexpected (in terms of nature, severity, or frequency) given (a) the research procedures that are described in the protocol-related documents, such as the IRB-approved research protocol and informed consent document; and (b) the characteristics of the participant population being studied;
- related or possibly related to participation in the research (possibly related means there is a reasonable possibility that the incident, experience, or outcome may have been caused by the procedures involved in the research); and
- suggests that the research places participants or others at a greater risk of harm (including physical, psychological, economic, or social harm) than was previously known or recognized."

Unanticipated problems may or may not be either adverse events or serious adverse events. This definition can include events such as breach of participant privacy, or hazardous conditions or risks related to participating in the research that are not related to a drug.

Safety Oversight

For studies that involve only minimal risk for participants, oversight by the principal investigator is often adequate. However, studies of greater risk and complexity may either benefit from or require different or independent safety oversight structures. Most familiar are Data and Safety Monitoring Boards (DSMBs) or Committees (DSMCs), groups of independent experts who oversee reports of study conduct, data quality, and safety information. DSMBs are usually governed by a charter which outlines how frequently meetings occur, what sorts of data will be reviewed, whether special meetings should be convened to address certain important or unexpected events, how meetings will be conducted, what constitutes a quorum, and what sorts of recommendations are expected. DSMBs are an important oversight mechanism in the protection of human participant safety. Relevant expertise independent of the study and its investigators is critical to the proper functioning of a DSMB. Thus, DSMBs must be carefully constituted and supported to perform effectively.[59]

Ulcerative, Vesicular, and Bullous Lesions

Sook Bin Woo, DMD, MMSc, FDSRCS (Edin)
Jane F. Setterfield, BDS, MD, FRCP
Martin S. Greenberg, DDS, FDS, RCSEd

Many ulcerative or vesiculobullous disease of the mouth have a similar clinical appearance. The oral mucosa is thin, and even slight trauma leads to rupture of vesicles and bullae forming eroded, red areas; a yellow fibrin membrane forms over the erosion and an ulcer develops. As such, vesiculo-bullous lesions that have a characteristic appearance on the skin (such as tense blisters of bullous pemphigoid) have a somewhat nonspecific appearance on the oral mucosa.

Taking a careful and detailed history often provides as much information as the clinical examination and guides the clinician during the clinical evaluation. Four pieces of information in particular help the clinician rapidly categorize a patient's disease and simplify the diagnosis: the length of time the lesions have been present (acute or chronic lesions), a past history of similar lesions (primary or recurrent disease, or episodic disease), the number of lesions present (single or multiple), and the location of lesions. In this chapter, the diseases are grouped according to the information just described. This information serves as a good starting point for the student who is just learning to diagnose these disorders, as well as for the experienced clinician who is aware of the potential diagnostic pitfalls.

A complete review of systems should be obtained for each patient, including questions regarding the presence of skin, eye, genital, pharyngeal, nasal, and rectal lesions as well as the presence of symptoms such as fever, joint pains, and muscle weakness to name a few. The clinical examination should include a thorough inspection of the exposed skin surfaces. Some knowledge of basic dermatology is helpful because many disorders occurring on the oral mucosa may also affect the skin.

Burket's Oral Medicine, Thirteenth Edition. Edited by Michael Glick, Martin S. Greenberg, Peter B. Lockhart, and Stephen J. Challacombe.

Dermatologic lesions are classified according to their clinical appearance and include the following frequently used terms that are also applicable in the oral mucosa:

1) *Macules*. These are lesions that are flush with the adjacent mucosa and that are noticeable because of their difference in color from normal skin or mucosa. They may be red due to increased vascularity or inflammation, or pigmented due to the presence of melanin, hemosiderin, and foreign material (including the breakdown products of medications). A good example in the oral cavity is the melanotic macule.
2) *Papules*. These are lesions raised above the mucosal surface that are smaller than 1.0 cm in diameter (some use 0.5 cm for oral mucosal lesions). They may be slightly domed, or flat-topped. Papules are seen in a wide variety of diseases, such as the yellow-white papules of pseudomembranous candidiasis.
3) *Plaques*. These are raised lesions that are greater than 1 cm in diameter; they are essentially large papules.
4) *Nodules*. These lesions are present within the deep mucosa. The lesions may also protrude above the mucosa forming a characteristic dome-shaped structure. A good example of an oral mucosal nodule is the irritation fibroma.
5) *Vesicles*. These are small blisters containing clear fluid that are less than 1 cm in diameter.
6) *Bullae*. These are elevated blisters containing clear fluid that are greater than 1 cm in diameter.
7) *Erosions*. These are red lesions often caused by the rupture of vesicles or bullae, or trauma and are generally moist on the skin. However, they may also result from thinning or atrophy of the epithelium in inflammatory disease such as lichen planus. These should not be mistaken for ulcers, which are covered with fibrin and are yellow.
8) *Pustules*. These are blisters containing purulent material and appear yellow.
9) *Ulcers*. These are well-circumscribed, sometimes depressed lesions with an epithelial defect that is covered by a fibrin membrane, resulting in a yellow-white appearance. A good example is an aphthous ulcer.
10) *Purpura*. These are reddish to purple discolorations caused by blood from vessels leaking into the connective tissue. These lesions do not blanch when pressure is applied and are classified by size as petechiae (less than 0.3 cm), purpura (0.4–0.9 cm), or ecchymoses (greater than 1 cm).

The first section of this chapter describes acute multiple lesions that tend to occur only as a single episode; the second portion of the chapter covers recurring ulcerative conditions; the third portion presents conditions characterized by chronic, continuous multiple erosions and ulcers; and the final section describes diseases that present with single ulcers. It is hoped that classifying the disorders in this way will help the clinician avoid the common diagnostic problem of confusing acute viral infections with recurrent oral conditions, such as recurrent aphthous stomatitis, or disorders that present as chronic progressive disease, such as pemphigus.

THE PATIENT WITH ACUTE MULTIPLE LESIONS

The major diseases that cause acute multiple oral ulcers include viral and bacterial stomatitis, allergic and hypersensitivity reactions (particularly erythema multiforme and contact allergic stomatitis), and lesions caused by medications (such as cancer chemotherapy) (see Chapter 17, "Hematologic Diseases").

Herpes Simplex Virus Infection

Etiology and Pathogenesis

The Herpesviridae family of viruses contains eight different viruses that are pathogenic in humans with one affecting simians (Table 3-1). This chapter discusses only herpes simplex virus (HSV)-1 and varicella-zoster virus (VZV) which cause multiple ulcers, and cytomegalovirus (CMV) and Epstein-Barr virus (EBV) infections, which usually cause single ulcers. Herpes viruses have a common structure: an internal core containing the viral genome, an icosahedral nucleocapsid, the tegument, and an outer lipid envelope containing viral glycoproteins on its surface that are derived from host cellular membranes.[1] Nonetheless, each of the herpesviruses is distinct.

HSV-1, an α-herpesvirus, is a ubiquitous virus, and 54% of adults aged 14–49 between 2005–2014 in the United States are seropositive for it.[2] In general, infections above the waist are caused by HSV-1 and those below the waist by HSV-2, although with changing sexual practices, it is not uncommon to culture HSV-2 from oral lesions and vice versa.[3] The primary infection, which occurs on initial contact with the virus, is acquired by inoculation of the mucosa, skin, and eye with infected secretions. The virus then travels along the sensory nerve axons and establishes chronic, latent infection in the sensory ganglion (such as the trigeminal ganglion).[4] Extraneuronal latency (i.e., HSV remaining latent in cells other than neurons such as the epithelium) may play a role in recurrent lesions of the lips.[5] Recurrent HSV results when HSV reactivates at latent sites and travels centripetally to the mucosa or the skin, where it is directly cytopathic to epithelial cells, causing recrudescent HSV infection in the form of localized vesicles or ulcers.[6]

The most common sites of infection are the oral and genital mucosa and the eye. HSV infection of the cornea

Table 3-1 Herpesviridae that are pathogenic in humans.

Type of Human herpesvirus (HHV)	Primary infection	Recrudescent lesions in healthy hosts	Recrudescent lesions in immunocompromised hosts
Herpes simplex virus 1 (HHV-1)	Gingivostomatitis, keratoconjunctivitis, genital and skin lesions	Herpes labialis ("cold sores"), intraoral ulcers, keratoconjunctivitis, genital and skin lesions	Ulcers at any mucocutaneous site, usually large and persistent; disseminated infection
Herpes simplex virus 2 (HHV-2)	Genital and skin lesions, gingivostomatitis, keratoconjunctivitis, neonatal infections, aseptic meningitis	Genital and skin lesions gingivostomatitis, aseptic meningitis	Ulcers at any mucocutaneous site, usually large, persistent and dermatomal; disseminated infection
Varicella-zoster virus (HHV-3)	Varicella (chickenpox)	Zoster (shingles)	Disseminated infection
Cytomegalovirus (HHV-4)	Infectious mononucleosis, hepatitis, congenital disease		Retinitis, gastroenteritis hepatitis, severe oral ulcers
Epstein-Barr virus (HHV-5)	Infectious mononucleosis-like, hepatitis, encephalitis		Hairy leukoplakia, lymphoproliferative disorders, mucocutaneous ulcers
HHV-6	Roseola infantum, otitis media, encephalitis		Fever, bone marrow suppression
HHV-7	Roseola infantum		
HHV-8	Infectious mononucleosis-like, febrile exanthema		Kaposi sarcoma, lymphoproliferative disorders, bone marrow suppression

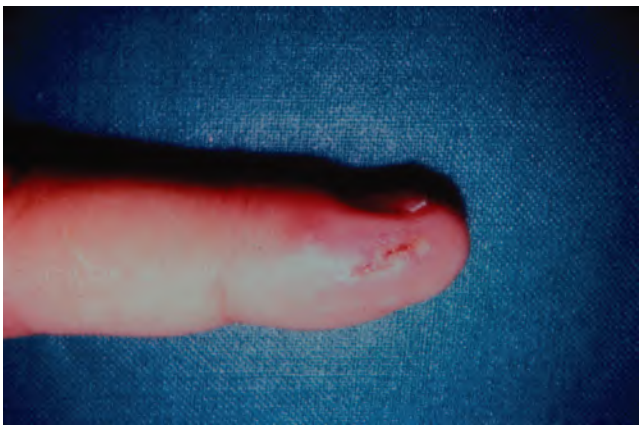

Figure 3-1 Primary herpetic whitlow on the finger of a dentist.

(keratitis) is a major cause of blindness in the world. HSV-1 or -2 may cause herpes whitlow, an infection of the fingers when virus is inoculated into the fingers through a break in the skin (Figure 3-1). This was a common occupational hazard (including within the dental profession) before the widespread use of gloves.[7,8] Other HSV-1 infections include herpes gladiatorum (infections of the skin spread through the sport of wrestling),[9] herpes encephalitis, HSV esophagitis, HSV pneumonia and neonatal and disseminated infection.[6]

HSV is an important etiologic agent in erythema multiforme, which is discussed below.[10,11] HSV has been recovered in the endoneurial fluid of 77% of patients with Bell palsy.[12] However, VZV has also been strongly implicated in the development of Bell palsy.[13] Treatment with antiviral therapy (especially with corticosteroids) within the first 48 hours resulted in better outcomes further supporting the concept of herpesvirus involvement in the pathogenesis of Bell palsy.[14] However, a recent study showed that approximately 60% of cases of Bell palsy were associated with HHV6, and only 13% with HSV.[15]

Clinical Manifestations

Primary Gingivostomatitis

The majority of primary HSV-1 infections are subclinical and generally occur in children and teenagers.[6,13] There is a 1- to 3-day viral prodrome of fever, loss of appetite, malaise, and myalgia that may also be accompanied by headache and nausea. Oral pain leads to poor oral intake, and patients may require hospitalization for hydration. The disease is self-limiting in otherwise normal patients and resolves within 10 to 14 days, typical for a viral illness.

Oral Findings

Within a few days of the prodrome, erythema and clusters of vesicles and/or ulcers appear on the keratinized mucosa of the hard palatal mucosa, attached gingiva and dorsum of the tongue, and the nonkeratinized mucosa of the buccal and labial mucosa, ventral tongue, and soft palate (Figures 3-2 and 3-3). Vesicles break down to form ulcers that are usually 1 to 5 mm and coalesce to form larger ulcers with scalloped borders and marked surrounding erythema. The gingiva is often

Figure 3-2 Primary herpetic gingivostomatitis with extensive involvement of the keratinized tissues of the tongue dorsum and nonkeratinized tissues of the ventral tongue and labial mucosa. *Source:* Courtesy of Dr. Nathaniel Treister, Boston, MA.

Figure 3-3 Primary herpetic gingivostomatitis with mild presentation: erythematous maxillary anterior gingiva with erythema and ulcer on upper labial mucosa and crusted lesion on lower lip.

Figure 3-5 Recrudescent intraoral herpes simplex virus infection in an immunocompetent patient with clusters of small coalescent ulcers on the keratinized palatal mucosa.

erythematous, and the mouth is extremely painful, causing difficulty with eating. Pharyngitis causes swallowing difficulties. Primary HSV infection in adults follows a similar pattern.[16]

Recrudescent Oral HSV Infection

Reactivation of HSV may lead to asymptomatic shedding of HSV, in the saliva and other secretions, an important risk factor for transmission; it may also cause ulcers to form. Asymptomatic shedding of HSV is not associated with systemic signs and symptoms and occurs in 8 to 10% of patients following dental treatment.[17] The term *recrudescent HSV* should be used to refer to the actual ulcerations caused by reactivated virus. Fever, ultraviolet radiation, trauma, stress, and menstruation are important triggers for reactivation of HSV.

Recrudescent HSV on the lips is called recurrent herpes labialis (RHL) and occurs in 20 to 40% of the young adult population.[18,19] These are associated with a prodrome of itching, tingling, or burning approximately 50% of the time, followed in succession by the appearance of papules, vesicles, ulcers, crusting, and then resolution of lesions (Figure 3-4).[20] Pain generally is present only within the first 2 days. There is a suggestion that patients who do not experience a prodrome develop lesions from extraneural latent HSV within the epithelium and these lesions are less responsive to topical therapy.[21]

Recrudescent intraoral HSV (RIH) in the immunocompetent host occurs chiefly on the keratinized mucosa of the hard palatal mucosa, attached gingiva, and dorsum of the tongue.[22] They present as 1 to 5 mm single or clustered painful ulcers

with a bright erythematous border (Figure 3-5). One common presentation is the complaint of pain in the gingiva 1 to 2 days after a scaling and prophylaxis or other dental treatment. Lesions appear as 1 to 5 mm painful vesicles but more often ulcers on the marginal gingiva.

HSV in Immunocompromised Patients

In immunocompromised patients (such as those undergoing chemotherapy, who have undergone organ transplantation, or who have acquired immune deficiency syndrome [AIDS]), RIH infection may occur at any site intraorally and may form atypical-appearing ulcers that may be several centimeters in size and may last several weeks or months if undiagnosed and untreated (Figures 3-6 and 3-7).[23,24] In one study, 50% of patients with leukemia and 15% of patients who had undergone renal transplantation developed RIH infections.[25] Single RIH ulcers are indistinguishable from recurrent aphthous ulcers if they occur on a nonkeratinized site.[26] These ulcers are painful and similar to HSV lesions seen in immunocompetent patients except that they may be larger and often occur on nonkeratinized sites. They appear slightly depressed with raised borders. The presence of 1 to 2 mm vesicles or satellite ulcers at the edges of the main ulcer is a helpful sign.

If undiagnosed and left untreated, RIH infection may disseminate to other sites and cause morbidity in the immunocompromised population.[27] This is a particular problem in patients undergoing hematopoietic stem cell transplantation, where reactivation of HSV occurs in approximately 70% of patients, prompting prophylaxis in patients who are seropositive.[28,29]

Figure 3-6 Recrudescent herpes simplex virus infection of the maxillary alveolar ridge mucosa in a patient with lymphoma.

Figure 3-7 Recrudescent herpes simplex virus infection of the lateral tongue and oral commissure in a patient with leukemia postallogenic transplantation.

Differential Diagnosis

Coxsackievirus infections (especially hand-foot-and-mouth disease) may present with widespread ulcerations of the oral cavity mimicking primary herpetic gingivostomatitis, but ulcers are generally not clustered and generalized gingival inflammation usually is not present. Laboratory tests (see below) identifies HSV.

RIH infection in the immunocompetent patient on the gingiva may resemble a localized area of necrotizing ulcerative gingivitis (see below). Laboratory tests are positive for HSV, and lesions of necrotizing ulcerative gingivitis are widespread and diffuse rather than localized, as is often seen in RIH.

Traumatic ulcers on the palatal mucosa (such as from pizza burns) may resemble RIH.

RIH infection in the immunocompromised host may occur at any intraoral site and can be differentiated from aphthous ulcers because the latter are episodic.

In the immunocompromised population, ulcers secondary to CMV infection, fungal infection, and neutropenia must also be considered. Differentiation between these entities is accomplished by biopsy, culture, and blood tests.

Erythema multiforme, often triggered by a prior HSV infection may appear as multiple, coalescent ulcers (see below).

Laboratory Diagnosis

Diagnosis is by culture, antigen identification, or nuclei acid amplification techniques.[30] HSV isolation by cell culture with further herpes typing is the gold standard test for the diagnosis since it grows readily in tissue culture, although the quantity of virus falls precipitously once healing begins. The advantage of a culture is that it has high sensitivity and specificity and allows for amplification of virions, typing, and testing for sensitivity to antiviral drugs. The disadvantage is that it needs specialized equipment, is expensive, is dependent on proper transport of the culture, and may take up to several days for a final result, although use of centrifugation-enhanced (shell vial) culture has reduced culture time to 1–3 days. HSV that reactivates in

the saliva (asymptomatic shedding) will also grow in culture and results have to be interpreted with caution.

Antigen detection by direct or indirect immunofluorescence using fluorescein-labeled, type-specific monoclonal antibodies on smears and scrapings (e.g., from vesicles) or via enzyme inked immunoassay on swabs are an alternative to cultures and provide similar sensitivity and specificity very quickly. Nuclei acid amplification tests are now readily available commercially using real-time polymerase chain reaction (PCR) for detecting and quantifying HSV and this is now the standard of care in most medical centers. It is highly sensitive but will capture HSV in recrudescent active infections and from asymptomatic shedding.

HSV can be identified from scrapings from the base of lesions (especially vesicles) smeared onto glass slides. These can be stained with Wright, Giemsa (Tzanck preparation), or Papanicolaou stain to demonstrate the characteristic multinucleated giant cells or intranuclear inclusions as seen on histopathology (see below). However, this does not distinguish between HSV or VZV and an antigen detection technique, as noted above, must also be employed.

Primary HSV infection is associated with elevated immunoglobulin (Ig)M titers that occur within days, followed several weeks later by permanent IgG titers (seroconversion) that indicate previous infection but confer no protection against reactivation. Recurrent infection is associated with a rise in IgG antibody titer in acute and convalescent sera, but a fourfold rise (a criterion that indicates active infection) is seen in only 5% of patients. The assay for HSV IgM is not particularly reliable for diagnostic purposes and overall, the use of serology to diagnose recurrent infection is not advised.

HSV lesions are not generally biopsied because the clinical appearance and history are characteristic, and infection is readily confirmed with any of the techniques mentioned above when necessary. However, if a biopsy is obtained, it will show the presence of multi-nucleated giant epithelial cells at the edge of the ulcer. The nuclei exhibit typical molding and have a ground-glass appearance (Figure 3-8). Since intact epithelium is necessary for the diagnosis, a biopsy for a lesion suspicious for HSV must always include epithelium adjacent to the ulcer or there may be a false negative result.

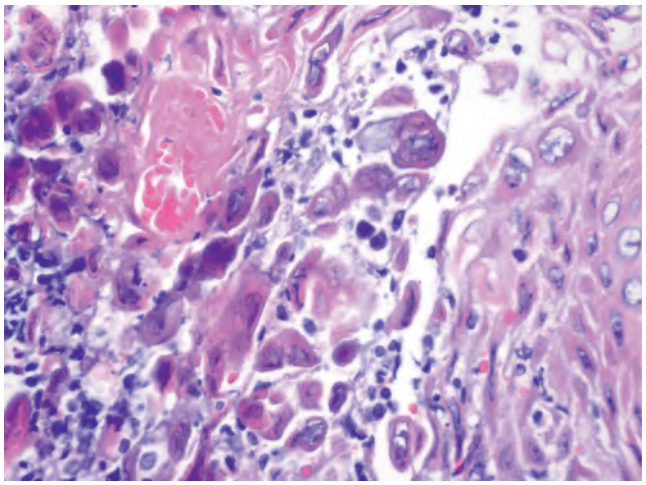

Figure 3-8 Biopsy of a herpes simplex virus ulcer demonstrating large epithelial cells with multiple ground-glass nuclei.

Table 3-2 Pain management and supportive care measures.

Pain Management
2% viscous lidocaine (swish 5 mL for 3–5 min. and spit out 4–5 times/d)
Liquid diphenhydramine (swish 5 mL for 3–5 min and spit out 5 4–5 times/d)
Combination of viscous lidocaine, diphenhydramine, and a covering agent (such as Kaopectate™ or Maalox™) in 1:1:1 ratio (swish 5 mL for 3–5 min and spit out)
0.1% diclonine hydrochloride
Benzydamine
Systemic analgesia
Supportive care
Hydration
Ice chips or popsicles
Soft bland diet
Antipyretics such as ibuprofen as needed (avoid aspirin products)*

*The use of aspirin products in children who have a viral illness (especially varicella infection, influenza, or coxsackievirus infection) has been associated with Reye syndrome, a potentially fatal condition characterized by fatty degeneration of the liver and encephalopathy.

Management

Primary HSV Infection

Management is directed toward pain control, supportive care, and definitive treatment (Table 3-2). In the past, healthy patients with primary herpetic gingivostomatitis were treated only with hydration and supportive measures. However, since the acyclovir family of drugs is inexpensive, safe, and readily available, it is appropriate to treat even primary infections definitively because it reduces viral shedding and infectivity.

Acyclovir inhibits viral replication and is activated by virally produced thymidine kinase. As such, it has little activity against nonvirally infected cells.[31] The use of acyclovir at 15 mg/kg five times a day in children reduces the duration of fever, reduces HSV shedding, halts the progress of lesions, improves oral intake, and reduces the incidence of hospital admissions.[32] Valacyclovir, the prodrug of

acyclovir, has three to five times the bioavailability of acyclovir and, together with famciclovir, are now widely used.

Recrudescent HSV

RHL can often be suppressed by reducing tissue damage, such as by using sunscreen.[33] Although RHL is self-limiting, the use of topical antiviral medications reduces shedding, infectivity, pain, and the size and duration of lesions. Topical antiviral medications such as 5% acyclovir cream,[34,35] 1% penciclovir cream,[36,37] and 10% docosanol cream are efficacious[38,39] if applied five to eight times a day (every two hours) at the first prodrome or sign of a lesion. Systemic therapy with valacyclovir (2 g 12 hours apart for one day) or famciclovir (1500 mg single dose) are both effective in aborting early lesions of RHL.[40] Suppression of HSV infection in patients who develop frequent episodes, large lesions, or erythema multiforme is effected with variable doses of acyclovir, valacyclovir and famciclovir.[41,42,43,44] Similar suppressive regimens can be used for patients susceptible to recrudescent HSV after dental procedures.[45]

HSV in Immunocompromised Patients

In general, HSV infections in immunocompromised hosts should be treated with systemic antivirals to prevent dissemination to other sites (e.g., HSV esophagitis) or systemically. The primary pathogen for herpes encephalitis and herpes pneumonitis is HSV-1. For patients undergoing hematopoietic cell transplantation, antiviral therapy such as acyclovir or valacyclovir at suppressive doses should be initiated for all patients who are HSV seropositive.[46] Resistance is seen in up to 6% of immunocompromised patients and usually stems from mutation of either virally-derived thymidine kinase that activates acyclovir, or from DNA polymerase.[47] In such cases, foscarnet or cidofovir are effective.[40] The dosage of the acyclovir family of drugs should be adjusted for age and renal health.

A number of vaccines and new therapies against HSV are currently under development.[48]

Varicella Zoster Virus (VZV) Infection

Biology and Pathogenesis

Primary infection with VZV, an α-herpesvirus, leads to varicella (chicken pox). As with all herpesviruses, the virus then becomes latent, usually in the dorsal root ganglia or ganglia of the cranial nerves.[49] Reactivation produces herpes zoster infection (HZI), commonly called shingles. The incidence of HZI increases with age and the degree of immunosuppression. There are 1.5 to 3 cases of HZI per 1000 subjects; this increases to 10 per 1000 in those over age 75 years.[50] Therefore, it is not uncommon to see HZI in the elderly, in patients undergoing cancer chemotherapy, in patients on chronic immunosuppressive drug therapy (such as those who have received organ transplants), and in patients with AIDS.[51] As with HSV, this virus is cytopathic to the epithelial cells of the skin and mucosa, causing blisters and ulcers. Transmission is usually by the respiratory route, with an incubation period of 2 to 3 weeks.[52]

Postherpetic neuralgia, a morbid sequela of HZI, is a neuropathy resulting from peripheral and central nervous system injury and altered central nervous system processing.[53]

Clinical Findings

Primary VZV or varicella infection generally occurs in the first two decades of life. The disease begins with a low-grade fever, malaise, and the development of an intensely pruritic, maculopapular rash, followed by vesicles that have been described as "dewdrop-like." These vesicles turn cloudy and pustular, burst, and scab, with the crusts falling off after 1 to 2 weeks. Lesions begin on the trunk and face and spread centrifugally. Central nervous system involvement may result in cerebellar ataxia and encephalitis.

Immunocompromised hosts usually experience more severe disease with more blisters, a bilateral distribution, a protracted course, and, not infrequently, with disseminated disease leading to encephalitis, hepatitis, and pneumonia. There is a significantly higher mortality rate.[54] Secondary bacterial infection by gram-positive cocci may have severe septic consequences.

Recrudescence of VZV leads to herpes zoster infection (HZI) or shingles which tends to occur in adult and starts with a prodrome of deep, aching, or burning pain, itching, and dysesthesia. There is usually little to no fever or lymphadenopathy. This is followed within 2 to 4 days by the appearance of crops of vesicles in a dermatomal or "zosteriform" pattern. This pattern describes the unilateral, linear, and clustered distribution of the vesicles, ulcers, and scabs in a dermatome supplied by one nerve. Thoracic/lumbar dermatomes are the most frequently involved, followed by the craniofacial area. Lesions heal within 2 to 4 weeks, often with scarring and hypopigmentation. Occasionally, HZI may occur without the appearance of dermatomal lesions (zoster sine eruptione or zoster sine herpete), which makes the diagnosis of this condition challenging; these patients often present with facial palsy. In fact, VZV has been detected in 3% of patients with Bell palsy.[13,15] A On rare occasions and especially in immunocompromised patients, HZI may involve not just the dorsal root ganglion but also the anterior horn cells, leading to myelitis; other rare complications include retinitis and encephalitis.[49]

One of the most important complications of HZI is postherpetic neuralgia, defined as pain that lingers for 120 days[53,55]

after the onset of the acute rash (see Chapter 12). Postherpetic neuralgia affects up to 20% of patients over age 65 and up to 30–50% of patients over age 80; affected individuals have debilitating pain, usually of a sharp, stabbing, burning, or gnawing nature lasting more than 1 month.[51,56] Some unfortunate patients experience pain for years. Predisposing factors include older age (most important), prodromal pain, and more severe clinical disease during the acute rash phase.[57,58]

Oral Manifestations

Primary VZV infection presents as minor acute ulcerations in the mouth that often pale in clinical significance when compared with the skin lesions.

In recurrent VZV infection, the ophthalmic division of the trigeminal (V) nerve is the cranial nerve most often affected (herpes zoster ophthalmicus); corneal involvement may lead to blindness.[51] Involvement of this nerve leads to lesions on the upper eyelid, forehead, and scalp with V_1; midface and upper lip with V_2; and lower face and lower lips with V_3 (Figure 3-9). With involvement of V_2, patients experience a prodrome of pain, burning, and tenderness, usually on the palate on one side. This is followed several days later by the appearance of painful, clustered 1 to 5 mm ulcers (rarely vesicles, which break down quickly) on the hard palatal mucosa or even buccal gingiva, in a distinctive unilateral distribution (Figure 3-10). Ulcers often coalesce to form larger ulcers with a scalloped border similar to those of HSV. These ulcers heal within 10 to 14 days, and postherpetic neuralgia in the oral cavity is uncommon. Involvement of V_3 results in blisters and ulcers on the mandibular gingiva and tongue.

Figure 3-9 Facial lesions of herpes zoster involving the third division of the trigeminal nerve.

Figure 3-10 Palatal lesions of herpes zoster involving the second division of the trigeminal nerve; note unilateral distribution. *Source:* Courtesy of Dr. Stephen Challacombe.

An uncommon complication of HZI involving the geniculate ganglion is Ramsay Hunt syndrome. Patients develop Bell palsy, vesicles of the external ear, and loss of taste sensation in the anterior two-thirds of the tongue.[52] HZI has been reported to cause resorption and exfoliation of teeth and osteonecrosis of the jawbones, especially in patients with HIV disease.[59–62]

Differential Diagnosis

The pain that is often experienced in the prodrome before the onset of vesicles and ulcers may lead to an incorrect diagnosis of pulpitis, leading to unnecessary dental treatment such as endodontic therapy.

HSV infection appears in a similar fashion and if mild and localized to one side may be mistaken for HZI; laboratory tests differentiate between the two. Other blistering/ulcerative conditions such as pemphigus or pemphigoid are chronic and/or progressive diseases that do not present unilaterally.

In severe cases of localized necrosis of the soft tissues and bone, acute necrotizing ulcerative periodontitis should be considered, particularly in the HIV population. Coinfection with CMV may occur in immunocompromised patients.[63] Medication- (such as bisphosphonate) and radiation-induced osteonecrosis of the jaws will have a history of exposure to bisphosphonate and radiation, respectively, and often is precipitated by dentoalveolar trauma in the absence of clustered ulcers.

In this age of bioterrorism, clinicians should be familiar with the signs of infection with vaccinia (smallpox virus), which presents with characteristic skin blisters and pustules.

Laboratory Findings

As with HSV infection, identification is by viral isolation using cell culture – a traditional method – although VZV is more fastidious and difficult to culture, use of fluorescein-labeled antibody to detect antigen, and use of molecular techniques such as real-time PCR using commercially available kits.[64,65] A simple smear stained with a standard laboratory stain would reveal the presence of multinucleated epithelial cells similar to HSV.

After primary infection, the patient seroconverts and IgG against VZV is detectable in the serum. HZI causes a transient rise in IgM and an increase in levels of IgG, but these are not reliable for diagnostic purposes.[66]

Biopsy is usually not required and is not the diagnostic test of choice since the clinical presentation is usually characteristic. If one should be performed, tissue should always include the intact epithelium adjacent to the ulcer since that is where the cytopathic effect in epithelium is best seen. VZV and HZI are cytopathic to the epithelial cells and result in the formation of multinucleated epithelial cells with viral inclusions, similar to and indistinguishable from HSV infection.

Management

As with HSV infection, management of oral lesions of varicella and HZI is directed toward pain control (particularly the prevention of postherpetic neuralgia), supportive care and hydration (see Table 3-2), and definitive treatment to minimize the risk for dissemination, particularly in immunocompromised patients. Aspirin use, especially in patients with VZV infection or oral viral infections may result in the development of Reye syndrome, which is potentially fatal, and ibuprofen is the preferred analgesic.[67]

Treatment of primary VZV infection and VZI includes the use of acyclovir (800 mg five times a day), valacyclovir (1000 mg three times a day or 1500 mg twice a day), famciclovir (500 mg three times a day), and brivudine (125 mg once a day) for 7 days and these should be started within 72 hours of disease onset.[68,69] This reduces infectivity, the severity of lesions, and hospitalizations for complications. However, acyclovir has poor bioavailability. These drugs also reduce the incidence of pain and postherpetic neuralgia. Combination therapy with 3-weeks of tapering corticosteroid therapy up-front reduces pain, and quickens return to normal activities.[68]

The first line of treatment for postherpetic neuralgia is gabapentin,[70] 5% lidocaine patch,[71] and 0.025–0.8% topical capsaicin, and the second line of treatment is with tricyclic antidepressants and corticosteroids.[55,68] The use of corticosteroids and antiviral therapy together in an attempt to reduce postherpetic neuralgia has not proved effective, although early treatment with famciclovir or valacyclovir may prevent it.[68,72] Case reports suggest that botulinum toxin may provide pain relief.[73]

A vaccine against VZV which contains live, attenuated virus reduces the incidence of varicella outbreaks, but because it establishes latency may be associated with increased zoster incidence.[74] Vaccination of older adults using Zostavax™ (live, attenuated virus), or Shingrix™ (recombinant VZV antigen) reduces incidence of HZI significantly and the latter, post-herpetic neuralgia.[75,76] The use of recombinant virus in a vaccine is more appropriate for use in immunocompromised hosts.

Cytomegalovirus (CMV) Infection

Etiology and Pathogenesis

CMV is a β-herpesvirus, and 50 to 100% of the population world-wide and 50% of the U.S. population has been exposed.[77,78] Risk for exposure increases with age, low socio-economic status, and crowded living conditions. Primary infection may be asymptomatic or cause an infectious mononucleosis-like disease. As with other members of Herpesviridae, CMV establishes latency within the connective tissue cells, such as the endothelium of blood vessels, mononuclear cells, and white blood cells in the connective tissue. Transmission is by direct transfer of infected white blood cells through intimate contact, vertical transmission, blood products, and transplanted organs.[79]

Clinical Findings

Primary CMV infection presents similarly to other viral infections with fever, malaise, and leucopenia and organ-specific findings such as gastroenteritis (most common), pneumonitis, retinitis and hepatitis, and even thromboembolism. Six to 7% of patients with infectious mononucleosis-like symptoms (fever, pharyngitis, and lymphadenopathy) have CMV or HSV infection rather than EBV infection.[80,81]

Manifestations of recrudescent infection and disease are most evident in the immunocompromised population, such as patients who have received organ transplants or those who have AIDS where CMV-related retinitis and gastroenteritis are common. A study on mucocutaneous CMV infection (mostly perianal) in patients with human deficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) revealed that CMV infection of mucocutaneous sites was usually part of a polymicrobial infection with HSV or VZV.[82] The authors suggest that CMV in such cases is not the pathogenic agent for these ulcers since the presence of those two α-herpesviruses alone could account for the ulceration and tissue damage. These authors also noted that CMV was often found in nonlesional skin.

In organ transplant recipients, CMV in the donor organ leads to a high incidence of CMV infection in the recipient.[83] It causes gastrointestinal and pulmonary disease in the first 100 days after allogenic hematopoietic stem cell transplantation.[84] There is growing evidence that CMV infection is associated with Guillain-Barré syndrome especially after renal transplantation, as well as polyradiculopathy and encephalitis in patients with AIDS.[83–85]

Oral Manifestations

CMV infection in the mouth in the immunocompromised patient tends to present as a single large ulcer and less often as multiple ulcers (Figure 3-11). They are usually painful and may have been present for weeks or months. Any site may be involved. Up to one-third of such ulcers are coinfected with other viruses of the herpes family, especially HSV and CMV. [86,87]

There have been occasional reports of mandibular osteomyelitis and tooth exfoliation associated with CMV and VZV infection.[63,88] Both viruses are associated with vasculopathy and thrombosis, which may be the underlying etiopathogenesis.[89,90]

Differential Diagnosis

As indicated earlier, CMV is often seen in association with HSV or VZV infections and, in such situations, may be a bystander rather than pathogenic. Therefore, evaluation for these other two viruses is essential for single or multiple ulcers in the immunocompromised population. In patients with HIV/AIDS, infections with mycobacteria, fungi, and other organisms must be ruled out.

Single ulcers present for weeks or months should be evaluated for squamous cell carcinoma or other malignancies. Since patients who develop such ulcers caused by opportunistic pathogens are often immunocompromised, one should have a high index of suspicion for a malignancy.

Figure 3-11 Cytomegalovirus ulcer on a background of hairy leukoplakia in a patient with AIDS.

Benign or malignant salivary gland tumors or soft tissue tumors may also become secondarily ulcerated from trauma. Single ulcers on the tongue may also represent traumatic ulcerative granuloma (see below).

Laboratory Tests

CMV infections of the oral cavity presenting as ulcers tend to be deep with viral particles residing in endothelial cells and tissue monocytes. As such, a culture of an ulcer infected by CMV is unlikely to be positive unless there is shedding of CMV from the ulcer surface. Furthermore, CMV may be difficult to grow in shell vial culture so current diagnosis of CMV infection is through real-time PCR viral nuclei acid identification from blood or plasma, and detection of pp65 antigen within leukocytes using a monoclonal antibody.[91] Antibody titers against CMV are unreliable for the diagnosis of active infection.

Biopsy for microscopic examination and/or to obtain tissue for culture is sensitive and specific for identification of CMV in oral ulcers.[88,91] CMV infection produces large intranuclear inclusions within endothelial cells and monocytes in the connective tissue, with an associated nonspecific chronic inflammation. The use of immunohistochemical techniques helps identify CMV if there are only a few infected cells. A biopsy has the advantage of also ruling out any of the other differential diagnoses discussed, such as other viruses or deep fungal infection. It is important to make sure that the biopsy includes normal epithelium because if the ulcer is coinfected with HSV or VZV, these would be identified on the biopsy in the intact epithelium adjacent to the ulcer.

Management

As with all ulcerative lesions, pain is managed with topical anesthetics and systemic analgesics as needed, with appropriate dietary modifications and good hydration (see Table 3-2). CMV infection is treated with ganciclovir 5 mg/kg IV twice daily, valganciclovir (a valine ester and oral prodrug of ganciclovir with approximately 10-fold bioavailability of ganciclovir) 900 mg twice daily, foscarnet, or cidofovir. Newer drugs that include letermovir and vaccines are in development.[92,93]

Epstein-Barr Virus Infection

Epstein-Barr mucocutaneous ulcer is discussed below in the section on solitary lesions.

Coxsackievirus Infection

Coxsackievirus (CV), a ribonucleic acid (RNA) virus, is a member of the genus *Enterovirus* and family Picornaviridae and has features in common with poliovirus. The genus

Enterovirus has several sero-types including enterovirus A, B, C, or D, CV A and CV B virus, poliovirus, and echovirus.[94] More than 90% of infections caused by the nonpolio enteroviruses are either asymptomatic or result in nonspecific febrile illness. The viruses replicate extensively in the lower gastrointestinal tract, and less so in the oropharynx, from where they shed. Transmission is therefore primarily by the fecal–oral route, although some shedding occurs in the upper respiratory tract.

Enterovirus infection is implicated in aseptic meningitis, acute encephalitis, acute paralysis, ocular infections, pleurodynia, myopericarditis, and respiratory illness. Enterovirus (EV) A17 and A6 are associated with more severe disease.[94] EVs, in particular B1, has been implicated in the pathogenesis of type 1 insulin-dependent diabetes mellitus.[95] CV B4 has also been implicated in the pathogenesis of primary Sjögren syndrome in one study, but this was refuted in another study.[96,97]

In the oral cavity, CV infections lead to three disease entities: hand-foot-and-mouth disease, herpangina, and lymphonodular pharyngitis.

Hand-Foot-and-Mouth Disease (HFM)

CVA16 and EV 71 are the most common cause of this vesicular exanthem, although more recently CVA6 has been reported to cause more severe infections. EV71 has been seen in large outbreaks in Southeast Asia. HFM disease, as with many CV infections, including herpangina, tends to be seasonal, occurs in epidemic clusters (such as schools and day care centers), and has high transmission rates.[98,99]

In comparing cases of HFM disease caused by EV71 with those caused by CVA16, EV71 is much more likely to be associated with severe central nervous system disease (such as meningitis and brainstem encephalitis), paralysis, pulmonary edema, and death.[100] In one study of patients with HFM disease and herpangina, 83% of cases were caused by EV71 and only 8% by CVA or CVB.[101] In another study of EV71 infections, 87% of cases manifested with HFM disease and 13% with herpangina.[102]

Clinical Findings

HFM disease usually afflicts children younger than 10 years in summer. Patients have a low-grade fever, emesis, and sore mouth; 75 to 100% of patients have a skin rash, especially on the hands and feet (dorsa, palms, and soles) and 30% on the buttocks.[94] The rash is first red and macular and then becomes vesicular. The incubation period is from 3–7 days and oropharyngeal shedding may last for 4 weeks while gastrointestinal shedding may last 8 weeks to many months.

Oral Manifestations

Patients are febrile and complain of a sore mouth and throat. Lesions begin as erythematous macules that become vesicles and quickly break down to ulcers. Lesions are usually located on the tongue, hard and soft palate, and buccal mucosa but can present on any oral mucosal surface.[94]

Herpangina

The word *herpangina* derives from *herpes*, meaning "vesicular eruption," and *angina*, meaning "inflammation of the throat." CVA (serotypes 1–10 and 22) are the most common viruses isolated from this disease.[94,103,104]

Clinical Findings

As with hand-foot-mouth disease, children under 10 are usually afflicted and outbreaks usually occur in epidemics in summer. Patients develop high fever, headache, and myalgia that usually last only 1 to 3 days.

Oral Manifestations

The first oral symptoms of herpangina are sore throat and pain on swallowing. There may be erythema of the oropharynx, soft palate, and tonsillar pillars. Small vesicles form, but these rapidly break down to 2 to 4 mm ulcers and these persist for 5 to 10 days (Figure 3-12).

Lymphonodular pharyngitis is associated with CVA10 and patients report a sore throat, and develop diffuse small nodules (likely lymphoid hyperplasia) in the oropharynx.[105]

Differential Diagnosis

Lesions of both HFM disease and herpangina may resemble primary herpetic gingivostomatitis. However, lesions on the palms and soles are typical for HFM disease, and ulcers

Figure 3-12 A cluster of ulcers on the tongue of a patient with herpangina. The patient also had lesions of the palate and posterior pharyngeal wall.

located only in the posterior oral cavity are typical for herpangina. Bright red and painful gingiva also characterize primary HSV infection, and this is uncommon in CV infections. Chickenpox presents with generalized vesicular skin lesions, but ulcers are not prominent in the oral cavity; patients also appear more ill. Infectious mononucleosis (primary EBV infection) may also present with sore throat and purulent exudates, but serology distinguishes this from CV infections.

Streptococcal infections of the throat generally do not produce vesicles or ulcers seen in HFM disease or herpangina but rather a purulent exudate, although the two may appear similar; cultures distinguish between the two.

Aphthous ulcers are generally not associated with fever or malaise except for the periodic fever syndrome.

Laboratory Tests

Diagnosis is usually made on clinical findings, and culture and biopsies are rarely necessary for diagnosis unless the presentation is atypical or the more virulent subtypes are suspected. CV infections may be diagnosed by culture (usually from the throat or stools), but real-time PCR is now employed for typing.[106]

Management

CV infections are self-limiting (unless complications arise or the patient is immunocompromised), and management is directed toward control of fever and mouth pain, supportive care, and limiting contact with others to prevent spread of the infection. Effective antiviral agents for CV are not available but vaccines are under development.[107]

Necrotizing Ulcerative Gingivitis and Periodontitis

Necrotizing ulcerative gingivitis (NUG), formerly known as acute necrotizing ulcerative gingivitis (ANUG), and its more severe counterpart, necrotizing ulcerative periodontitis (NUP), were reclassified in 2017 by the American Academy of Periodontics under the category of "Necrotizing Periodontal Disease."[108] These are acute ulcerative-inflammatory conditions of the gingiva and periodontium, respectively, that are associated with polymicrobial infection. During World War I, NUG was dubbed "trench mouth" since it was frequent among the soldiers in the trenches. NUG and NUP have strong associations with immune suppression (especially AIDS), debilitation, smoking, stress, poor oral hygiene, local trauma, and contaminated food supply. Diabetes may also be a risk factor.[109] It is unclear if NUG is a forerunner of NUP, but they are often seen in patients with AIDS. Both NUP and noma thrive in communities characterized by a large low socioeconomic class and extreme poverty.[110,111]

Etiology and Pathogenesis

The more important and constant of the microbes involved include *Treponema* species, *Prevotella intermedia*, *Fusobacterium nucleatum*, *Peptostreptococcus species*, *Porphyromonas gingivalis*, *Selenomonas* species, *Aggregatibacter actinomycetemcomitans* and *Campylobacter*.[112,113] In HIV patients, candida and herpesvirus are also commonly present.[114] Since some of these fusospirochetal organisms are common in the periodontal tissues, many believe that it is the permissive environment of an immunocompromised host that allows these microbes to proliferate. The tissue destruction is most probably a result of the production of endotoxins and/or immunologic activation and subsequent destruction of the gingiva and adjacent tissues. In addition, patients show reduced neutrophil chemotaxis and phagocytosis, resulting in poor control of infection. Some have identified herpesviruses within the crevicular fluid,[112] but such viruses shed readily in oral secretions, particularly in areas where there is tissue destruction and therefore maybe nonpathogenic bystanders.

If there is underlying systemic illness, NUG and NUP can spread rapidly from the gingiva to the periodontium and into the soft tissues, giving rise to cancrum oris, noma, or orofacial gangrene.[111] This is particularly devastating in children who are malnourished and live in poverty and is seen not infrequently in Africa. *Fusobacterium necrophorum* is likely to play an important role in the progression of NUP to cancrum oris because this organism produces a dermonecrotic toxin, hemolysin, leukotoxin, and proteolytic enzymes, all leading to extensive tissue destruction.[112] It may also stimulate the growth of *P. intermedia*.

Clinical Findings

NUG and NUP may or may not be associated with fever and malaise, although submandibular lymphadenopathy is usually present. This may be more prominent in patients with an underlying immunodeficiency.

However, noma generally is accompanied by fluctuating fever, marked anemia, high white cell count, general debilitation, and a recent history of some other systemic illness, such as measles.[111]

Oral Manifestations

NUG has a rapid and acute onset. The first symptoms include excessive salivation, a metallic taste, and sensitivity of the gingiva. This rapidly develops into extremely painful and ery-thematous gingiva with scattered punched-out ulcerations, usually on the interdental papillae, although any part of the marginal gingiva may be affected (Figure 3-13). There is accompanying malodor, and there may be gingival bleeding. Because of the pain associated with the gingivitis, there is usually abundant

Figure 3-13 Necrotizing ulcerative gingivitis with typical punched out, necrotic, and ulcerated interdental papillae. *Source:* Courtesy of Dr. Hani Mawardi, Boston, MA.

Figure 3-14 Fusospirochetal palatal lesions in a neutropenic patient.

build-up of dental plaque around the teeth because it may be too painful to perform effective oral hygiene.

Patients who are immunocompromised and neutropenic are prone to developing such lesions (Figure 3-14). In patients with AIDS, the prevalence of NUP is strongly predictive of a CD4 count below 200 cell/mm^3.[115] In this population; these areas may lead to osteonecrosis or necrosis of the soft tissues (Figure 3-15).[116]

In patients in whom there is severe immunodeficiency or malnutrition, NUG and NUP may progress to noma (Figure 3-16). The overlying skin becomes discolored, and perforation onto the skin ensues. The orofacial lesions are cone-shaped, with the base of the cone within the oral cavity and the tip at the skin aspect. There is sloughing of the oral mucosa followed by sequestration of the exposed, necrotic bone and teeth. Without treatment, the mortality rate is 70 to 90%.[112]

Differential Diagnosis

The acute onset of erythematous and ulcerated gingiva of NUG may suggest a diagnosis of primary herpetic gingivostomatitis and this is readily ruled out with a culture and by PCR. Desquamative gingivitides (caused by lichen planus, mucous membrane pemphigoid, pemphigus vulgaris, and hypersensitivity reactions) may present primarily on the gingiva, with no skin findings. However, these conditions are not of acute onset but rather chronic and/or progressive over months and years and are characterized by inflammation rather than necrosis.

Figure 3-15 Necrotizing ulcerative periodontitis with osteonecrosis in a patient with AIDS.

Figure 3-16 Erythema multiforme with target lesions of the skin of the hand.

Neutropenic ulcers in patients on cancer chemotherapy may appear similar, leading to extensive ulceration and necrosis of the marginal gingiva and other mucosal surfaces.

Single large necrotic ulcers of noma suggest deep fungal infections or infections with the herpes family of viruses, especially in immunocompromised patients. Squamous cell carcinoma is also a consideration in this group of patients.

Laboratory Testing

Secretions from the gingival sulcus grow mixed flora but in particular will be positive by culture or PCR for *Treponema* species, *Prevotella intermedia*, *Fusobacterium nucleatum*, and other bacteria as indicated above. Necrotizing gingival lesions may also be caused by microbes other than fusospirochetes, such as *Pseudomonas aeruginosa*.[117]

A biopsy usually is not helpful in making a diagnosis, although biopsies may be performed to rule out some other condition that may have a similar clinical presentation. The lesions demonstrate ulceration, extensive necrosis, leukocytoclasia, and a mixed inflammatory infiltrate. More than half of the cases in patients who were HIV positive were immunoreactive for HIV p24 within focal histiocytes, whereas EBV RNA was identified in 1 (6%) of 17 cases.[118]

Management

This is directed toward supportive care and pain control (see Table 3-2), definitive treatment, and identification of underlying predisposing factors. In patients who are malnourished, nutritional rehabilitation is essential to halt the progress of gingival lesions to noma.

Definitive treatment of NUG and NUP consists of gentle débridement to remove as much of the debris and plaque as possible; this is best accomplished under topical anesthesia during the first few visits. The use of chlorhexidine digluconate mouth rinse led to resolution in >90% of cases.[119] Patients with more extensive disease and/or systemic symptoms may require antibiotics active against gram-negative anaerobes, such as β-lactams.[116] Interestingly, metronidazole, which has little activity against spirochetes, also is effective, suggesting that resolution can occur without treatment of the entire microbial complex.[120]

Once the acutely painful episodes have resolved, scaling and root planing to completely remove all residual plaque and calculus are indicated. Periodontal surgery may be necessary to correct gingival and periodontal defects. It may be appropriate to test the patient for HIV or other immunosuppressive conditions, such as blood dyscrasia.

Cases of noma need aggressive treatment with nutritional supplementation, antibiotics, and tissue débridement. Nevertheless, survivors exhibit significant disfigurement and functional impairment from tissue loss and scarring.[113]

Erythema Multiforme

Erythema multiforme (EM) is an acute, self-limited, inflammatory mucocutaneous disease that manifests on the skin and often oral mucosa, although other mucosal surfaces, such as the genitalia, may also be involved.[121–123] It represents a hypersensitivity reaction to infectious agents (majority of cases) or medications. In general, EM is classified as EM minor if there is less than 10% of skin involvement and there is minimal to no mucous membrane involvement, whereas EM major has more extensive but still characteristic skin involvement, with the oral mucosa and other mucous membranes affected.[122] However, there is likely a subset of EM that affects the oral mucosa only without skin involvement. Historically, fulminant forms of EM were labeled Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis [TEN (Lyell disease)]. However, more recent data suggest that EM is etiopathogenetically distinct from those two latter conditions, and they are discussed separately below.

Etiology and Pathogenesis

EM is a hypersensitivity reaction, and the most common inciting factor is infection, particularly with HSV. Drug reactions to NSAIDS, anticonvulsants, or other drugs play a smaller role.[121] Cases of oral EM precipitated by benzoic acid, a food preservative, have been reported.[123,124]

Some studies show that recurrent EM is associated with HSV infection both by history of HSV infection 1 to 3 weeks before onset of EM, seropositivity for HSV antibodies, and identification of HSV antigens.[125] Using PCR techniques, HSV gene products have been identified in 71 to 81% of cases of recurrent EM.[10,11] It is postulated that HSV antigens incite a T cell-mediated delayed-type hypersensitivity reaction that generates interferon-γ, with the amplified immune system recruiting more T cells to the area. Cytotoxic T cells, natural killer cells, and/or cytokines destroy the epithelial cells. It has been suggested that CD34+ cells, Langerhans cell precursors, carry fragments of HSV DNA to the skin where it incites EM.[126]

A condition reported as mycoplasma-induced rash and mucositis (MIRM) appears similar to EM and also SJS in that patients, almost always pediatric, present with extensive oral and mucosal lesions but usually less prominent skin lesions.[127] However, infection with Chlamydia pneumonia may cause similar lesions.[128] Some have classified such lesions under Mycoplasma-associated SJS but current classification considers it a distinct entity because of the much milder skin presentation.

Clinical Findings

EM generally affects those between ages 20 and 40 years, with 20% occurring in children.[121] Patients with recurrent EM have an average of 6 episodes a year (range 2–24), with a mean duration of 9.5 years; remission occurred in 20% of cases.[125] Episodes usually last several weeks.[121,122] There may be a prodrome of fever, malaise, headache, sore throat, rhinorrhea, and cough. These symptoms suggest a viral (especially respiratory tract) infection, and this is not surprising since infectious agents are known to trigger EM.

Skin lesions appear rapidly over a few days and begin as red macules that become papular, starting primarily in the hands and moving centripetally toward the trunk in a symmetric distribution. The most common sites of involvement are the upper extremities, face, and neck. The skin lesions may take several forms—hence the term *multiforme*. The classic skin lesion consists of a central blister or necrosis with concentric rings of variable color around it called typical "target" or "iris" lesion that is pathognomonic of EM; variants are called "atypical target" lesions (Figure 3-16). The skin may feel itchy and burnt. Postinflammatory hyperpigmentation is common in dark-skinned individuals and may be worsened by sun exposure.

Oral Findings

The oral findings in EM range from mild erythema and erosion to large painful ulcerations (Figures 3-17 and 3-18).[123] When severe, ulcers may be large and confluent, causing difficulty in eating, drinking, and swallowing, and patients with severe EM may drool blood-tinged saliva. Extensive lip involvement with inflammation, ulceration, and crusting is common (Figure 3-19).

Oral lesions are present in 23 to 70% of patients with recurrent EM.[125–130] The most commonly affected sites are the lips (36%), buccal mucosa (31%), tongue (22%), and labial mucosa (19%).[128] Genital and ocular sites are affected in 25 and 17% of cases, respectively.[125]

The concept of pure oral EM is controversial and not universally accepted since some dermatologists believe that the characteristic appearance and distribution of skin lesions are the sine qua non for the diagnosis of EM. Nevertheless, cases of oral EM without skin involvement have been reported.[131] Intraoral lesions are irregular bullae, erosions, or ulcers surrounded by extensive erythema. Crusting and bleeding of the lips are common, but not always present.[124,132]

Differential Diagnosis

Primary HSV gingivostomatitis with its viral prodrome and erosions and ulcerations may resemble oral EM, but these lesions are culture positive for HSV and do not usually present with the typical skin rash. Oral ulcers of HSV are

Figure 3-17 Intraoral erythema multiforme with coalescent aphthous-like ulcers and erythema of the buccal mucosa.

Figure 3-18 Erythema multiforme with target lesions on the skin of the fingers and intraoral ulcers. *Source:* Courtesy of Dr. Adam Lipworth, Boston, MA.

Figure 3-19 Erythema multiforme with hemorrhagic crusts of the lips.

usually smaller, well circumscribed, and clustered, whereas EM lesions are larger and irregular. Autoimmune vesiculobullous disease such as pemphigus and pemphigoid may have oral ulcers and skin lesions, although skin lesions are bullous in nature and not maculopapular, without the centripetal progression seen in EM. They are chronic, slowly progressive diseases that usually persist for months, whereas EM heals within weeks.

Hemorrhagic crusts on the lips are seen in paraneoplastic autoimmune multiorgan syndrome/paraneoplastic pemphigus (associated with malignancies, see below) and Stevens-Johnson syndrome (often drug-induced, see below). The latter may be difficult to distinguish from EM.

Recurrent oral EM in the absence of skin findings may be confused with recurrent aphthous ulcers (see below), but aphthous ulcers present as discrete ovoid or round ulcers, whereas ulcers of EM are more diffuse and irregular with marked erythema.

Laboratory Findings

The diagnosis is made primarily on clinical findings and a recent history of recrudescent HSV infection. IgG and IgM levels are not a reliable test for recrudescence or asymptomatic reactivation although they may be suggestive. A negative IgG level rules out HSV as an etiologic agent.

Early lesions show lymphocytes and histiocytes in the superficial dermis around superficial dermal vessels. This is followed by hydropic degeneration of basal cells, keratinocyte apoptosis and necrosis, subepithelial bulla formation, and a lymphocytic infiltrate.[133] Leukocyte exocytosis is also usually noted.

Management

Mild oral EM can be managed with systemic or topical analgesics for pain and supportive care since the disease is self-limiting and resolves within a few weeks. More severe cases are usually managed with systemic corticosteroids although patients often worsen on discontinuation of steroid therapy. Topical steroids may also help resolve lesions. Cases suspected of being HSV-associated should be treated with antiviral medications, and prophylaxis may prevent recurrences. Treatment with acyclovir at the first sign of disease in recurrent EM controls disease in approximately half of patients.[125] Other treatment modalities include dapsone, hydroxychloroquin, mycophenolate mofetil, azathioprine, colchicines, methotrexate, and intravenous immunoglobulin. [134]

Continuous acyclovir at 400 mg twice a day prevents development of EM in most patients with HSV-associated recurrent disease, whereas EM not related to HSV responded well to azathioprine (100–150 mg/d).[127] Other studies have also shown good suppression of recurrent HSV-associated EM using 500 mg of valacyclovir twice a day or 250 mg of famciclovir twice daily.[44,135] Dapsone (100–150 mg/d) and antimalarials are partially successful in suppressing recurrent outbreaks but may be associated with significant side effects.[127]

Stevens-Johnson Syndrome (SJS) and Toxic Epidermal Necrolysis (TENs)

Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are both rare severe necrolytic mucocutaneous disorders resulting from hypersensitivity to medications and are clinically and etiopathogenetically distinct from EM. A diagnosis of SJS is made if there is less than 10% of body surface involvement, SJS-TEN overlap syndrome if 10–30% of body surface is involved and TEN if >30% is involved.[136,137] The mortality rate of SJS and TEN are 1–5% and 25–35% respectively. SJS and TEN start with a prodrome of fever and malaise and the development of generalized eruption of macules, papules, atypical target lesions, vesicles, and bullae. The more common inciting drugs include allopurinol (most common), anticonvulsants, antibiotics, and NSAIDs.[137] In Han Chinese, development of SJS/TEN to the aromatic anticonvulsants—such as carbamazepine, phenytoin, and lamotrigine—is highly associated with HLA-B*1502[138] while HLA-B*5801 is strongly associated with allopurinol associated SJS/TEN universally.[139]

The mucosal surfaces of the eye, genitalia, and mouth are almost always severely affected by SJS/TEN, always with skin involvement. The typical oral manifestation is hemorrhagic crusts on the vermilion and extensive ulcerations and erythema on the oral and other mucosal surfaces (Figures 3-20, 3-21). These lesions resemble oral lesions of paraneoplastic autoimmune multiorgan syndrome/paraneoplastic pemphigus, which are long-standing and associated with malignancy (see below) as well as EM.

Figure 3-20 Stevens-Johnson syndrome. Lips and labial mucosa (*A*), skin (*B*), and penile (*C*) lesions in a 17-year-old male with Stevens-Johnson syndrome.

Figure 3-21 Toxic epidermal necrolysis with necrolysis or peeling of the epidermis. *Source:* Courtesy of Dr. Adam Lipworth, Boston, MA.

Histopathologically, most of the disease is localized in the epidermis, presumably this being the site where the drug or its metabolite is bound, with less inflammation in the dermis as is usually seen in EM.

Because of the severity of this condition, treatment is generally with intensive supportive care because of loss of skin barrier, intravenous immunoglobulin, systemic steroids, cyclosporine, plasmapheresis, cyclosporine, and tumor necrosis factor alpha-inhibitor.[140,141] Because of the strong genetic associations with HLA haplotypes, in the future, some of such severe cutaneous adverse reactions may be substantially reduced by pharmacogenetic screening.[142]

Plasma Cell Stomatitis and Oral Hypersensitivity Reactions

Etiology and Pathogenesis

This is a group of conditions that have protean manifestations. Oral hypersensitivity reactions may take the following forms:

1) Acute onset of ulcers such as in oral EM (discussed above).
2) Red and white reticulated lesions of a lichenoid hypersensitivity reaction (discussed in Chapter 4, "Red and White Lesions of the Oral Mucosa").
3) Fixed drug eruption.
4) Marked erosion and erythema especially on the gingiva with or without ulceration called plasma cell stomatitis (PCS).
5) Swelling of the lips/angioedema (see Chapter 19, "Immunologic Diseases").
6) Oral allergy syndrome that presents mainly with symptoms of itching with or without swelling of the oral structures and oropharynx.

This discussion concentrates on lesions of PCS. PCS generally causes erythema and less often ulcers, but is included here for completeness.

PCS is a hypersensitivity reaction that was first described in the late 1960s and early 1970s and was likely a contact stomatitis to a component of chewing gum.[143] Since then, sporadic cases have continued to be reported, and these are all likely caused by a sensitizing contactant, whether or not the contactant is identified. These include khat (*Catha edulis*),[144] components of toothpaste,[144,145] mint candies,[146] and household cleaners.[147] Sometimes, the terms *mucous membrane plasmacytosis* and *plasma cell orificial mucositis* are used because there may be involvement of the upper respiratory tract.[148] Because of the intense plasma cell infiltration, it is believed that this is a B cell-mediated disorder, with T cells augmenting the response. Some believe that this is caused by components of plaque bacteria, although this is not a universally accepted concept.[149]

Clinical Findings

PCS occurs within days of exposure to the contactant, with most signs and symptoms limited to the oral cavity. Some lesions may affect the periorificial tissues or the oropharynx, leading to upper airway symptoms of hoarseness, dysphagia, and mild airway obstruction.[148] Endoscopy may reveal erythematous and thickened mucosa, often with a cobblestoning pattern from the edema. An obvious allergen/contactant is not always identified.[148,150]

Oral Manifestations

PCS occurs within a few days of exposure. It presents as brightly erythematous macular areas of the oral cavity, almost always involving the marginal and attached gingiva or alveolar mucosa and often involving other soft tissues, such as the maxillary and mandibular sulcus, tongue, or buccal mucosa (Figure 3-22). Ulcers may be present, and there may be epithelial sloughing and desquamation. The gingiva may also be swollen and edematous. Patients may

Figure 3-22 Plasma cell gingivitis presenting as desquamative gingivitis.

complain of pain and sensitivity and bleeding of the gingiva on brushing. Angular cheilitis with fissuring and dry, atrophic lips have been reported.[143,151]

Some cases reported as PCS consisted of a very localized area of erythematous gingiva, usually around a single tooth and measuring usually < 1 cm.[149] Interestingly, two adults in this series also demonstrated plasma cell balanitis. It is unclear if this represented classic PCS since most cases of PCS tend to be diffuse.

Differential Diagnosis

The differential diagnosis for PCS includes any of the desquamative gingivitides, such as erythematous/erosive lichen planus, and the autoimmune vesiculobullous disorders, such as mucous membrane pemphigoid and pemphigus vulgaris. The lesions will become chronic if the patient continues to be exposed to an undetected allergen. A biopsy for both routine histology and direct immunofluorescence studies to rule out mucous membrane pemphigoid and pemphigus vulgaris is necessary to make the diagnosis.

Another condition that PCS can mimic is pubertal or pregnancy-induced gingivitis and plaque-associated gingivitis. The difference in the histopathology is in the density of plasma cells since nonspecific gingivitis generally also is associated with a plasma cell infiltrate. The clinical appearance of diffuse red gingiva with a history of recent exposure to a new topical agent helps make the diagnosis, especially if discontinuation of the agent leads to resolution. Some previous cases reported as PCS may constitute such plaque-associated and pubertal gingivitis.[149] Chronic granulomatous gingivitis caused by components of polishing agents such as pumice also often present with sensitive or painful erythematous gingiva. A biopsy will show the presence of particulate matter in the gingival connective tissue.

Mouth-breathers often present with erythematous and sometimes edematous gingiva, usually around the upper anterior teeth. A good history and correlation with the histopathologic findings help differentiate this from PCS.

Erythematous candidiasis may present with marked gingival erythema (often linear) without the usual white curdy papules of "thrush" or pseudomembranous candidiasis and will resolve with anti-fungal therapy. *Candida* may also secondarily infect an area of PCS.

Fixed drug eruptions are rare in the oral cavity and present as areas of ulceration or erosion that recur at the same site whenever exposed to a certain medication.[152]

PCS should not be confused with a direct contact irritation of the tissues such as from strongly flavored foods and dentifrices.[153] This would occur in any individual and does not represent a hypersensitivity reaction because ulcers are caused by the noxious and caustic nature of the chemical causing a mucosal burn.

Laboratory Findings

A biopsy is the most useful diagnostic test for this condition, followed by patch testing to identify the allergen.

A biopsy of the gingiva in PCS shows parakeratosis, epithelial hyperplasia, neutrophilic exocytosis, and numerous spongiotic pustules in the absence of *Candida*.[143,154] The most significant finding is dense sheets of plasma cells in the lamina propria; many dilated capillaries lie close to the surface, accounting for the marked erythema. Eosinophils are not seen usually.[148] Immunoperoxidase stains will invariably show the plasma cell infiltrate to be polyclonal, typical for a reactive/inflammatory process, and not monoclonal, which typifies neoplastic lesions.[73]

Management

PCS is self-limiting and will generally, but not always, regress if the contactant is identified and removed. Nevertheless, pain control and anti-inflammatory agents may be helpful during the healing process. Topical steroids may help reduce inflammation and speed healing.[155] Some lesions have resolved with intralesional triamcinolone injections, although the gingiva is a particularly difficult location for such injections.[156] Cases have also responded well to prednisone.[150] Gingivectomies may be needed to recontour lesions that are long-standing and more fibrotic. One case showed improvement with 2% fusidic acid.[157]

THE PATIENT WITH RECURRING ORAL ULCERS

Recurring oral ulcers are among the most common problems seen by clinicians who manage diseases of the oral mucosa. There are several diseases that should be included in the differential diagnosis of a patient who presents with a history of recurring ulcers of the mouth, including recurrent aphthous stomatitis, Behçet syndrome, recrudescent HSV infection, and recurrent oral EM. HSV infection and EM were discussed earlier in this chapter.

Recurrent Aphthous Stomatitis (RAS)

RAS is a disorder characterized by recurring ulcers confined to the oral mucosa in patients with no other signs of disease. RAS is considered a diagnosis of exclusion since hematologic deficiencies, immune disorders, and connective tissue diseases may cause oral aphthous-like ulcers clinically similar to RAS.

RAS affects approximately 20% of the general population, but when specific ethnic or socioeconomic groups are studied, the incidence ranges from 5% to 50%.[158] RAS is classified according to clinical characteristics: minor ulcers, major

ulcers (Sutton disease, periadenitis mucosa necrotica recurrens), and herpetiform ulcers (Table 3-3). There are cases in which a clear distinction between minor and major ulcers is blurred, particularly in patients who experience severe discomfort from continuous or frequent episodes of multiple ulcers. These lesions have been referred to as "severe" minor ulcers or complex aphthosis.

Etiology and Pathogenesis

It was once assumed that RAS was a form of recurrent HSV infection, and there are still clinicians who mistakenly call RAS "herpes." Many studies done during the past 50 years have confirmed that RAS is not caused by HSV.[159] This distinction is particularly important at a time when there is specific effective antiviral therapy available for HSV that is ineffective for RAS. "Herpes" is an anxiety-producing word, suggesting a sexually transmitted disease among many laypersons, and its use should be avoided when it does not apply. There have been theories suggesting a link between RAS and a number of other microbial agents, including oral streptococci, *Helicobacter pylori*, VZV, CMV, and human herpesvirus (HHV)-6 and HHV-7, but there are presently no conclusive data linking RAS to a specific microorganism.[160]

The major factors presently linked to RAS include genetic factors, hematologic or immunologic abnormalities, and local factors, such as trauma and smoking. There is increasing evidence linking local immune dysfunction to RAS, although the specific defect remains unknown. During the past 30 years, research has suggested a relationship between RAS and various immune abnormalities including: lymphocytotoxicity, antibody-dependent cell-mediated cytotoxicity, defects in lymphocyte cell sub-populations, an alteration in the CD4 to CD8 lymphocyte ratio,[161] and dysfunction of the mucosal cytokine network, resulting in an exaggerated cell-mediated immune response.[162]

The best-documented factor is heredity. A study of 1303 children from 530 families demonstrated an increased susceptibility to RAS among children of RAS-positive parents. Another study demonstrated that patients with RAS-positive parents had a 90% chance of developing RAS, whereas patients with no RAS-positive parents had a 20% chance of developing the lesions.[163] Further evidence for the inherited nature of this disorder results from studies in which genetically specific human leukocyte antigens (HLAs) have been identified in patients with RAS, particularly in certain ethnic groups.[164] There have been studies linking minor RAS to genetic factors associated with immune function, particularly genes controlling release of the proinflammatory cytokines. A unified model of etiology postulates that triggers such as stress, or hormonal changes trigger a cascade of proinflammatory cytokines directed against oral mucosa.[165]

Figure 3-23 Iron deficiency anemia with ulcers on tongue.

Hematologic deficiency, particularly of serum iron, folate, or vitamin B12, appears to be an etiologic factor in 5%–10% patients with aphthous-like ulcers although these lesions more often occur on keratinized mucosa (Figure 3-23). Studies of RAS populations from the United Kingdom show a higher level of nutritional deficiency than studies performed in the United States.[166]

Aphthous-like ulcers may also be seen in celiac disease, an autoimmune disease caused by intolerance to gluten and childhood periodic fever syndromes such as periodic fever, aphthosis, pharyngitis and adenopathy (PFAPA) syndrome[167] (see Chapter 25 Pediatric Oral Medicine).

It was initially reported in the 1960s that there was a negative correlation between RAS and a history of smoking, and many clinicians have reported that RAS is exacerbated when patients stop smoking. A study measuring a nicotine metabolite present in the blood of smokers confirmed that the incidence of RAS is significantly lower among smokers. The nicotine metabolites are believed to decrease levels of proinflammatory cytokines and increase anti-inflammatory cytokines.[159,168]

Other factors that have been reported associated with RAS include anxiety, periods of psychological stress, localized trauma to the mucosa, menstruation, upper respiratory infections, and food allergy.

Oral Findings

The first episodes of RAS most frequently begin during the second decade of life. The lesions are confined to the oral mucosa and begin with prodromal burning from 2 to 48 hours before an ulcer appears. During this initial period, a localized area of erythema develops. Within hours, a small white papule forms, ulcerates, and gradually enlarges over the next 48–72 hours. The individual lesions are round-to-ovoid, symmetric, and shallow (similar to viral ulcers), but no tissue tags are present from ruptured vesicles, which helps distinguish RAS from diseases that start as vesicles, such as pemphigus, and pemphigoid. Multiple lesions are

often present, but the number, size, and frequency vary considerably (Figures 3-24 through 3-27). The buccal and labial mucosae are most commonly involved. Lesions rarely occur on the heavily keratinized palatal mucosa or gingiva. In mild RAS, the lesions reach a size of 0.3–1.0 cm and begin healing within a week. Healing without scarring is usually complete in 10–14 days.

Most patients with RAS have between two and six lesions at each episode and experience several episodes a year. The disease is an annoyance for the majority of patients with mild RAS, but it can be painfully disabling for patients with multiple minor RAS or major RAS. Patients with major ulcers develop deep lesions that are larger than 1 cm in diameter and last for weeks to months (Figure 3-25). In the most severe cases, large portions of the oral mucosa may be covered with large deep ulcers that can become confluent, and are extremely painful, interfering with speech and eating. These patients may occasionally require hospitalization for intravenous feeding and treatment with systemic corticosteroids. The lesions may last for months and sometimes be misdiagnosed as squamous cell carcinoma, granulomatous disease, or a blistering disease such as pemphigus. The lesions heal slowly and leave scars that may result in decreased mobility of the uvula and tongue.

The least common variant of RAS is the herpetiform type, which tends to occur in adults. The patient presents with more than 10 small punctate ulcers, measuring <5 mm, scattered over large portions of the oral mucosa.

Figure 3-24 Recurrent aphthous ulcer of the labial mucosa.

Figure 3-25 Major recurrent aphthous ulcer involving the tongue of a patient with HIV disease.

Differential Diagnosis

RAS is the most common cause of recurring oral ulcers and is essentially diagnosed by exclusion of other diseases. A detailed history, examination, and when necessary laboratory testing by a knowledgeable clinician should distinguish RAS from primary acute lesions such as viral stomatitis or erythema multiforme or from chronic multiple lesions such as pemphigus or pemphigoid, as well as from other conditions associated with recurring ulcers, such as RIH, connective tissue diseases, drug reactions, and other dermatologic disorders. The history should include obtaining symptoms, which may suggest oral ulcers from HIV, connective tissue disease such as lupus erythematosus, gastrointestinal complaints suggestive of inflammatory bowel disease, and associated skin, eye, genital, or rectal lesions.

Laboratory Findings

Laboratory tests should be ordered when patients do not follow the usual pattern of RAS; for example, when episodes of RAS become more severe, begin past the age of 25, or are accompanied by other signs and symptoms. Biopsies are only indicated when it is necessary to exclude other diseases, particularly granulomatous diseases such as Crohn disease, sarcoidosis, or blistering diseases such as pemphigus or pemphigoid (Figure 3-26).

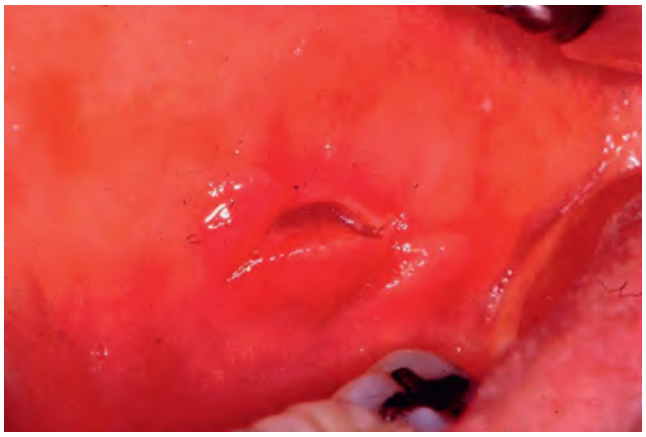

Figure 3-26 Oral ulcer involving the buccal mucosa of a patient with Crohn's disease.

Patients with severe minor aphthae or major aphthous ulcers should have known associated factors investigated, including connective tissue diseases and hematologic abnormalities, such as reduced levels of serum iron, folate, vitamin B12, and ferritin. Patients with abnormalities in these values should be referred to an internist for further management. HIV-infected patients, particularly those with CD4 counts below 100/mm^3, may develop major aphthous ulcers, and, occasionally, such oral ulcers are the presenting sign of AIDS.

Biopsies reveal only a superficial ulcer covered by a fibrinous exudate with granulation tissue at the base and a mixed acute and chronic inflammatory infiltrate. Studies of early lesions of RAS demonstrate an infiltration of large granular lymphocytes and helper-induced CD4 lymphocytes with focal degeneration of basal cells and the formation of small intraepithelial vesicles. The appearance of the ulcer is associated with the appearance of cytotoxic suppressor lymphocytes.[169]

Management

Management is tailored to the severity of the disease. In mild cases with two or three small lesions, use of a protective emollient such as Orabase™ often alleviates pain and facilitates healing. Pain relief of minor lesions can be effected with a topical anesthetic agent such as benzocaine or lidocaine. In more severe cases, the use of a high-potency topical steroid preparation, such as fluocinonide, betamethasone, or clobetasol, placed directly on the lesion, shortens healing time and reduces the size of the ulcers. The effectiveness of the topical steroid is partially based on good instruction and patient compliance regarding proper use. The steroid gel can be carefully applied directly to the lesion after meals and at bedtime two to three times a day or mixed with an adhesive such as Orabase prior to application. Larger lesions can be treated by placing a gauze sponge containing the topical steroid on the ulcer and leaving it in place for 15–30 minutes to allow for longer contact of the medication. Other topical preparations that have shown promise in decreasing the healing time of RAS lesions include use of chlorhexadine or a topical tetracycline such as doxycycline, which can be used either as a mouthrinse or applied as a paste directly to the lesions.[170] Intralesional steroid injections can be used to treat large indolent major RAS lesions. It should be emphasized that no available topical therapy reduces the frequency of new lesions. Use of lasers had been studied as a method of pain relief for patients with large ulcers.

When patients with major aphthae or severe cases of multiple minor aphthae do not improve sufficiently with topical therapy, use of systemic therapy should be considered. Drugs that have been reported to reduce the number of ulcers in selected cases of major aphthae include colchicine, pentoxifylline, dapsone, short bursts of systemic steroids, and thalidomide.[169,171] Each of these drugs has the potential for side effects, and the clinician must weigh the potential benefits versus the risks.[171]

Thalidomide, a drug originally marketed as a nonaddicting hypnotic in the 1950s, was withdrawn from the market in the early 1960s due to its association with severe, deforming, and life-threatening birth defects. Further investigation demonstrated that thalidomide has significant anti-inflammatory and immunomodulatory properties and is useful in treating a number of diseases, including erythema nodosum leprosum, discoid lupus erythematosus, graft-vs-host disease, multiple myeloma, and Behçet syndrome. The drug has also been shown to reduce both the incidence and severity of major RAS in both HIV-positive and HIV-negative patients.[172] The use of thalidomide for RAS should be reserved for management of severe major RAS where other less toxic therapies, including high-potency topical steroids, colchicine, and pentoxifylline, have failed to control the disease.[173] Thalidomide must be used with extreme caution in women during childbearing years owing to the potential for severe life-threatening and deforming birth defects. All clinicians prescribing thalidomide in the United States must be registered in the REMS (Risk Evaluation Mitigation Strategy) program for thalidomide and patients receiving the drug must be thoroughly counseled regarding effective birth control methods that must be used whenever thalidomide is prescribed. For example, two methods of birth control must be used, and the patient must have a pregnancy test monthly. Other side effects of thalidomide include peripheral neuropathy, gastrointestinal complaints, and drowsiness. Monitoring patients taking long-term thalidomide for the development of peripheral neuropathy with periodic nerve conduction studies is recommended.

Behçet's Disease (Behçet Syndrome)

Behçet's disease (BD) was initially described by the Turkish dermatologist Hulusi Behçet as a triad of symptoms including recurring oral ulcers, recurring genital ulcers, and eye involvement. BD is now understood to be a multisystem disorder with many possible manifestations. The highest incidence of BD has been reported in eastern Asia, the Middle East, and the eastern Mediterranean, particularly Turkey and Japan, where BD is a leading cause of blindness in young males; however, cases have been reported worldwide, including Europe and North America.[174]

Etiology and Pathogenesis

BD is a systemic perivasculitis characterized by hyperactivity of neutrophils with enhanced chemotaxis and elevated proinflammatory cytokine IL-8, IL-17, and TNF-α playing a

major role in the pathogenesis.[175] The HLA-B51 genotype is most frequently linked to BD, especially in patients with severe forms of the disease in Asia.[176]

Clinical Manifestations

The highest incidence of BD is in young adults between the ages of 25 and 40, with the oral mucosa as the most common site of involvement. The genital area is the second most common site of involvement and presents as ulcers of the scrotum and penis in males and ulcers of the labia in females. The eye lesions consist of uveitis, retinal vasculitis, vascular occlusion, optic atrophy, and conjunctivitis. Blindness is a possible complication of the disease, and periodic evaluation by an ophthalmologist is necessary.

Systemic involvement occurs in over half of patients with BD. Skin lesions resembling erythema nodosum or large pustular lesions occur in over 50% of patients with BD. These lesions may be precipitated by trauma, and it is common for patients with BD to have a cutaneous hyperreactivity to intracutaneous injection or a needlestick (pathergy). Arthritis occurs in greater than 40% of patients and most frequently affects the knees, ankles, wrists, and elbows. The affected joint may be red and swollen, as in rheumatoid arthritis, but involvement of small joints of the hand does not occur, and permanent disability does not result.[174]

In some patients, central nervous system involvement is the most distressing component of the disease. This may include brainstem syndrome, involvement of the cranial nerves, or neurologic degeneration resembling multiple sclerosis that can be visualized by magnetic resonance imaging of the brain.[177] Other reported signs of BD include thrombophlebitis, intestinal ulceration, venous thrombosis, and renal, cardiac, and pulmonary disease. Both pulmonary involvement and cardiac involvement are believed to be secondary to vasculitis, which may involve all layers of large blood vessels Involvement of large vessels is life threatening because of the risk of arterial occlusion or aneurysms.

BD in children, which most frequently presents between the ages of 9 and 10 years, has similar manifestations to the adult form of the disease, but oral ulcers are a more common presenting sign in children, whereas uveitis is less common. Oral lesions are the presenting symptom in more than 95% of children with BD. A variant of BD, MAGIC syndrome, has been described. It is characterized by mouth and genital ulcers with inflamed cartilage.[178]

Oral Findings

The most common site of involvement of BD is the oral mucosa. Recurring oral ulcers appear in more than 90% of patients; these lesions cannot be distinguished either clinically or histologically from RAS (Figure 3-27). Some patients experience mild recurring oral lesions; others have deep, large, scarring lesions characteristic of major RAS. These lesions may appear anywhere on the oral or pharyngeal mucosa.

Differential Diagnosis

Because the signs and symptoms of BD overlap with those of several other diseases, particularly the connective tissue diseases, it has been difficult to develop criteria that meet with universal agreement. A collaborative study developed the following diagnostic criteria based on a point system where 4 or more points is strongly associated with BD: oral, ocular, and genital lesions score 2 points each, while skin lesions, and neurologic and vascular manifestations score 1 point each (Figure 3-28). Positive pathergy test is an optional test but also scores 1 if positive.[179]

Laboratory Findings

BD is a clinical diagnosis based up the criteria described above. Laboratory tests are used to rule out other diseases,

Figure 3-27 Ulcer of the tongue of a patient with Behçet's disease.

Figure 3-28 Early skin lesion of pemphigus vulgaris.

such as connective tissue (e.g., lupus erythematosus) and hematologic diseases causing severe neutropenia.

Management

The management of BD depends on the severity and the sites of involvement. Patients with sight-threatening uveitis, vascular, GI, or central nervous system lesions require aggressive therapy with systemic steroids, immunosuppressive drugs, interferon alpha, or anti-TNF biologics.[180] Pentoxifylline, which has fewer side effects than immunosuppressive drugs or systemic steroids, has also been reported to be effective in decreasing disease activity, particularly of oral and genital lesions.[181] Dapsone, colchicine, and thalidomide have also been used effectively to treat mucosal lesions of BD.[182] Apremilast, a biologic which decreases proinflammatory cytokines, was shown in a placebo controlled clinical trial to decrease the incidence and severity of oral and genital ulcers in a majority of patients[183] and is taken orally.

THE PATIENT WITH CHRONIC MULTIPLE LESIONS

Patients with chronic multiple persistent oral ulcerative lesions often have a delayed diagnosis as the clinical presentation may be confused with other recurrent ulcerative disorders including EM or RAS. The clinician can avoid misdiagnosis by carefully questioning the patient on the initial visit regarding the natural history of the lesions. In recurring disorders such as severe RAS or EM, the patient may experience continual new episodes of ulceration of the oral mucosa, but individual lesions heal and new ones form. In the category of disease described in this section, the same lesions are present for weeks to months often expanding in size. The major diseases in this group that can affect the oral mucosa are pemphigus vulgaris (PV), paraneoplastic pemphigus (PNP), bullous pemphigoid (BP), mucous membrane pemphigoid (MMP), linear IgA disease (LAD), epidermolysis bullosa acquisita (EBA), and erosive lichen planus. Lichen planus is discussed in Chapter 4.

Pemphigus

Pemphigus includes a group of autoimmune, potentially life-threatening diseases that cause blisters, peeling or erosions of the skin and/or mucous membranes, characterized by intraepidermal or epithelial acantholysis. The predisposition to develop the autoantibodies that cause pemphigus is genetically determined, but the triggering mechanism that initiates the immune response is unknown, though occasionally drugs may be implicated.

The major variants of pemphigus are pemphigus vulgaris (PV), pemphigus foliaceus, and paraneoplastic pemphigus (PNP). Pemphigus vegetans is a variant of pemphigus vulgaris, and pemphigus erythematosus is a variant of pemphigus foliaceus. Pemphigus vulgaris and paraneoplastic pemphigus frequently present with oral lesions and will be discussed in detail below. Pemphigus foliaceus (PF) is much less common than PV and only affects the skin. The increased number of pemphigus foliaceus cases in South America (Brazil and neighboring countries) and North Africa (Tunisia and neighboring countries) is the result of an endemic form of the disease in these areas, where it affects mostly young adults. In fogo selvagem, the endemic form of pemphigus foliaceus in Brazil, an initial immune response against the sand fly salivary antigen LJM11 is speculated to cause a cross-reaction with the PF antigen desmoglein 1.

Pemphigus Vulgaris (PV)

PV is the most common form of pemphigus, accounting for over 80% of cases.

Etiology and Pathogenesis

Both genetic and environmental factors are associated with the onset of pemphigus. Pemphigus is a polygenic disease with an increased prevalence of low titers of disease-associated autoantibodies in healthy first-degree relatives of patients. A strong association with pemphigus vulgaris has been observed for HLA-DRB1*0402 (which is predominant in Ashkenazi Jews), HLA-DRB1*1401, HLA-DRB1*1404 and HLA-DQB1*0503 (which are both prevalent in non-Jewish patients of European and Asian descent).[184]

Environmental factors under consideration include viruses (such as herpes simplex), dietary factors, and physiological and psychological stressors. Several drugs have been implicated in the induction of pemphigus and though uncommon, the diagnosis is challenging as the clinical presentation is indistinguishable and the latency period may be several months. There are three groups of chemical structures that have been suggested to cause drug-induced pemphigus: thiol drugs (e.g., captopril, carbimazole, and penicillin), phenol drugs (e.g., rifampicin, levodopa, and aspirin) and nonthiol, nonphenol drugs (e.g., calcium channel blockers, ACE-inhibitors and nonsteroidal antiinflammatory drugs). PF is the most common pattern observed in up to 70% of thiol-induced cases while nonthiol drugs tend to trigger a PV phenotype. Initial management is to stop the offending drug and, if needed, additional conventional treatment. The disease may continue in 50% in spite of drug withdrawal while others recover completely. Recovery following drug withdrawal is more likely in thiol-triggered cases.[185]

The underlying mechanism responsible for lesions in PV is the binding of IgG and sometimes IgA autoantibodies to transmembrane glycoprotein adhesion molecules present on desmosomes called desmogleins.[186,187] Desmoglein 1 (Dsg1) is the dominant glycoprotein expressed in the skin and though also present throughout the epithelia in mucous membranes, the dominant molecule in mucosal desmosomes is desmoglein 3 (Dsg3). Individuals genetically susceptible to pemphigus harbor desmoglein reactive B and T cells.[188] Patients with PV mainly involving the mucous membranes have antibodies primarily against Dsg3, but patients with PV involving both the skin and mucosa will have antibodies against both Dsg3 and Dsg1.[189] Evidence for the relationship of the IgG autoantibodies to PV lesion formatio, includes studies demonstrating the formation of blisters on the skin of mice after passive transfer of IgG from patients with PV.[190] The precise mechanism of the acantholysis after pemphigus IgG binds to Dsg 3 on the cell surface is unknown. There is, however, evidence to support signaling molecules and metabolic pathways in the development of acantholysis, involving, for example, p38 mitogen-activated protein kinase (MAPK) and its downstream effectors ultimately leading to a reduction in the number of desmosomes. It has been shown that activation of autoreactive T cells responsive to Dsg 1 and 3 in the context of HLA-DRB1*04:02 leads to the induction of IgG autoantibodies and loss of epidermal adhesion.[191] This concept has been developed into a potential therapeutic strategy. Using a chimeric autoantibody receptor (CAAR) on T cells in this case Dsg, adapted T cells specifically kill anti-Dsg3 B cells in a PV mouse model.[192,193]

Epidemiology

The incidence of pemphigus depends upon geographical location. In Central Europe and the United States, it is estimated to be between 1 and 7 patients/million/year. It occurs more frequently in the fifth to sixth decades of life, although rare cases have been reported in children. Although universally encountered, there is a racial predisposition noted among Ashkenazi Jews and Asian subgroups including those originating from Gujurat in India. Generally, PV is more common than pemphigus foliaceus (PF), with ratios ranging from 4:1 to 9:1.

Clinical Manifestations

General

The classic lesion of PV is a thin-walled bulla arising on otherwise normal skin or mucosa. The blister or bulla rapidly breaks but may continue to extend peripherally, eventually leaving larger areas denuded of skin (Figures 3-28 and 3-29). A characteristic sign of the disease, the Nikolsky sign, may be elicited by application of gentle lateral pressure to an erosion or blister. It is not however recommended as it is painful and while typically seen in PV may also be seen in other blistering conditions.

There are three broad clinical subgroups of PV: mucosal-dominant type (limited cutaneous involvement) associated with blisters in the deep layers of the oral mucosa owing to anti-Dsg 3 IgG autoantibodies; mucocutaneous type (both mucosal and cutaneous involvement) with blisters in the deep layers of the oral mucosa and epidermis, owing to anti-Dsg 3 and anti-Dsg 1 IgG autoantibodies, respectively; and cutaneous type (cutaneous involvement alone) with predominantly anti-Dsg 1 IgG autoantibodies.

The majority of patients will present with oral lesions and thus the dental profession will often encounter these patients first. Skin lesions when present may involve any surface including the scalp, anogenital skin, and periungual areas with an average lag period of 4 months. Lesions on the scalp may result in a chronic, thickened hyperkeratotic areas that can become secondarily infected. In flexural sites the skin can appear thickened or "vegetating" and may be referred to as pemphigus vegetans.

In severe cases of PV, the conjunctival, nasopharyngeal, laryngeal, esophageal, or anogenital mucosae may be involved and patients may become cachexic and dehydrated. Endoscopic examination, particularly where esophageal symptoms are present, should be performed to determine the severity of the lesions. Mucocutaneous PV tends to be a more severe disease, proving slower to respond to treatment and less likely to achieve remission off-treatment than purely mucosal PV. Rarely patients with pemphigus develop acute fulminating disease, but, in most cases, the disease develops more slowly, usually taking months to develop to its fullest extent. Since the advent of corticosteroids most patients will improve relatively quickly. However, there is significant morbidity and occasionally a mortality rate in elderly patients and

Figure 3-29 Extensive involvement of the skin in a patient with pemphigus vulgaris.

in patients requiring high doses of corticosteroids who develop infections and bacterial septicemia.

Oral Findings

Eighty to 90% of patients with PV develop oral lesions sometime during the course of the disease, and in 60% of cases, oral lesions are the first sign. It is common for the oral lesions to be present for weeks to months before the skin lesions appear. In a subgroup of patients, PV may affect the oral mucosa as the sole site. Thus, dental specialists and primary care physicians need to recognize the oral clinical signs. There is evidence to suggest that early treatment leads to be more rapid disease control, however the delay in diagnosis may be several months.

Intraorally, while transient blisters may be reported by the patient and are occasionally seen, more typically, PV presents with multiple shallow irregular erosions. These correspond to the loss of a thin irregular layer of epithelium leaving a denuded erythematous base. As the ulcers are not full thickness, that is, penetrating the corium, there is not a yellow sloughy base (Figures 3-30 and 3-31). The edges of the lesion particularly may continue to extend peripherally over a period of weeks until they involve larger areas of the oral mucosa. Most commonly, lesions start on the buccal mucosa, often in areas of trauma along the occlusal plane. The palatal mucosa, tongue, and gingiva are other common sites of involvement. As lesions start to heal, they form a more defined margin and eventually develop a white appearance before resolving completely. When ulcers are present on the dorsum of the tongue, these may be longstanding and may eventually heal with loss of the papillae. Elsewhere in the mouth, long-term damage or scarring is not a feature of this condition.

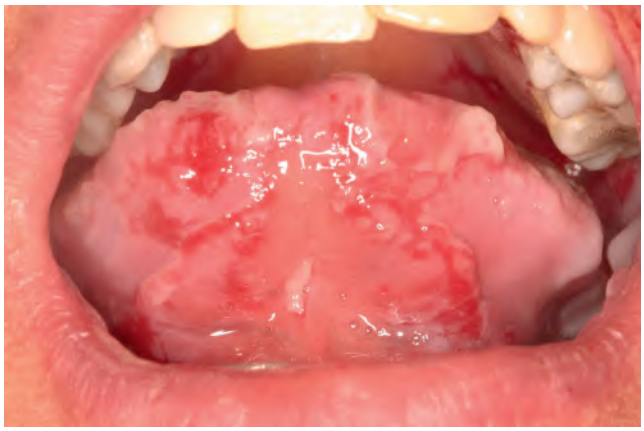

Figure 3-30 Pemphigus vulgaris presenting as shallow, irregular red erosions of the ventral tongue with ulcers and tissue tags.

Figure 3-31 Pemphigus vulgaris presenting as ragged erosions of the gingival margin.

Differential Diagnosis

If an accurate history and examination is performed, the clinician should be able to distinguish the lesions of pemphigus from those caused by acute viral infections, such as primary herpetic stomatitis or recurrent EM, as these are generally transient and spontaneously remitting. While recurrent EM can rarely give rise to almost persistent ulceration, individual lesions will heal over 2 to 3 weeks. It is also important for the clinician to distinguish pemphigus lesions from RAS. While RAS lesions may be severe, individual lesions heal and recur often in a different site. The Stevens-Johnson–Toxic epidermal necrolysis (SJS-TEN) spectrum must also be considered in patients with an abrupt onset of mucocutaneous lesions, but this is usually in the context of a new medication and patients are generally very unwell. In pemphigus, the same lesions continue to extend peripherally over a period of weeks to months. Lesions of PV are not round and symmetric like RAS lesions but are erythematous, shallow, and irregular and often have detached epithelium at the periphery. In some cases, the lesions may start on the gingiva as desquamative gingivitis. It should be remembered that desquamative gingivitis is not a diagnosis in itself; these lesions must be biopsied to distinguish PV from subepithelial blistering diseases such as mucous membrane pemphigoid or lichen planus.

Laboratory Findings

PV is diagnosed by biopsy and this can be taken from either oral mucosa or skin. Two samples are taken, one for histology and a second for direct immunofluorescence (DIF). The latter is the gold standard test for diagnosis. In blistering skin or oral diseases, the ideal sample includes a new intact vesicle less than 24 hours old for histopathology. However, because intact blisters are rarely seen, the biopsy specimen should be taken from the advancing edge of the lesion, where areas of characteristic suprabasilar acantholysis may

be observed by the pathologist. Specimens taken from the center of a denuded area are nonspecific histologically as well as clinically. Occasionally more than one set of biopsies is necessary before the correct diagnosis can be made.

The separation of cells, called acantholysis, takes place in the lower layers of the stratum spinosum (Figure 3-32).

A second biopsy for direct immunofluorescence (DIF) should be performed whenever PV is included in the differential diagnosis. This study is best performed on a biopsy specimen taken from clinically normal-appearing perilesional mucosa or skin, and placed in Michel's transport medium. In the laboratory, fluorescein-labeled antihuman immunoglobulins are placed over the patient's tissue specimen. In cases of PV, the technique will detect IgG bound to the surface of the keratinocytes (Figure 3-33). It distinguishes PV from the subepidermal immunobullous diseases.

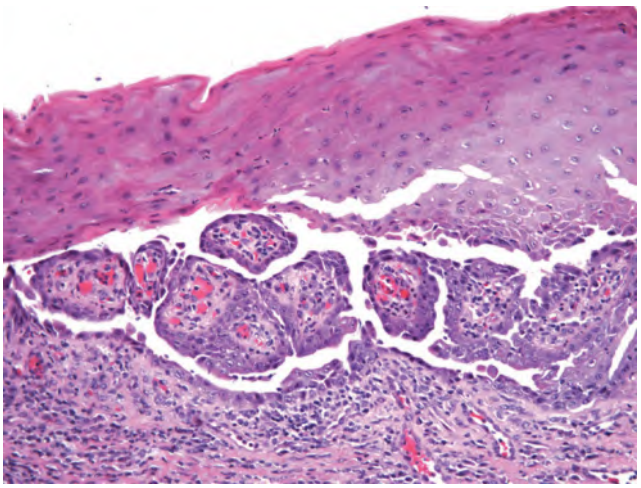

Figure 3-32 Photomicrograph of pemphigus vulgaris showing suprabasilar bulla with acantholysis.

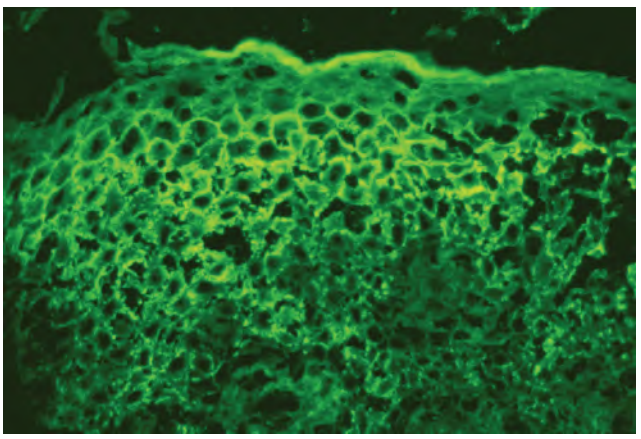

Figure 3-33 Direct immunofluorescence study of pemphigus vulgaris showing intercellular deposition of IgG.

In PV, if the adjacent "normal" tissue is sampled, the result is positive in 100% samples.[194]

Indirect immunofluorescent (IIF) antibody tests performed on a patient's serum are helpful in distinguishing PV from pemphigoid and other chronic oral lesions and in following the progress of patients during treatment. In this technique, serum from a patient with a bullous disease is placed over a prepared slide of a mucosal structure (usually monkey esophagus), or salt-split human skin and autoantibodies present in the serum will bind to the target antigens. The slide is then overlaid with fluorescein-tagged antihuman immunoglobulin. Patients with PV have circulating anti-DSG antibodies that bind to the keratinocyte surfaces and are detected using the fluorescent microscope. The titer of the antibody has been related to the level of clinical disease and may be repeated periodically during treatment to determine disease activity.[195] The association, however, is not always present with some patients having active disease and negative IIF and vice versa. An enzyme-linked immunosorbent assay (ELISA) is more sensitive than IIF and can distinguish anti-DSG1 antibodies from anti-DSG3 in serum samples.[196] The ELISA can distinguish PV from pemphigus foliaceous and may be helpful in determining disease activity and prognosis.[197] Recent work has shown that saliva is potentially a useful alternative to serum for ELISA with desmoglein 3 IgG detectable in saliva by ELISA with a similar sensitivity to serum (61% saliva vs. 74% serum).[198]

Management

Optimal patient management begins with achieving an early diagnosis, when lower doses of medication can be used for shorter periods of time to control the disease. Thereafter it is dependent upon several factors including the severity and activity of the disease and patient comorbidities. Clinical and patient reported outcome measures have been devised and validated for use in PV. These clinical tools combined with ELISA results enable clinicians to have a more objective way to assess response to treatment and ultimately determine disease remission. For combined oral and skin disease, the Pemphigus Disease Activity Index (PDAI) [199] and the Autoimmune Bullous Skin Disease Intensity Score (ABSIS)[200] have been validated.[201] In a comparative validation study for oral PV, the most sensitive tool was the Oral Disease Severity Score (ODSS)[202] which has the benefit of being applicable to all oral AIBD and Oral LP. Patient reported outcome measures in use include the Autoimmune Bullous Disease Quality of Life (ABQOL) questionnaire and the Treatment of Autoimmune Bullous Disease Quality of Life (TABQOL) questionnaire.[203,204]

Following initial assessment, patient management may be divided into two phases as agreed by the international pemphigus committee: induction of remission and remission

maintenance.[205] In remission induction, the initial aim of treatment is to induce disease control, defined as new lesions ceasing to form and established lesions beginning to heal (median 3 weeks). During a consolidation period, which varies in length, the aim is for 80% of mucosal and skin lesions to have healed with no new lesions for at least 2 weeks. Oral lesions are often the most resistant and careful oral disease severity assessment is paramount.The mainstay of treatment for this phase is high doses of systemic corticosteroids, usually given in dosages of 1 to 2 mg/kg/d in severe disease and 0.5–1 mg/kg/d in milder cases. The second phase of management is remission maintenance. During this phase, the ultimate goal of treatment should be to maintain remission on prednisolone 10 mg daily or less, with 10 mg being the dose designated arbitrarily as "minimal therapy" by international consensus with adjuvant drugs facilitating remission. The UK consensus guidelines group recommend the daily dose be reduced by 5–10 mg every 2 weeks down to 20 mg daily, then by 2–5 mg every 2–4 weeks down to 10 mg daily, and thereafter reduce slowly in increments of 1 mg.[206]

When substantial doses of steroids are required for weeks or months, adjuvant therapy is usually recommended, to maintain remission and to reduce the total steroid dose as well as the associated serious complications. The most commonly used adjuvants are the immunosuppressive drugs mycophenolate mofetil and azathioprine. Other agents used include cyclophosphamide, IVIG and methotrexate and alternative interventions include immunoadsorption, plasmapheresis, or plasma exchange. There is weak evidence only to support the use of dapsone and more studies are required. Overall, the evidence for benefit of adjuvants in PV has been variable. A systematic review and meta-analysis, which included 10 trials and pooled adjuncts together, concluded that they were not beneficial for achieving remission but collectively decreased risk of relapse by 29%.[207]

In 2017, the first RCT to conclusively demonstrate the benefit of an adjuvant drug was published, showing that rituximab (a monoclonal antibody against the CD20 molecule of B lymphocytes) combined with short-term prednisolone had superior efficacy to prednisolone alone, with rates of complete remission of PV, off all treatment, of 89% compared with 34% at 2 years.[208] Prednisolone could be stopped in around 70% patients initially treated with rituximab leading to a two-fold decrease in the number of severe treatment side effects. The FDA have since approved rituximab as a first line agent in moderate and severe PV. This approach is revolutionizing the management of PV and the long-term complications of treatment will become much less significant.

As many patients with oral PV will fit the category of moderate PV, the above systemic options including rituximab will be necessary. However, for those with mild oral disease, a combination of topical corticosteroids and low dose oral prednisone may suffice alongside optimal oral hygiene.

Paraneoplastic Pemphigus (PNP)

PNP is a rare, severe blistering disease first reported in five patients in 1990.[209] It is a multiorgan disease associated with an underlying neoplasm, which may precede the onset, co-present, or follow on. The underlying tumor is most frequently a non-Hodgkin lymphoma followed by chronic lymphocytic leukemia, thymoma or Castleman disease. PNP is also referred to as paraneoplastic autoimmune multiorgan syndrome (PAMS) because of the involvement of other systems, such as the lungs in particular, and the variable skin findings namely pemphigus, pemphigoid, EM-like, graft-vs.-host disease-like and lichen planus-like lesions.

Etiology and Pathogenesis

Patients with PNP develop IgG autoantibodies against multiple antigens, including desmoglein 3, desmoglein 1, and various proteins of the plakin family. Antidesmoglein antibodies, -desmocollin, and -A2ML1, may all contribute to the induction of acantholysis, whereas the relevance of the anti-plakin autoantibodies is not yet understood. T cell-mediated cytotoxicity is involved in the pathogenesis and induces more severe and refractory oral lichenoid stomatitis or mucositis, as well as polymorphic lichenoid skin eruptions.

Epidemiology

Paraneoplastic pemphigus mostly occurs in patients 45–70 years of age, with equal prevalence in both sexes.

Clinical Findings

General

Patients with PNP develop severe blistering and erosions of the mucous membranes and skin. The onset of the disease is often rapid, and oral and conjunctival lesions are both common and often severe. Skin lesions may resemble the inflammatory lesions of a drug reaction, lichen planus, or EM, as well as the blisters seen in pemphigus (Figure 3-34). Lesions of the palms and soles are suggestive of PNP. The scalp is usually spared.[210] In severe cases, the lesions may mimic TEN and often also involve the respiratory epithelium. Unlike EM or TEN, the lesions of PNP continue to progress over weeks to months. Death usually results from severe infection due to the immunosuppressive therapy, associated malignancy, and progressive pulmonary involvement (bronchiolitis obliterans).[211]

Oral Findings

Oral ulcers and erythema are the most common manifestation of PNP, and the oral disease is frequently extensive (a panstomatitis) and painful. The lesions are frequently

Figure 3-34 Extensive lesions of the tongue in a patient with paraneoplastic pemphigus.

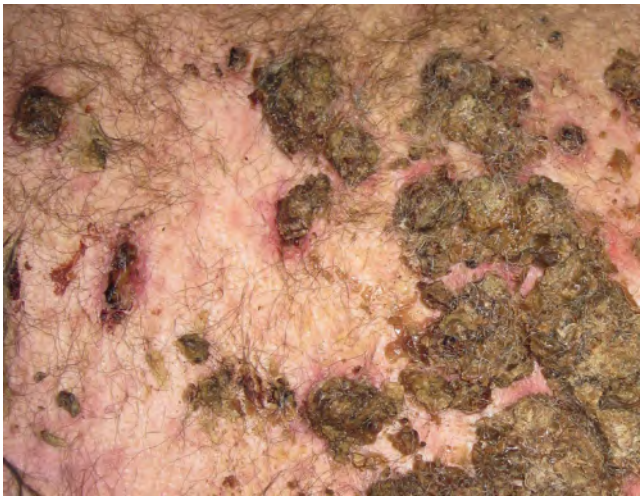

Figure 3-35 Pemphigus vegetans with vegetative lesions of the skin. Courtesy of Dr. Adam Lipworth, Boston, MA.

inflamed and necrotic, with large erosions covering the lips, tongue, and soft palate (Figure 3-35). Hemorrhagic crusts on the lips are characteristic.

Differential Diagnosis

The differential diagnosis is usually pemphigus vulgaris but includes other dermatological disorders including severe mucocutaneous LP or the subepidermal blistering diseases.

Laboratory Findings

Histopathology of lesions of PNP includes changes suggestive of EM, lichen planus, pemphigoid, and pemphigus. There is inflammation at the dermal–epidermal junction and keratinocyte necrosis in addition to the characteristic acantholysis seen in PV. DIF studies show deposition of IgG along the basement membrane similar to pemphigoid, as well as on the keratinocyte surface, forming a lattice pattern similar to PV. IIF demonstrates antibodies that not only bind to epithelium but to liver, heart, and bladder tissue as well.[212] Rat bladder is considered a useful substrate for differentiating PNP from PV as it does not contain desmogleins and therefore in the right clinical setting is specific for desmoplakin antibodies detected in PNP. Negative rat bladder IIF, however, does not preclude the diagnosis of PNP. Immunoblotting with epidermal extract is considered the gold standard for diagnosis; the 210 kDa envoplakin and 190 kDa periplakin being highly sensitive and specific for PNP.[213] ELISAs have also now been developed for these antigens.

Management

Patients with PNP secondary to localized tumors such as Castleman disease improve with the surgical removal of the tumor. Patients with PNP resulting from lymphoma, however, have a poor prognosis and usually die within 2 years from a combination of the underlying disease, respiratory failure, and extensive mucocutaneous involvement.

Use of a combination of prednisone and immunosuppressive drug therapy may help to control the severity of the skin lesions, but the oral, conjunctival, and pulmonary disease is frequently resistant to treatment. Rituximab and intravenous immunoglobulins can be helpful in these cases. High potency topical steroid therapy, topical tacrolimus, and intralesional steroid injection can be helpful in reducing the severity of oral mucosal lesions.

Subepithelial Bullous Disorders

The subepithelial bullous dermatoses are a group of mucocutaneous blistering diseases characterized by the development of autoantibodies to autoantigens in the basement membrane zone. This is a complex zone containing several interlinking macromolecules that connect the basal keratinocyte of the epithelium to the underlying corium or in the skin the epidermis to the dermis.

The diseases in this group include bullous pemphigoid, mucous membrane pemphigoid, linear IgA disease, and epidermolysis bullosa aquisita. There is significant overlap among these diseases, and the diagnosis is based upon clinical manifestations combined with routine histopathology and immunopathological tests identifying autoantibody reactivity with specific target antigens. When one of these diseases is included in the differential diagnosis, a biopsy for DIF should be obtained.

Bullous Pemphigoid (BP)

BP is the most common autoimmune subepidermal blistering skin disease. It occurs mainly in adults over the age of 60 years and may last from a few months to several years

with a variable course. There are several subtypes but the most frequent is the classical BP presentation with intact blisters on an erythematous base. Oral lesions are infrequent but where encountered are usually in this variant. They are typically transient, often mild, and are seen in those with more severe skin disease. It is important to remember that the majority of patients seen in oral medicine departments with a history of skin lesions and a presumptive diagnosis of BP will in fact have mucous membrane pemphigoid.

Etiology and Pathogenesis

BP has both genetic and environmental associations. It is associated with the class II allele DQB1*03:01 and has been reported in conjunction with other diseases as would be expected in an elderly population. However, the association is significantly higher than might be expected in neurological disorders such as Parkinson's disease, dementia, and multiple sclerosis; thromboembolic disorders, such as strokes, or certain drug therapies, such as antibiotics, antihypertensive, loop diuretics and dipeptidyl peptidase-IV inhibitors, and checkpoint inhibitors.

BP is an autoimmune disease caused by the binding of autoantibodies to specific antigens found in the lamina lucida region of the basement membrane on the hemidesmosomes of epithelial basal cells. These antigens are glycoproteins referred to as bullous pemphigoid antigens, BP 180 and BP 230.[214] Binding of antibody to antigen activates both leukocytes and complement, causing localized damage to the basement membrane, resulting in vesicle formation in the subepithelial region. Studies have shown a correlation between disease activity and serum titers of IgG antibodies against the immunodominant domain of BP180, the NC16a domain, and other epitopes on BP180. Once anti-NC16A autoantibodies bind to BP180, several pathways are activated, including complement activation and deposition, neutrophilic chemotaxis with release of proteases, and elastases that promote the disruption of the BMZ leading to blister formation. [215]

Epidemiology

Bullous pemphigoid (BP) is the most frequent AIBD in Central Europe. Its incidence reaches around 20/million/year but is much higher in the very elderly.

Clinical Manifestations

General

The characteristic skin lesion of BP is a tense blister on an inflamed base accompanied by urticarial plaques that chiefly involve the scalp, abdomen, extremities, axilla, and groin (Figure 3-36). Pruritis is a common feature of the skin lesions. Patients with BP may experience one episode or recurrent bouts of lesions with a wide spectrum of disease severity. A recent systematic review and meta-analysis included 25 studies and demonstrated a 1-year combined mortality rate of 23.5%. Higher mortality rates were obtained in Europe (26.7%) followed by Asia (20.5%) and the US (15.1%), possibly related to an increased number of comorbidities and older age in European patients in comparison to Americans and Asians, respectively.[216]

Figure 3-36 Bullous pemphigoid resulting in tense skin blisters. *Source:* Courtesy of Dr. Adam Lipworth, Boston, MA.

Oral Findings

Oral involvement occurs in 10% to 20% of BP patients.[217] The oral lesions of BP are smaller, form more slowly, and are less painful than those seen in PV. The oral lesions are clinically and histologically indistinguishable from oral lesions of mucous membrane pemphigoid, but early remission of oral lesions in BP is typical. Desquamative gingivitis if present is more suggestive that the patient has MMP. It is recognized that a small subgroup of MMP patients do present with a BP-like cutaneous eruption, but the skin resolves with treatment while the oral mucosal lesions persist.

Differential Diagnosis

Oral diseases that appear clinically similar to BP include mucous membrane pemphigoid (MMP), ulcerative LP, PV, and the other subepithelial bullous dermatoses. The ulcerative form of LP frequently has the characteristic white lacy lesions or Wickham striae and may have a violaceous hue if the lips are affected (see Chapter 4). PV usually has more extensive ragged erosions involving several oral mucosal surfaces. The other subepithelial bullous dermatoses (described below) appear clinically similar to MMP and can only be distinguished by immunofluorescent, ELISA, or molecular techniques.

Laboratory Findings

Routine histology of a biopsy specimen demonstrates separation of the epithelium from the connective tissue at the

basement membrane zone and an inflammatory infiltrate that is usually rich in eosinophils, particularly in skin biopsies.

DIF study of a biopsy specimen taken from perilesional-inflamed tissue demonstrates deposition of IgG and C3 bound in a linear band to the basement membrane. IIF study of serum obtained from patients with BP demonstrates IgG antibodies bound to the epidermal aspect using the salt-split skin technique (see below). The salt-split skin test is particularly useful in distinguishing BP from EBA, the latter producing IgG antibodies localized to the dermal side of the salt-split skin (floor of the blister). It has been shown that epidermal binding sera, if examined carefully at high magnification, shows an n-serrated fluorescent pattern to distinguish it from dermal binding sera, which give a u-serrated pattern.[218] Circulating autoantibodies against pemphigoid antigens BP 180, specifically the NC16A domain which is the main target antigen, and BP 230, can be detected in serum samples using ELISA and are useful in both diagnosis and monitoring of disease activity.[219]

Management

Patients with localized oral lesions of BP may be treated with high-potency topical steroids, such as clobetasol or betamethasone, whereas patients with more extensive disease require use of systemic corticosteroids alone or combined with immunosuppressive drugs such as azathioprine, cyclophosphamide, mycophenolate, or rituximab.[220] Patients with moderate levels of disease may minimize use of systemic steroids by use of dapsone, or tetracycline, doxycycline, or minocycline, which may be combined with niacinamide.[221]

Mucous Membrane Pemphigoid [MMP]

MMP is a rare chronic autoimmune subepithelial blistering disease that primarily affects the squamous epithelia; that is, the mouth, conjunctivae, upper airways, anogenital sites, and skin. It results in mucosal blistering, ulceration, and subsequent scarring in sites of predilection. Historically it has sometimes been referred to as cicatricial pemphigoid, but this term has now been superseded by MMP as it does not always scar. A multidisciplinary approach including dermatologists, ENT surgeons, ophthalmologists, and others as indicated is paramount in these patients.

Etiology and Pathogenesis

The primary lesion of MMP occurs when IgG and/or IgA autoantibodies directed against basement membrane zone (BMZ) antigens, lead to an inflammatory response with subepithelial separation and vesicle formation. The main antigens involved in disease pathogensis include epitopes on BP180 (the membrane proximal NC16a domain as in BP), as well as epitopes on the C-terminal domain) and laminin 332. Other proposed autoantigens include BP230, a6b4 integrin, and type 7 collagen. Subsets of MMP have been identified by the technique of immunofluorescent staining of skin that has been split at the basement membrane zone with the use of 1M sodium chloride prior to DIF (the "salt-split skin" technique).[222] The majority of cases of MMP demonstrate IgG directed against antigens on the epidermal side of the salt-split skin, which have been identified as BP Ag2 (BP180) or BP230. However, cases of MMP have also been identified where the antigen is present on the dermal side of the split. This latter antigen has been identified as laminin-332 (previously referred to as epiligrin or laminin 5, an adhesion molecule that is a component of the anchoring filaments of the basement membrane.[222–224] MMP associated with laminin-332 has been reported to carry a higher risk of association with an underlying malignancy, but the evidence for this is not yet conclusive.[225] Further research is required regarding the possible association with malignancy, and clinicians should consider a possible underlying malignancy in newly diagnosed dermal binding MMP patients.[226] HLA DQB*0301 is significantly associated with MMP[227] and is associated with T cell recognition of BMZ antigens. Drugs have rarely been associated also with the onset of MMP; for example, the gliptin antidiabetic agents.

Epidemiology

Mucous membrane pemphigoid has an annual incidence of 1.3–2.0 per million inhabitants in France and Germany. The mean age at onset varies in studies between 55–65 years and it is approximately twice as common in females. It is seen predominantly in Caucasian patients, though it is universal.

Clinical Manifestations

General

Lesions of MMP may involve any mucosal surface, but the oral mucosa is the most frequently reported site. Ahmed and Hombal amalgamated 16 case series of 457 cases and Setterfield studied 140 cases of patients drawn from a full range of clinics.[228,229] Their data has shown that the oral mucosa was affected in 85–87% patients and the conjunctiva in 64–5%. While the oral mucosa is relatively protected from scarring in the eye, MMP can lead to scarring and adhesions developing between the bulbar and palpebral conjunctiva called symblepharon (Figure 3-37). Subsequent corneal damage is common, and progressive scarring may lead to blindness in some patients. Ulceration and scarring may also affect the nasopaharynx (15–28%), genital mucosa (17–26%), esophagus (4–10%), and larynx (4–8%). In all sites, it causes pain and stricture formation and in the larynx may be life threatening leading to hoarseness, difficulty in breathing, and asphyxiation. Esophageal involvement may cause

Figure 3-37 Mucous membrane pemphigoid of the conjunctiva with symblepharon formation.

Figure 3-38 Moderately severe desquamative gingivitis of mucous membrane pemphigoid.

dysphagia, leading to debilitation and frequent dilatations. Skin lesions, present in 24–39%, often affect the head and neck but may be generalized and often scar.[228,229]

Oral Findings

Oral lesions occur in 85% of patients with MMP. Intraoral sites include the gingiva

(80%), buccal mucosa (58%), palate (26%), alveolar ridge (16%), tongue (15%), and lower lip (7%).[230,229] Desquamative gingivitis may occur alone or in addition to other intraoral sites. It typically manifests as erythema of the attached gingiva with or without blistering and ulceration. It may be localized or generalized (Figures 3-38 and 3-39). Lesions elsewhere may present as patches of erythema, intact blisters, or ulcers with a yellow base and well-defined margin (Figure 3-40). Scarring, while unusual in the oral mucosa, may be seen as a loss of sulcal depth, scarring of the buccal mucosa or soft palate. Broadly, three oral phenotypes are recognized: pure gingival lesions, extragingival lesions, or both.

Figure 3-39 Moderate desquamative gingivitis of mucous membrane pemphigoid.

Differential Diagnosis

In the oral mucosa the differential diagnosis includes the autoimmune blistering diseases and lichen planus. Desquamative lesions resemble the lesions of erosive lichen planus and PV and in all cases of desquamative gingivitis, biopsy should include both routine histology and DIF for definitive diagnosis.

Laboratory Findings

Patients with suspected MMP should have biopsy specimens taken from a perilesional site for routine histology and from an adjacent normal site for DIF studies.[231] A large retrospective study has shown a 94% positivity for linear IgG, IgA, and/or C3 at the BMZ from perilesional biopsies and 90% positivity from a separate normal buccal punch.

Figure 3-40 Intact vesicle of buccal mucosa in a patient with mucous membrane pemphigoid.

Where patients had pure desquamative gingivitis, a sample taken from the adjacent reflected alveolar mucosa was positive in 100% patients. The failure rate for DIF is usually due to mechanical problems largely due to loss of epithelium. Histopathology reveals subepithelial clefting with preservation of basal cells and a mixed inflammatory cell infiltrate (Figure 3-41 and Figure 3-42). IIF using salt-split skin detects the presence and titer of anti-BMZ IgG and IgA antibodies and localizes the binding to the roof or base. The presence of both IgG and IgA is associated with a more severe disease and the IgG antibody titer is related to disease severity.[232,233] ELISA tests commercially available can identify BP180 NC16a antibodies (in both serum and saliva),[234] BP230, and collagen type 7 (see section Epidermolysis bullosa acquisita below). An important aspect of diagnosis is the detection of laminin 332 antibodies.[235] At present there is no commercially available ELISA and sera need to be sent to national referral centers for molecular testing if dermal binding.

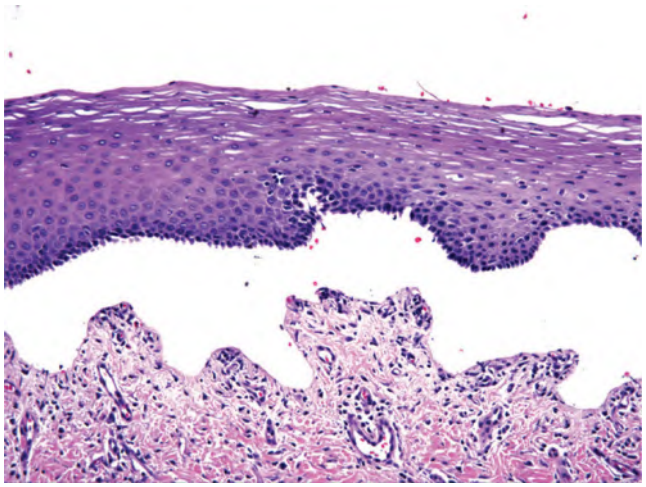

Figure 3-41 Photomicrograph of mucous membrane pemphigoid showing intact basal cells and subepithelial bulla.

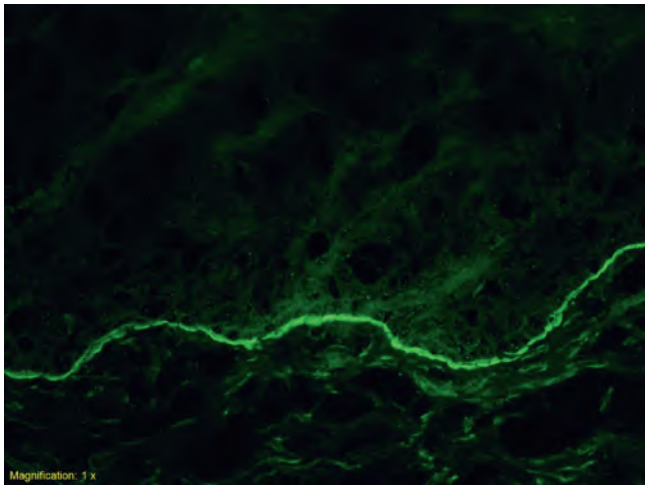

Figure 3-42 Direct immunofluorescence study of mucous membrane pemphigoid showing linear IgG deposition in the basement membrane zone.

Management

Management of MMP depends on the severity of symptoms and sites of involvement. A multidisciplinary approach is necessary for optimal patient care. The degree of morbidity varies but for the majority of patients presenting to oral medicine, it is a mild to moderately severe condition that may last for many years necessitating long-term treatment. To date there is limited good evidence upon which to base treatment. Studies are largely limited to retrospective case series. However, there are recommended approaches based upon the evidence available.[226,236] Fundamental to assessing disease severity and response to treatment is the use of a clinical outcome score. The ODSS has now been validated for use in MMP and has been shown to have the optimal sensitivity when compared to other methods proposed at present.[237]

For mild oral disease, optimizing oral hygiene and use of topical corticosteroids either directly in a paste, such as clobetasol and Orabase (a custom made tray can be used) or as a mouthwash, such as betamethasone sodium phosphate 0.5 mg or fluticasone propionate 400 lg in10 mL of water as a 3-min rinse can be helpful. (Figure 3-43). Intralesional triacinolone to localized ulcers may be effective. For mild to moderate disease, doxycycline can be tried or if ineffective dapsone (always check for glucose-6-phosphate deficiency) or sulfapyridine.[238,239] Dapsone always causes a degree of hemolysis and occasionally methemoglobinemia, and thus careful monitoring is necessary. Another rare side effect of dapsone is hypersensitivity syndrome, characterized by fever, lymphadenopathy, skin eruptions, and occasional liver involvement. For more severe oral lesions or where there is multisite involvement, often immunosuppressive treatment is needed, including low dose systemic steroids,

Figure 3-43 Soft custom-made trays may be used to hold topical steroids to treat desquamative gingivitis.

immunosuppressive drug therapy such as azathioprine, mycopheolate mofetil or methotrexate, or rituxumab. Pulsed intravenous (IV) cyclophosphamide, IV immunoglobulin, and rituximab are reserved for recalcitrant disease.[240,241]

An important aspect of management at present is how to investigate patients with confirmed laminin 332 autoantibodies. There is a body of evidence to suggest that this subgroup of patients may have an increased risk of developing an underlying malignancy. However, this remains an area for ongoing work. A thorough history and examination must be undertaken in patients with MMP and dermal binding sera and all routine age appropriate routine cancer screening undertaken. The neoplasms reported are usually adenocarcinomas though hematological malignancies have rarely been described. At present the extent of investigation to be recommended is unclear.

Linear IgA Disease (LAD)

LAD is a rare acquired subepithelial autoimmune blistering disease characterized by the deposition of predominantly IgA rather than IgG in the basement membrane. LAD occurs in children below the age of 10 (historically referred to as chronic bullous disease of childhood) and adults older than 60. While rare, it is the most common cause of autoimmune blistering in childhood. The clinical manifestations may resemble MMP, BP, and EBA. It is important to note that the majority of adults with linear IgA and a predominantly mucosal disease must be considered to have MMP.[226]

Etiology and Pathogenesis

The cause of the majority of cases is unknown, but some reported cases have been drug-induced (e.g., vancomycin, amiodarone and nonsteroidal anti-inflammatory agents) or are associated with systemic diseases, including hematologic malignancies, ulcerative colitis, or connective tissue diseases, such as dermatomyositis.[242,243] The target antigens associated with a majority of cases of LAD are the shed ectodomain of BP180, a 120, or 97kDa antigen detected on immunoblotting. It is associated with HLA-B8, HLA-CW7, and HLA DR3. In the older group, the disease has a more benign course and where associated, withdrawal of the offending drug results in remission

Epidemiology

It has an incidence of 25–1.0/million population in Europe.

Clinical Manifestations

General

The skin lesions of LAD are characterized by annular pruritic papules and blisters, giving a "cluster of jewels" appearance. In children, the skin of the lower abdomen, genitalia, and perineum are involved while in adults, the disease affects the face, extensor surfaces, hands, and feet. Ocular involvement may be seen in adults and children.

Oral Findings

Oral lesions are common in LAD and may be seen in up to 70% of patients. These lesions are clinically indistinguishable from the oral lesions of MMP, with blisters and erosions of the mucosa frequently accompanied by desquamative gingivitis.[244–246]

Laboratory Findings

Routine histology demonstrates subepithelial separation similar to MMP, but DIF study will show deposition of IgA and, occasionally, IgG and C3. Neutrophils are a prominent feature within the blister. IIF is usually negative, but when positive, will demonstrate circulating IgA antibodies against a basement membrane antigen.[247]

Management

The majority of patients will have a disease triggered by a drug and therefore identification is key. As in MMP, topical corticosteroids may be helpful. Dapsone and sulfapyridine are often effective when topical steroids alone are insufficient. More severe cases may require a combination of systemic corticosteroids and immunosuppressive drug therapy such as mycophenolate mofetil

Epidermolysis Bullosa Acquisita (EBA)

EBA is a very rare chronic mucocutaneous immunobullous disease with two predominant subtypes: the classic form, which is characteristically associated with prominent scarring, and the inflammatory form that resembles BP.

Etiology and Pathogenesis

IgG and occasionally IgA antibodies target the NC1 or occasionally the NC2 domain of type VII collagen, which forms the anchoring fibrils in the lower basement membrane. Damage and loss results in sub-basilar bullae.[248]

Epidemiology

EBA is a rare autoimmune blistering disease with an annual incidence of less than 0.5/million. It may occur at any age in adulthood and is associated with HLA-DR2 in African-Americans and HLA-DRB1*15:03 in African descent patients in France. It may be associated with Crohn's disease and systemic lupus erythematosus

Clinical Manifestations

Both subtypes of EBA may present with oral mucosal lesions. The classic type associated with mechanobullous lesions on

trauma prone sites such as the elbows and knees is typically more severe in the mucous membranes and scarring is prominent. Extensive oral ulceration may affect any site in the mouth but typically involves the tongue and may lead to ankyloglossia and microstomia. Other mucosal sites such as the esophagus, conjunctivae, and larynx may be involved. In the inflammatory type with more widespread skin lesions, the oral mucosa may also be affected with ulceration and mild gingival inflammation.

Differential Diagnosis

MMP but tongue and lip involvement is more typical in EBA and much less frequent in typical MMP.

Laboratory Findings

An oral biopsy typically shows a subepithelial split often with minimal inflammation. DIF typically shows linear BMZ IgG and C3 which in an area of blistering is localized to the base of the split. The pattern is u-serrated in contrast to MMP and BP which is n-serrated.[218] IIF is positive in approximately 50% sera; IgG specificity can be confirmed with an ELISA.

Management

The treatment is as described for MMP and LAD, with therapy depending upon the extent and severity of the clinical lesions. EBA can be very recalcitrant to treatment; however, dapsone is often a useful drug and may be combined with colchicine. Systemic corticosteroids, immunosuppressive drugs, rituximab, or intravenous immunoglobulin may be required to control the lesions in severe widespread EBA.

THE PATIENT WITH SINGLE ULCERS

The most common cause of single ulcers on the oral mucosa is trauma. The diagnosis is usually based on the history and physical findings. However, squamous cell carcinoma is always in the differential diagnosis for a nonhealing ulcer. As such, all ulcers present for 2 to 4 weeks without evidence of healing should be biopsied to rule out squamous cell carcinoma or other pathology, and in the immunocompromised patients, deep fungal or viral infection. Oral cancer is discussed in detail in Chapter 7.

Infections that may cause a chronic oral ulcer include CMV ulcers (see above); mycobacterial infections (including atypical mycobacterial infections); the endemic mycoses such as histoplasmosis, blastomycosis, and coccidioidomycosis; nonendemic invasive fungal infections such as mucormycosis, aspergillosis, and cryptococcosis; syphilis; and parasitic infections such as leishmaniasis. These infectious oral ulcers are described detail in Chapter 21, "Infectious Diseases."

Traumatic Injuries Causing Solitary Ulcerations

Etiology and Pathogenesis

Single mucosal ulcers may be caused by direct physical mechanical, thermal, or chemical trauma to the mucosa or even vascular compromise, causing tissue damage and ulceration. Acute bite injuries, an example of direct physical/mechanical trauma, occur often on the oral mucosa and may be particularly severe if this occurs when the mucosa is numb after local anesthesia has been given for dental procedures. Traumatic injuries may also result from malocclusion, ill-fitting dental prostheses, overzealous toothbrushing and flossing, self-injurious habits, and oral piercings.[249,250]

Thermal injuries including electrical burns are sometimes seen in children who inadvertently chew on electrical wiring. More commonly, thermal burns occur on the palatal mucosa from ingesting hot foods and beverages (such as hot pizza or coffee). The use of a microwave oven to reheat foods often results in differential heating so that cheese and pastry fillings may be overheated compared with other parts of the food, leading to burns.[251] An iatrogenic cause of thermal injury is from a heated dental instrument inadvertently contacting the mucosa. The burn is usually more serious if the mucosa has been anesthetized and there is prolonged contact.[252]

Chemical trauma is caused by patients or dentists placing noxious and caustic substances directly on the mucosa either as a therapeutic measure or unintentionally. Sucking on, chewing, or hours-long contact of medications formulated to be swallowed (such aspirin or oral bisphosphonates) may also lead to severe oral ulcers.[253] Mouthwashes or other over-the-counter oral care products with high alcoholic content, hydrogen peroxide, or phenols used too frequently or undiluted can cause mucosal ulcerations.[254]

Some over-the-counter medications for treating aphthous ulcers contain high concentrations of silver nitrate, phenols, or sulfuric acid and should be used with caution. Ulcers have also resulted in the use of denture cleansers as an oral rinse.[255] Prolonged contact of methacrylate monomer on the mucosa may also lead to necrosis of the mucosa. Necrosis of the bone and mucosa has been reported from chemicals used in endodontics if these are pushed past the apices of teeth.[256]

Vascular compromise leads to oral ulcers and two main patterns are identified. One is a condition known as necrotizing sialometaplasia where there is local infarction of the salivary gland tissue leading to overlying ulceration, exfoliation of the necrotic tissue, and healing. Many etiologies have been identified including vasoconstrictors, sustained pressure, and bulimia and the most common location for this condition is the hard palatal mucosa although any location

that contains salivary glands may be affected.[257] Another is systemic vasculitis, where inflammation of vessels leads to thrombosis and infarction. Tongue necrosis is a particularly well documented aspect of giant cell (temporal) arteritis.[258]

Oral Findings

These present as acute ulcerations and necrosis of the mucosa with a clear antecedent history of injury (Figure 3-44). The extent of the ulceration depends on the agent involved and the site depends on the activity involved.

Electrical burns in particular are caused by high heat, are generally fairly extensive, involve the lips, and are generally seen in young children and toddlers. The initial lesions are charred and dry appearing. However, after a few days, this charred crust sloughs, and there may be excessive bleeding when the underlying vital structures are exposed.

Burns from hot foods and beverages are generally small and localized to the hard palatal mucosa or lips and are usually seen in teenagers and adults (Figure 3-45). The area usually presents as an area of tenderness and erythema that develops into ulcers within hours of the injury. It may take several days to heal depending on the extent of the injury.

Ulcers from vascular compromise such as necrotizing sialometaplasia and vasculitic lesions last for weeks and months.

Figure 3-44 Traumatic ulcer of the lateral tongue, healing.

Figure 3-45 Ulcer from hot pizza burn on the palatal mucosa.

Differential Diagnosis

Careful history taking and identification of the causative agent clinch the diagnosis. However, in all cases, patients should be carefully monitored for healing to ensure that a secondary infection does not develop or that another cause of an oral ulcer, such as oral cancer, was mistakenly overlooked.

Laboratory Testing

None is required if there is a clear history of injury to the site. Culture may be needed if the areas do not heal well or if suppuration develops, suggesting a secondary bacterial infection. A biopsy should be performed if the ulcer does not heal within a few weeks. If leakage of an endodontic filler is suspected, periapical films should be taken.

Biopsy is not necessary if the etiology is obvious. However, if a biopsy is done, the mucosa will show ulceration with acute and chronic inflammation. The epithelium adjacent to the ulcer shows varying degrees of coagulation and necrosis. Care must be taken to rule out the presence of infectious agents that may secondarily infect the site (such as HSV on the hard palatal mucosa).

Biopsies of necrotizing sialometaplasia show distinct stages of infarction of mucous glands to metaplasia of ducts to healing. For a diagnosis of giant cell arteritis, patients must fulfill three of the five criteria as set out by the American College of Rheumatology: age over 50, recent onset of localized headache, temporal artery tenderness or decreased temporal artery pulse, raised erythrocyte sedimentation rate greater than or equal to 50 mm/h, and positive temporal artery biopsy.[259]

Management

Smaller lesions caused by less severe thermal or chemical injury heal on their own once the irritant is removed. Pain control can be achieved with topical anesthetics (such as viscous lidocaine). Topical steroids or intralesional steroid injections may be useful. Avoidance of re-injury is also important, and this may be effected by counseling patients regarding the avoidance of use of caustic substances and the correct use of medications. Dentists also should be careful to take protective measures when using caustic substances or heated instruments.

Electrical burns are generally deep and more extensive, and healing often results in scarring and contracture. If the corners of the mouth are involved, microstomia may result. Children benefit from the use of microstomia prevention devices during this healing period, although surgical correction may still be

required to restore function and esthetics. Antibiotics may be necessary to prevent a secondary infection since these burns often take several weeks to heal.[260] Necrotizing sialometaplasia heals on its own while ulcers of vasculitic origin will generally require treatment with systemic corticosteroids.[261]

Traumatic Ulcerative Granuloma (Eosinophilic Ulcer of Tongue)

Etiology and Pathogenesis

This ulcerative condition of the oral cavity is considered traumatic in nature, although less than 50% of patients recall a history of injury. These lesions have been experimentally induced in animals by inflicting crush injury on the tongue, the most common site of these lesions.[262] It is likely that the penetrating nature of the inflammation results in myositis that leads to chronicity. However, other acute or chronic ulcerative conditions left untreated may become deep and penetrating. Similar lesions are seen on the ventral tongue in infants caused by the tongue rasping against newly erupted primary incisors, a condition known as Riga-Fede disease. Patients with familial dysautonomia and other conditions, such as Riley–Day syndrome and Lesch–Nyhan syndrome, who have congenital incapacity to sense pain, often also develop similar ulcerative and necrotic ulcers because they are unaware of the self-inflicted injury.[263]

Clinical Manifestations

There is a bimodal age distribution with one group in the first two years of life, where lesions are associated with erupting primary dentition.[264] The second group is in adults in the fifth and sixth decades.[265]

Oral Findings

In children, the ulcers involve the anterior ventral or dorsal tongue associated with erupting mandibular or maxillary incisors, respectively. The tongue is the site of involvement in approximately 60% of adult cases, usually on the posterior and lateral aspects.[266]

An ulcer develops that may not be painful in two-thirds of cases and may persist for months. A history of trauma is elicited in only 20–50% of cases. The ulcer generally appears cleanly punched out, with surrounding erythema and keratosis if present for weeks or months (Figures 3-46 and 3-47). They range from 0.5 cm to several centimeters in size. The surrounding tissue is usually indurated and long-standing lesions are often depressed. Other sites that may be involved include the buccal mucosa and labial mucosa, floor of the mouth, and vestibule, all sites where there is abundant underlying skeletal muscle. Five percent are multifocal, and recurrences are not uncommon. In some cases, the lesions present as an ulcerated, mushroom-shaped, polypoid mass on the lateral tongue.[267]

Figure 3-46 Traumatic ulcerative granuloma of the tongue, a typical site; note the surrounding keratosis.

Figure 3-47 Traumatic ulcerative granuloma of the buccal mucosa; note the depressed appearance of the ulcer and surrounding keratosis.

Differential Diagnosis

In children, the diagnosis is usually obvious because of the presence of newly erupted dentition and the location of the ulcers.

The long duration of these lesions, presence of induration, lack of pain, and lack of surrounding erythema readily distinguish them from RAS, although major aphthous ulcers are often associated with scarring and induration and may develop into traumatic ulcerative granuloma. The presence of a single, chronic, painless ulcer with induration raises the suspicion for squamous cell carcinoma (especially if it is on the tongue), salivary gland malignancy, or lymphoma. Rare cases that had been diagnosed as traumatic ulcerative granuloma have subsequently been shown to represent CD30+ T-cell lymphomas.[268] An infectious etiology should also be considered, especially deep fungal or CMV infection, particularly in immunocompromised hosts. Another entity, EBV-associated mucocutaneous ulcers, may

appear similar and also contain CD30+ cells; these have been reported in immunocompromised and immunosenescent (elderly) patients.[269]

Laboratory Findings

A biopsy is almost always required to confirm the clinical diagnosis and to rule out a malignancy or other conditions. Excision of the lesion often results in complete resolution of the ulcer.

The mucosa is ulcerated, but unlike an aphthous ulcer, the inflammation is deeply penetrating, with chronic inflammatory cells infiltrating the underlying skeletal fibers. There is muscle degeneration associated with variable numbers of eosinophils and mononuclear histiocyte-like histiocytes/macrophages. Immunoperoxidase staining is important to rule out a lymphoma, especially the CD30+ type.[270]

Management

A careful history is important to rule out continued trauma to the site, although this is sometimes difficult to elicit and then prevent, especially if trauma occurs during sleep. Intralesional steroid injections performed over a few weeks will often resolve these lesions. Wound debridement also often leads to complete resolution, although up to one-third of cases recur. The use of a nightguard on the lower teeth may help reduce nighttime trauma from parafunctional habits.

Red and White Lesions of the Oral Mucosa

RED AND WHITE TISSUE REACTIONS

One challenging aspect of oral medicine is that many lesions of different conditions look alike. The same diagnosis may also manifest in various ways. Thus, in order to become a successful clinician in differential diagnosis, appreciation of the very versatile appearances of the same disease requires considerable clinical acumen and experience. It is also important to appreciate that the oral mucosa in some patients may appear to be different from what we perceive as normal-looking mucosa.

There are different ways of classifying oral mucosal lesions. One is in accordance with the most prominent colors in which they can manifest. The difference that we (or our patient) see often is the change of color. Observing those changes is important as they guide us in establishing the diagnosis.[1] Although many shades of different colors may appear in the mouth indicating pathologic changes, two of the most striking ones are red and white. Following this rather rough and nonspecific truncation, we need to refine the features to obtain the correct diagnosis.

"White lesion" stands for any mucosal area that appears whiter than its adjacent tissue. It does not represent a specific etiologic or microstructural group of mucosal conditions. Its surface is usually also of a different texture, or may be raised from its surroundings. When considering red and white

Burket's Oral Medicine, Thirteenth Edition. Edited by Michael Glick, Martin S. Greenberg, Peter B. Lockhart, and Stephen J. Challacombe.

lesions, we are assuming that the epithelial integrity is still preserved, as otherwise we would have ulceration. Indeed, within the time course of a single oral condition, we can see different stages and intensities. Its current red and/or white appearance can progress toward an ulcerative stage (e.g., in lichen planus), which may appear whitish or yellowish due to fibrinous exudate and pseudomembranes. Therefore, there is a temporal component to the clinical appearance of the condition with a tendency to change over time. Thus, classifying those oral conditions exclusively according to their red or white appearance cannot be fully feasible. All red and white lesions may present in combinations of all of the above.

White lesions of oral mucosa are white as a consequence of several possible structural occurrences:[2]

1) Increased thickness of the corneal layer (in keratinized epithelium).
2) Keratinization of epithelium that does not normally contain a corneal layer (nonkeratinized epithelium). Both (1) and (2) manifest as hyperkeratosis (Figures 4-1 and 4-2).
3) Formation of abnormal keratin.
4) Epithelial edema: intra- and extracellular accumulation of fluid in the epithelium may also result in clinical whitening (Figure 4-3).
5) Abnormal keratinization occurring prematurely within individual cells or groups below the stratum granulosum (dyskeratosis often also contains hyperkeratosis).

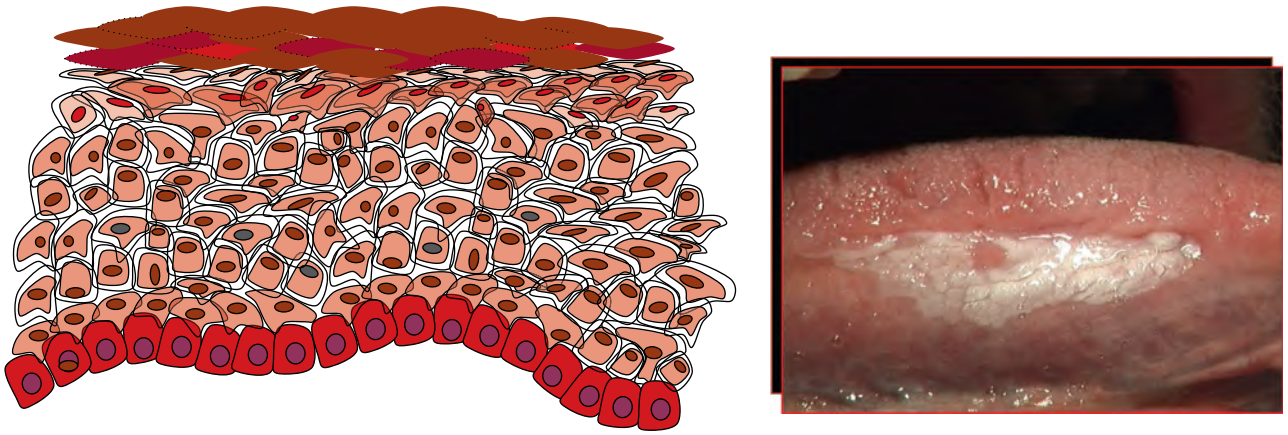

Figure 4-1 Mechanisms leading to a white appearance of the oral mucosa due to an increased production of keratin (hyperkeratosis).

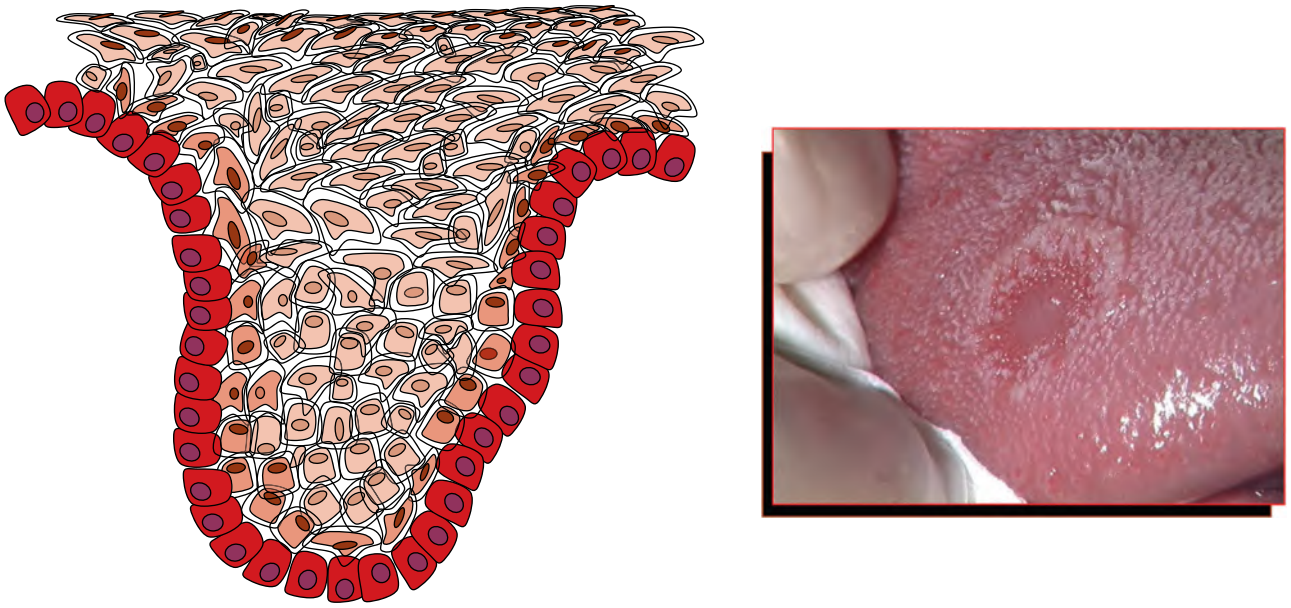

Figure 4-2 Mechanisms leading to a white appearance of the oral mucosa due to an abnormal but benign thickening of stratum spinosum (acanthosis).

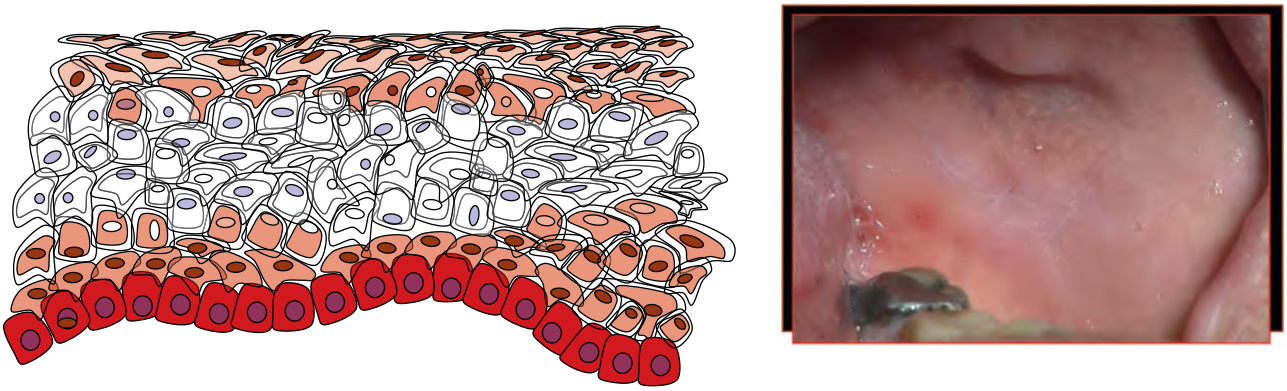

Figure 4-3 Mechanisms leading to a transparent white appearance of the oral mucosa due to intra- and extracellular accumulation of fluid in the epithelium (leukodema).

6) Subepithelial superficial fibrosis, which with its decreased vascularity network causes a diffuse whitish appearance; Any overall epithelial thickening (acanthosis) itself does not seem to cause whiteness.

Keratins are a family of fibrous scleroproteins, which form intermediate filaments necessary for maintaining the structural integrity of keratinocytes and thus for epithelial protection and support. Keratin present in the white oral lesion is likely to be different from keratin normally occurring in oral mucosa (e.g., that produced on the hard palate or attached gingiva). This type of keratin resembles the keratin on the skin, and absorbs water when overly hydrated by oral fluids, resulting in swelling and a white appearance similar to that of skin immersed in water for a prolonged time. Any of those also changes the refractive index as well as causes different reflection and dispersion of light waves, which we see as white.

Apart from structural epithelial changes, a white or "whitish" appearance may result from exogenous deposits, such as microbial colonies (e.g., candidal mycelium) and their effects on the host surface (exudate, necrotic cellular debris, and metabolic products). Fungi can, thus, produce whitish pseudomembranes consisting of sloughed epithelial cells, fungal mycelium, and neutrophils, which are loosely attached to the oral mucosa (Figure 4-4).

Clinicians should be aware of the possibility of being misled by the color of fibrin pseudomembranes. There are many shades of grayish and whitish fibrin pseudomembranes that to the unskilled eye can resemble the white appearance of hyperkeratosis, whereas it is fibrin covering an ulcerated area. Sometimes a fibrin pseudomembrane can present a yellowish appearance and one should not mistake it for purulent matter or infection.

The pink appearance of oral mucosa results from tissue translucency, allowing the light to pass through the epithelium into the lamina propria and reflect the blood vessels containing hemoglobin.

A red lesion of the oral mucosa may develop as the result of atrophic epithelium (Figure 4-5), characterized by a reduction in the number of epithelial cells. It may also be the result of loss of the superficial cell layers (superficial erosion, Figure 4-6) or increased vascularization due to proliferation of vessels. Redness or erythema may further be caused by dilatation of vessels associated with inflammation of the oral mucosa, reduced epithelial keratinization, and, importantly, cellular proliferation signifying a possible malignancy.

Oral mucosal lesions also present with different tissue surface consistency, and white lesions may appear as reticular, plaque-like, papular, or pseudomembranous, which affect the clinical appearance of the lesions. Most red, and particularly most white, lesions are benign. Red lesions may also display a change of surface texture, which may become granular, velvety, and rough. It is important to note those features, as they are suggestive of neoplasia. Palpation of white and red lesions is necessary in addition to inspection, as indurated lesions should draw additional suspicion for possible malignancy.[3]

Our clinical approach to differential diagnosis should appreciate many other features of the lesion (Table 4-1). These include presence of *pain*, *single* versus *multiple* lesions, *distribution* in specific areas, the *borders* toward the unaffected tissue (clear or hazy, straight or crooked), *onset*, *duration*, *change in shape* and *size*, whether it is *raised* in comparison to surrounding mucosa, its *relapsing* nature, and reasons for *improvement* or *exacerbation*.

In addition to more detailed assessment of oral condition, we also need to obtain a closer and better understanding of the whole patient. A patient's specific systemic condition and associated medications are potentially very closely related to oral disease, so knowing and understanding them may be very relevant to the oral condition. However, there are cases in which patients are unaware of their systemic conditions. Thus, by recognizing oral lesions,

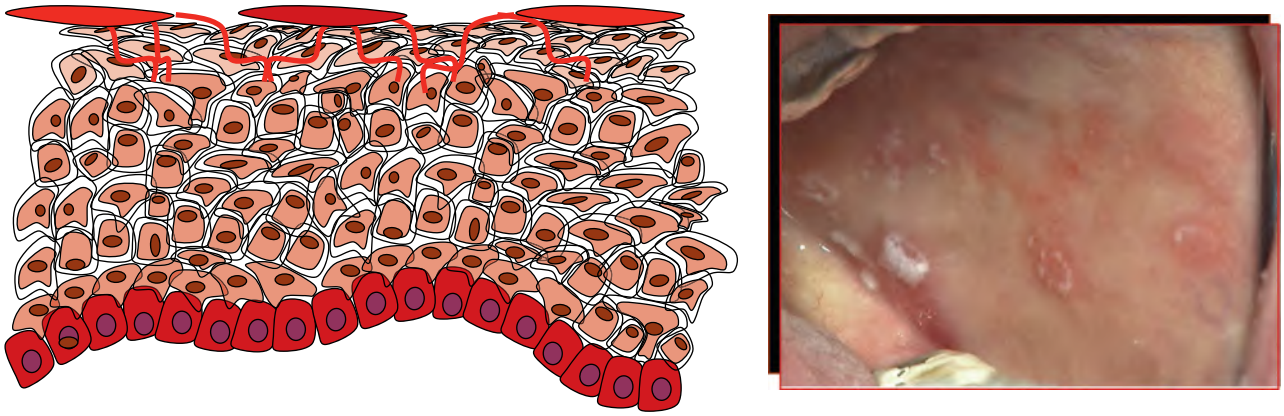

Figure 4-4 Mechanisms of a white appearance of the oral mucosa due to microbes, particularly fungi, which can produce whitish pseudomembranes consisting of sloughed epithelial cells, fungal mycelium, and neutrophils, which are loosely attached to the oral mucosa (plaques).

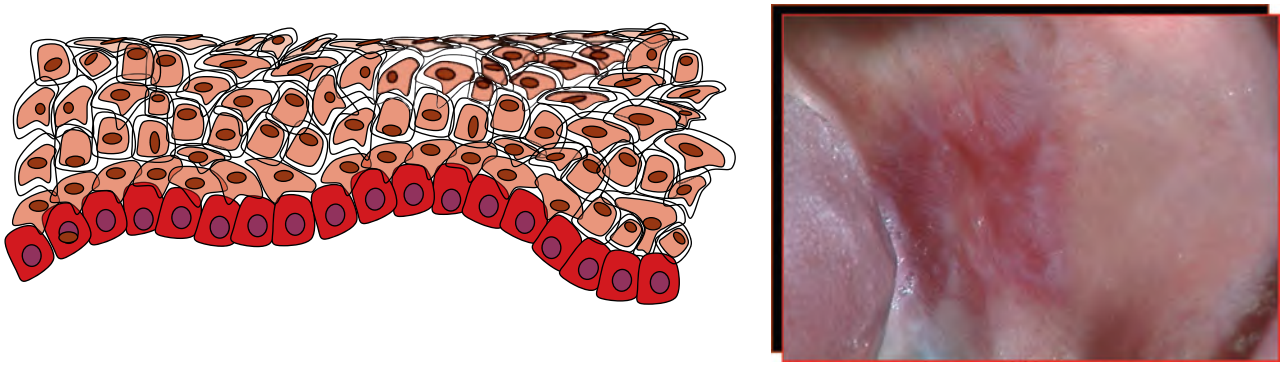

Figure 4-5 Mechanisms leading to a red appearance of the oral mucosa; a red lesion of the oral mucosa may develop as the result of an atrophic epithelium (atrophy).

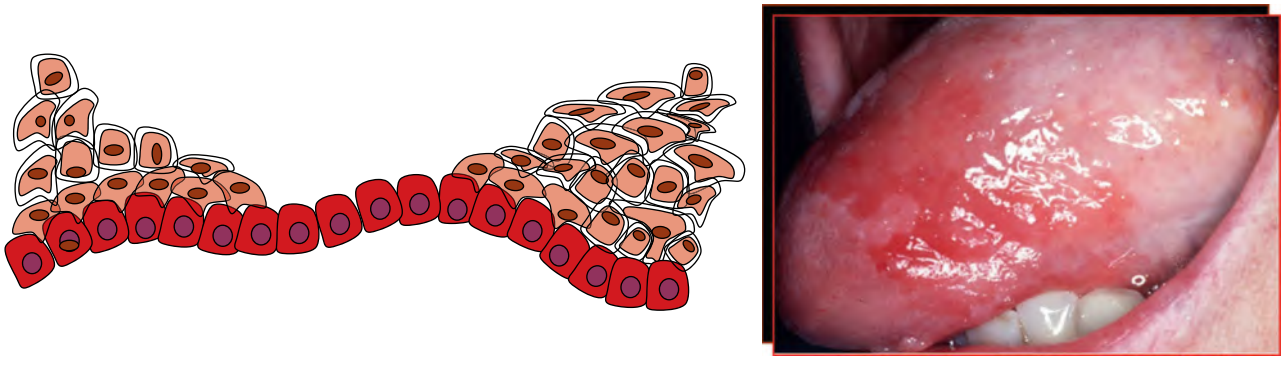

Figure 4-6 Mechanisms leading to a red appearance of the oral mucosa characterized by a reduction in the number of epithelial cells or increased vascularization; that is, dilatation of vessels and/or proliferation of vessels.

we sometimes note the initial indication of possibly undiagnosed systemic disease. Age can also be a significant factor in differentiating between similarly presenting conditions, which is perhaps more important for some other instances than most of those described in this chapter, such as the relevance of enlarged neck lymph nodes in children (frequent reactive lymphadenitis) and adults aged 65 years or older (more likely to represent malignancy), as well as in cases of mouth ulcers in young and old patients (discussed elsewhere).

Table 4-1 Main clinical characteristics of red or white lesions.

Is pain present?
Are lesions single or multiple?
Are lesions bilateral or unilateral?
Is the distribution of lesions linked to mucosal type?
Are lesion borders defined or indistinct?
Date of onset
Are lesions associated with changes of the skin?
Duration of lesion
Any changes in shape, size, or texture with time?
Any previous response to therapy?
What makes the pain or the lesions worse?
Have lesions healed and recurred?

INFECTIOUS DISEASES

Oral Candidiasis

Oral candidiasis is the most prevalent opportunistic infection affecting the oral mucosa. It is common, but often wrongly considered by the unskilled as a culprit for many oral conditions or white lesions. In the vast majority of cases, oral candidiasis is caused by *Candida albicans*. *C. albicans* is one of the components of normal oral microflora and more than 60% of people carry this organism. Rate of carriage increases with age of the patient and *C. albicans* can be found in over 60% of dentate patients over the age of 60 years. Most candidal infections only affect mucosal linings, and vaginal candidiasis is said to affect 50% of the female population of the planet at one time or another. There are many different additional *Candida* species that can be seen in the oral cavity, including C. *glabrata*, *C. guillermondii*, *C. krusei*, *C. tropicalis*, *C. parapsilosis*, *C. pseudotropicalis*, and *C. stellatoidea*. Candidiasis is often referred to as a disease of the diseased and is associated with underlying hematologic or immunologic deficiencies and a huge increase in the numbers of oral candida, as well as the conversion from the commensal yeast form (saprophytic stage) to the infecting pathogenic (parasitic) form. Thus it is incumbent on clinicians to determine the reasons for oral candidiasis, not just prescribe antifungals.

Candidiasis is said to affect in particular the very young, the very old, the very dry, and the very sick. Every candidiasis starts after local or systemic factors enable commensal *Candida* to become pathogenic. Those local factors include lack of saliva (medications causing dry mouth, autoimmune diseases, head and neck radiotherapy), denture wearing, topical steroid use, use of antibiotics or immunosuppressive drugs, systemic conditions including diabetes, anemia, or HIV, as described in detail in this chapter. Rare systemic manifestations of candidal infections may have a fatal course and are major causes of morbidity and mortality, causing a variety of diseases from mucosal infections to deep tissue disease, which may lead toward candidemia and organ involvement. Systemic candidal infections are mostly limited to hospital patients who are immunocompromised or with other severe comorbidities.[4]

Oral medicine largely deals with oral mucosal candidal infections, but also considers local or systemic disturbances that may predispose to fungi becoming invasive instead of remaining commensal. Candidal infections encountered in an oral medicine setting usually do not result in serious consequences for overall health, but can produce discomfort (inflammation may cause tenderness) or may change a person's appearance (e.g., angular cheilitis). Successful treatment depends on identifying and eliminating predisposing factors. On rare occasions, a longstanding intractable candidal infection in individuals with disturbed immune responses may produce granulomatous reactions.

Classification

There have been a number of classifications, but the most useful is that which combines chronicity with clinical presentation, as seen in Table 4-2. Pseudomembranous lesions present with removable small white plaques (see later), while erythematous lesions present essentially as red lesions with no white plaques.[5] These are both superficial forms of candidiasis, whereas all chronic hyperplastic forms are associated with hyphae driving down within the epithelium (Table 4-2). Oral forms may also be associated with candidiasis affecting extraoral sites, usually in conditions or genetic diseases where normal innate or adaptive host responses are compromised (Table 4-3).

Etiology and Pathogenesis

C. albicans, *C. tropicalis*, and *C. glabrata* comprise together over 80% of the species isolated from human mucosal candidal infections. To invade the mucosal lining, the microorganisms must adhere to the epithelial surface, therefore candidal strains with better adhesion potential are more virulent than strains with poorer adhesion ability.[6] Penetration of the epithelial cells by yeasts is facilitated by their production of lipases and proteinases, and for the yeasts to remain within the epithelium, they must overcome constant desquamation of surface epithelial cells.[7]

There is an association between oral candidiasis and the influence of local and general predisposing factors. The local predisposing factors (Table 4-4) are able to promote growth of the yeast or to affect the immune response of the oral mucosa. General predisposing factors are often related to an individual's immune and endocrine status (Table 4-4). Drugs

Table 4-2 Classification of oral candidiasis.

Type	Examples
Pseudomembranous—acute	Thrush
Pseudomembranous—chronic	With inhalers
Erythematous—acute atrophic	After antibiotic therapy
Erythematous—chronic atrophic	Denture stomatitis; in HIV
Chronic hyperplastic (nodular and plaque-like subtypes)	Candidal leukoplakia, median rhomboid glossitis
Candida-associated lesions	Denture stomatitis; angular cheilitis

Table 4-3 Candidiasis affecting extraoral sites and conditions predisposing to candidiasis.

Diffuse chronic mucocutaneous candidiasis
Erythematous candidiasis endocrinopathy syndrome
Chronic severe combined immunodeficiency
DiGeorge syndrome
Chronic granulomatous disease
HIV disease

Table 4-4 Predisposing factors for oral candidiasis.

Local Predisposing Factors for Oral Candidiasis and *Candida*-Associated Lesions	General Predisposing Factors for Oral Candidiasis
Denture wearing	Immunosuppressive diseases
Smoking	Immunosuppressive drugs
Inhalation steroids	Chemotherapy
Topical steroids	Endocrine disorders, e.g., diabetes
Hyperkeratosis	Hematinic deficiencies
Quality and quantity of saliva	Systemic antibiotics
Atopic constitution	Impaired health status
Imbalance of the oral microflora	

as well as diseases that suppress the adaptive and innate immune systems can affect the susceptibility of the mucosal lining. Pseudomembranous candidiasis is also associated with fungal infections in young children, who have neither a fully developed immune system nor a fully developed oral microflora.

Denture stomatitis and angular cheilitis are referred to as *Candida*-associated infections, as they are always associated with raised counts of intraoral *Candida* and also since bacteria may cause these infections.

Epidemiology

The prevalence of candidal strains as part of the commensal oral flora shows large geographic variations, often also related to the method of culture, but an average figure of 50% is generally accepted. Candidal strains are more frequently isolated from women and the vaginal carriage is similar. Hospitalized patients have a higher prevalence, presumably related to comorbidities. In complete denture wearers, the prevalence of *Candida* associated with denture stomatitis has been reported as nearly 70%. There is a view that candidiasis is frequently over-reported in those without experience of the normal anatomy of the oral cavity. Thus, even slight elongation of the filiform papillae on the dorsum of the tongue may be erroneously diagnosed as candidiasis, as may be almost any white patch in the oral cavity. This misconception is found not only among lay people, but also among many medical and dental professionals.

Clinical Findings

Pseudomembranous Candidiasis

The acute form of pseudomembranous candidiasis (thrush; see Table 4-2) is recognized as the classic candidal infection (Figure 4-7). The infection predominantly affects patients taking antibiotics, immunosuppressant drugs, or having a disease that suppresses the immune system.

The infection typically presents with loosely attached membranes comprising fungal organisms and cellular debris (desquamated epithelial cells and polymorphonuclear lymphocytes), which leaves an inflamed, sometimes bleeding area if the pseudomembrane is removed. Less pronounced infections sometimes have clinical features that are difficult to discriminate from food debris like egg and yoghurt. There is also a chronic form of pseudomembranous candidiasis, often associated with immunodeficiency. The clinical presentations of acute and chronic

Figure 4-7 Pseudomembranous candidiasis at the soft palate, uvula, and palatoglossal arches during the immunosuppressive phase following heart transplantation.

Figure 4-8 Erythematous candidiasis caused by inhalation steroids (A) on the dorsum of the tongue and (B) the associated contact (kissing) lesion on the hard palate.

pseudomembranous candidiasis are indistinguishable. The chronic form may emerge as the result of HIV infection, as patients with this disease may be affected by a pseudomembranous candidal infection for a long period of time. Patients treated with steroid inhalers may also show pseudomembranous lesions of a chronic nature. Patients infrequently report symptoms from their lesions, although some discomfort may be experienced from the presence of the pseudomembranes.

Erythematous Candidiasis

The erythematous form of candidiasis was previously referred to as atrophic oral candidiasis. However, an erythematous surface may not just reflect atrophy but can also be explained by increased vascularization. In addition, the erythematous form seen on the tongue in HIV infection is associated with loss of lingual papillae and a contact lesion on the hard palate. Lesions of erythematous candidiasis have a diffuse border (Figure 4-8), which helps distinguish them from erythroplakia, which usually has a sharper demarcation and often appears as a slightly submerged lesion. Quantitative analysis of *Candida* counts in saliva will reveal raised counts in all forms of candidiasis. The infection is also seen in the palate and the dorsum of the tongue of patients who are using inhalation steroids. Other predisposing factors that can cause erythematous candidiasis are smoking and treatment with broad-spectrum antibiotics. The acute and chronic forms present with identical clinical features.

Chronic Hyperplastic Candidiasis (Chronic Plaque Type and Nodular Candidiasis)

The chronic plaque type of oral candidiasis is synonymous with the older term *candidal leukoplakia*. A white irremovable plaque characterizes the typical clinical presentation, which may be indistinguishable from oral leukoplakia (Figure 4-9). A histologic feature (see later) is the penetration of candidal hyphae through the epithelial cells and the associated subepithelial chronic inflammatory response (Figure 4-10). This often results in mild to moderate dysplasia, especially in the chronic plaque type and the nodular type of oral hyperplastic candidiasis (Figure 4-11). This is considered reversible with treatment, but very rarely cases go on to malignant transformation. It has been hypothesized that *Candida* species may induce this transformation through their capacity to catalyze nitrosamine production, which is carcinogenic.[8]

Median Rhomboid Glossitis

Median rhomboid glossitis is clinically characterized by an erythematous lesion in the center of the posterior part of the dorsum of the tongue (Figure 4-12). As the name indicates, the lesion has an oval configuration. This area of erythema results from atrophy of the filiform papillae and the surface may be lobulated. The etiology is not fully clarified, but biopsies yield candidal hyphae in more than 85% of the lesions.[9] Smokers and denture wearers have an increased risk of developing median rhomboid glossitis, as well as patients using inhalation steroids. Sometimes a concurrent erythematous lesion may be observed in the palatal mucosa (contact lesion). Median rhomboid glossitis is asymptomatic, and management is restricted to a reduction of predisposing factors and systemic antifungals.

Although it may cause concern for patients who either discover the lesion themselves (e.g., while self-examining in search for symptoms, such as in burning mouth syndrome) or via health professionals, the lesion does not entail any increased risk for malignant transformation. Unlike the lateral and ventral tongue, cancer is very rare on the dorsal

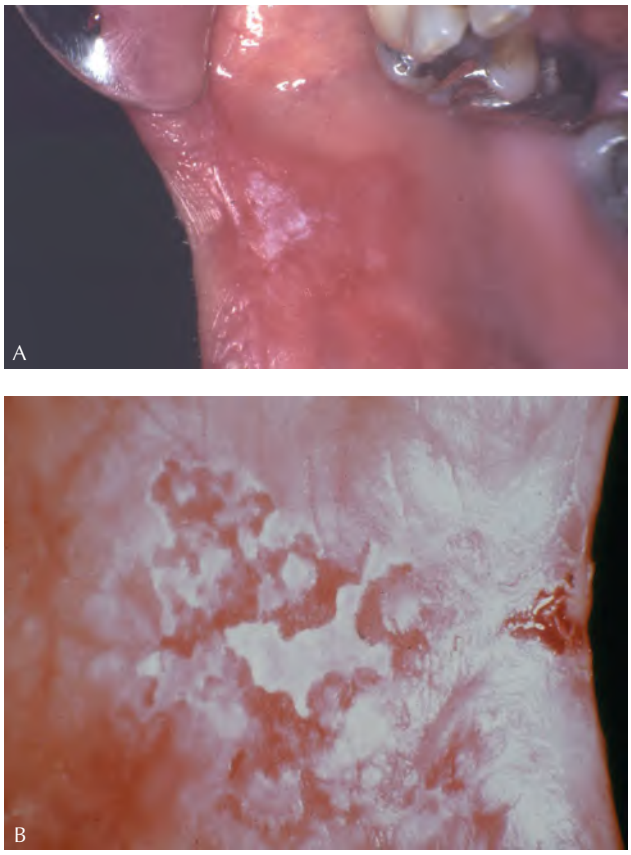

Figure 4-9 (A) Chronic hyperplastic candidiasis inside the right commissure. This white plaque is not removable, was bilateral, and histology (Figure 4-10) showed hyphae penetrating through epithelial cells. (B) Plaque type chronic candidiasis in the right buccal mucosa.

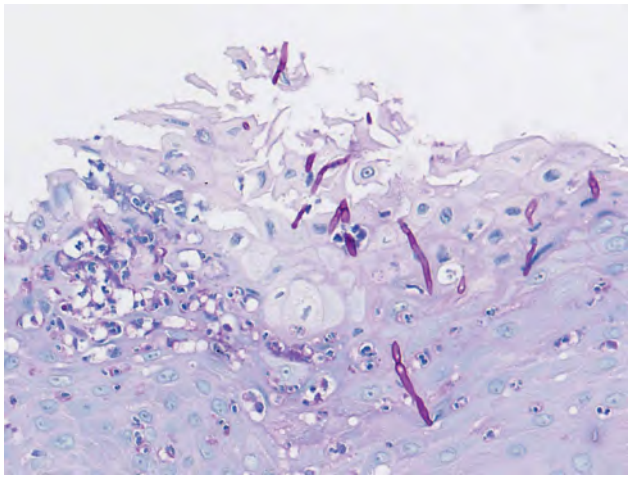

Figure 4-10 Periodic acid–Schiff (PAS) staining of a biopsy from chronic hyperplastic candidiasis (Figure 4-9A) showing invading hyphae drilling through oral epithelial cells.

tongue and virtually nonexistent right in its center. If a biopsy of median rhomboid glossitis is taken, one should be aware that it can easily be misinterpreted by pathologists as being malignant.[10] Although it is a benign lesion, histologically it

Figure 4-11 Chronic nodular candidiasis in the left retrocommissural area.

Figure 4-12 Median rhomboid glossitis apparently arising from the junction of the posterior third and anterior two-thirds of the tongue. Histology confirmed chronic hyperplastic candidiasis.

simulates cancer, which is why it has been styled "pseudoepitheliomatous hyperplasia" (epithelioma is a historical term for cancer). Elongated rete pegs resemble nests of cancer cells. Histopathology findings of deeper layers show muscular fibrosis and hyalinization (which are increased by excision). Therefore, neither biopsy nor surgical intervention is recommended in cases of median rhomboid glossitis.

Denture Stomatitis

The most prevalent site for denture stomatitis is the denture-bearing palatal mucosa (Figure 4-13), whether acrylic or

Figure 4-13 Chronic atrophic candidiasis (denture stomatitis) type III with a granular mucosa in the central part of the palate.

chrome cobalt. It is unusual for the mandibular mucosa to be involved. *Candida* resides on the denture surface, and the erythema appears to be a mucosal reaction to *Candida* and other microorganisms.

Denture stomatitis is classified into three different types:

- Type I is limited to erythematous sites caused by trauma from the denture.
- Type II affects a major part of the denture-covered mucosa.
- Type III has a granular mucosa (reactive proliferation of underlying fibrous tissue) in addition to the features of type II. The denture serves as a vehicle that accumulates sloughed epithelial cells and protects the microorganisms from physical influences such as salivary flow.

The microflora is complex and may, in addition to *C. albicans*, contain bacteria from several genera, such as *Streptococcus*, *Veillonella*, *Lactobacillus*, *Prevotella* (formerly *Bacteroides*), and *Actinomyces* strains. It is not known to what extent these bacteria participate in the pathogenesis of denture stomatitis. Nearly every patient with denture stomatitis will report wearing dentures overnight. Thus, denture stomatitis is the consequence of continuous irritation, both microbial and mechanical from the upper denture, on the underlying mucosal surface. The term "denture sore mouth" is a misnomer, as it normally does not produce any symptoms and is usually diagnosed by the dentist, since patients are frequently unaware. Oral medicine specialists still get referrals with a misdiagnosis of allergy to the denture.

Angular Cheilitis

Angular cheilitis presents as infected fissures of the commissures of the mouth, often surrounded by erythema (Figure 4-14). The lesions are frequently co-infected with both *Candida albicans* and *Staphylococcus aureus*. Atopy, vitamin B_{12} deficiency, iron deficiencies, and loss of vertical dimension are all associated with this disorder. The reservoir for *Candida* in the cheilitis is intraoral, so treatment must not be limited to the commissures. Many patients with angular cheilitis will also have denture stomatitis.

Oral Candidiasis Associated with HIV

More than 90% of AIDS patients have had oral candidiasis during the course of their HIV infection, and the infection is considered a portent of AIDS development (Figure 4-15). Oropharyngeal candidiasis is related to the degree of immunosuppression and is most often observed in patients with CD4 counts <200 cells/mL. The most common types of oral candidiasis in conjunction with HIV are chronic pseudomembranous candidiasis, erythematous candidiasis of the middle of the tongue and palate, and angular cheilitis. As a result of antiretroviral therapy (ART), the prevalence of

Figure 4-14 *Candida*-induced bilateral angular cheilitis. Treatment must include the intraoral *Candida* reservoir.

Figure 4-15 Erythematous candidiasis of the central part of the tongue in an AIDS patient. Hairy leukoplakia can be seen at the right lateral border.

oral candidiasis has decreased substantially. Oral candidiasis associated with HIV infection is presented in more detail in Chapter 21, "Infectious Diseases."

Clinical Manifestations of Mucocutaneous Candidiasis

More widespread candidiasis (see Table 4-3), besides oral involvement, is accompanied by systemic mucocutaneous candidiasis and other immune deficiencies. Chronic mucocutaneous candidiasis (CMC) embraces a heterogeneous group of disorders, but is characterized by recurrent or persistent infections affecting the nails, skin, and oral and genital mucosae caused by *Candida* species (Figure 4-16A).[11] The face and scalp may be involved, and granulomatous masses can be seen at these sites. Approximately 90% of patients with CMC also present with oral candidiasis. The oral manifestations may involve the tongue (Figure 4-16B) and white plaque-like lesions are seen in conjunction with fissures. CMC can occur as part of endocrine disorders, including hyperparathyroidism and Addison's disease. Recent studies revealed that an impairment of interleukin-17 (IL-17) immunity underlies the development of CMC. Th17 cells produce IL-17 and play an important role in host mucosal immunity to *Candida*. Impaired phagocytic function by neutrophilic granulocytes and macrophages caused by myeloperoxidase deficiency have also been associated with CMC.

Chédiak–Higashi syndrome, an inherited disease with a reduced and impaired number of neutrophilic granulocytes, lends further support to the role of the phagocytic system in candidal infections, as these patients frequently develop candidiasis. Severe combined immunodeficiency (SCID) syndrome is characterized by a defect in the function of the cell-mediated arm of the immune system. Patients with this disorder frequently contract disseminated candidal infections. Thymoma is a neoplasm of thymic epithelial cells that also is associated with systemic candidiasis. Thus, both the innate and adaptive immune systems are critical to prevent the development of systemic mucocutaneous candidiasis.

Diagnosis and Laboratory Findings

The presence of candidal microorganisms as a member of the commensal flora complicates the discrimination of the normal state from infection. *Candida* cells can be found in 60% of people in numbers of up to 500 cfu/mL as normal commensals. However, in infection, these numbers may increase to over 10,000 cfu/mL and any increase to over 1000 cfu/mL may be seen in candidal infections. It is imperative that both clinical findings and laboratory data (Table 4-5) are balanced in order to arrive at a correct diagnosis. Sometimes antifungal treatment has to be initiated to assist in the diagnostic process, with a good clinical response indicating a retrospective diagnosis. Smears (cytology) are useful for indicating hyphae, and salivary culture for indicating numerically raised counts. Swabs indicate neither hyphae nor counts, but can confirm the presence of raised amounts of *Candida*.

Smears from the infected area comprise epithelial cells, debris, and *Candida*. The material is fixed in isopropyl alcohol and air-dried before staining with periodic acid–Schiff (PAS). The detection of several yeast organisms in the form of hyphae- or pseudohyphae-like structures is usually considered a sign of infection, although these structures can occasionally be found in normal oral mucosa. This technique is particularly useful when pseudomembranous oral candidiasis and angular cheilitis are suspected (Table 4-6). Cultivation of saliva, oral washings, or swabs are performed on Sabouraud agar and in the case of saliva or washings the cfu/mL can be determined (Table 4-7). To discriminate between different candidal species, an additional examination can be performed on chromogenic agar (e.g., Pagano–Levin agar). Imprint culture technique can also be used

where sterile plastic foam pads (2.5 × 2.5 cm) are moistened in Sabouraud broth and placed on the infected mucosal or denture surface for 60 seconds. The pad is then firmly pressed onto Sabouraud agar, which will be cultivated at 37 °C. The result is expressed as colony forming units per cubic milliliter (cfu/mL[2]). This method is a valuable adjunct in the diagnostic process of erythematous candidiasis and in denture stomatitis, where high counts will be found on the denture but not on the palate.

In chronic plaque type and nodular candidiasis, cultivation techniques have to be supplemented by a biopsy and histopathologic examination (Table 4-6). This examination is primarily performed to identify the presence of any epithelial dysplasia and to identify invading candidal hyphae by PAS staining (Figure 4-10).

If clinical signs of *Candida* infection are not evident, then undertaking laboratory investigations may not be appropriate, and sometimes the clinical signs are so obvious (e.g., pseudomembranous candidiasis) that laboratory tests may not be needed and antifungal therapy may be initiated without confirmatory tests. Tests may also be helpful if the expected response to treatment does not materialize. These may include speciation and testing for antifungal sensitivity, especially for the azoles. Some species (e.g., *C. krusei*, *C. glabrata*) have natural resistance to azoles, and others may become resistant after previous exposure.

Management

Treatment for fungal infections, which usually includes antifungal regimens, will not always be successful unless the clinician addresses predisposing factors that may cause recurrence. Local factors are often easy to identify but sometimes not possible to reduce or eradicate. Antifungal drugs have a primary role in such cases. In smokers, cessation of the habit may result in disappearance of the infection even without antifungal treatment (Figure 4-17). Superficial mucosal infections are often best treated with topical antifungals, whereas chronic hyperplasic types will respond best to systemic therapy. The most commonly used antifungal drugs belong to the groups of polyenes or azoles (Table 4-8).

Polyenes such as nystatin and amphotericin are usually the first choices in treatment of primary oral candidiasis and are both well tolerated. Polyenes are not absorbed from the gastrointestinal tract and are not associated with development of resistance. They exert the action through a negative effect on the production of ergosterol, which is critical for the yeast's cell membrane integrity. Polyenes can also affect the adherence of the fungi to epithelial cells.

Whenever possible, elimination or reduction of predisposing factors should always be the first goal for treatment of denture stomatitis as well as other opportunistic infections. This involves improved denture hygiene and a recommendation not to use the denture while sleeping. The denture hygiene is important to remove nutrients, including desquamated epithelial cells, which may serve as a source of nitrogen, which is essential for the growth of the yeasts. Denture cleaning also disturbs the maturity of a microbial environment established under the denture. As porosities in the denture can harbor microorganisms, which may not be removed by physical cleaning, the denture should be stored in antimicrobial solution during the night. Different solutions, including alkaline peroxides, alkaline hypochlorites, acids, and disinfectants, have been suggested. Chlorhexidine may also be used, but can discolor the denture and also counteracts the effect of nystatin.[12]

Surgical excision of type III denture stomatitis is sometimes advised in an attempt to eradicate microorganisms present in the deeper fissures of the granular tissue. However, this is neither sensible nor necessary, and it should not even be considered. Improved hygiene, better-fitting dentures, and not wearing them overnight should clear the inflammation and edema sufficiently.

Table 4-7 *Candida* Isolation in the clinic and quantification from oral samples.

Method	Main Steps	Advantages	Disadvantages
Smear	Scraping, smearing directly onto slide	Simple and quick	Low sensitivity
Salivary culture	Patient expectorates 2 mL saliva into sterile container; vibration; culture on Sabouraud agar by spiral plating; counting	Quantifies actual counts against normal range Useful to monitor response to therapy	Longer chairside time; not useful for xerostomics Does not identify site of infection
Oral rinse	Subject rinses for 60 s with phosphate-buffered saline at pH 7.2, and returns it to the original container; cultured and counted as in previous methods	Simple method Sensitive Normal ranges available	Recommended in hyposalivation Does not identify site of infection
Impression culture	Maxillary and mandibular alginate impressions; casting in agar fortified with Sabouraud broth; incubation	Useful to determine relative distributions of yeasts on oral surfaces	Useful mostly as a research tool
Imprint culture	Sterile plastic foam pads moistened with Sabouraud broth, placed on lesion for 60 s; pad pressed on Sabouraud agar plate and incubated; colony counter used	Sensitive and reliable; can discriminate between infected and noninfected sites	Reading above 50 CFU/cm^2 can be inaccurate Useful mostly as a research tool

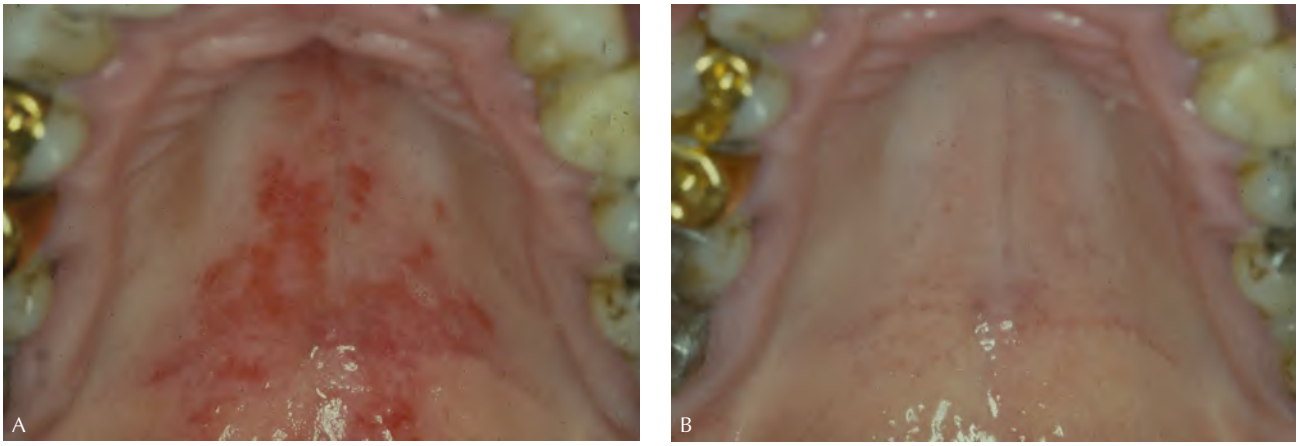

Figure 4-17 Palatal erythematous candidiasis in a cigarette smoker (A) before treatment; (B) after treatment.

Topical treatment with azoles such as miconazole is the treatment of choice for angular cheilitis, often infected by both *S. aureus* and candidal strains. This drug has a biostatic effect on *S. aureus* in addition to the fungistatic effect (but also augments warfarin). Antiseptic ointment can be used as a complement to the antifungal drugs if *Staphylococcus* is suspected. If angular cheilitis comprises an erythema surrounding the fissure, a mild steroid ointment may be required in addition to the antifungal to suppress the inflammation. To prevent recurrences, treatment of the intraoral reservoir of *Candida* is essential and patients may benefit from applying a moisturizing cream, which may prevent new fissure formation.

Systemic azoles may be used for deeply seated primary candidiasis, such as chronic hyperplastic candidiasis and median rhomboid glossitis with a granular appearance, and for therapy-resistant infections, mostly related to compliance failure. There are several disadvantages with the use of azoles. They are known to interact with warfarin, leading to an increased bleeding propensity. This adverse effect may also be present with topical application, as the azoles are fully or partly resorbed from the gastrointestinal tract. Development of resistance is particularly compelling for fluconazole in individuals with HIV disease. In such cases, ketoconazole and itraconazole have been recommended as alternatives. However, cross-resistance has been reported between fluconazole on the one hand and ketoconazole, miconazole, and itraconazole on the other. The azoles are also used in the treatment of secondary oral candidiasis associated with systemic

Table 4-8 Antifungal agents used in the treatment of oral candidiasis.

Drug	Form	Dosage	Comments
Amphotericin	Lozenge, 10 mg	Slowly dissolved in mouth 3–4 times/day after meals for 2 weeks minimum	Negligible absorption from gastrointestinal tract When given intravenously for deep mycoses may cause thrombophlebitis, anorexia, nausea, vomiting, fever, headache, weight loss, anemia, hypokalemia, nephrotoxicity, etc.
	Oral suspension, 100 mg/mL	Placed in mouth after food and retained near lesions 4 times/day for 2 weeks	
Nystatin	Cream	Apply to affected area 3–4 times/day	Negligible absorption from gastrointestinal tract Nausea and vomiting with high doses
	Pastille, 100,000 U	Dissolve 1 pastille slowly after meals 4 times/day, usually for 7 days	
	Oral suspension, 100,000 U	Apply after meals 4 times/day, usually for 7 days, and continue use for several days after postclinical healing	
Clotrimazole	Cream	Apply to affected area 2–3 times/day for 3–4 weeks	Mild local effects Also has antistaphylococcal activity
	Solution	5 mL 3–4 times/day for 2 weeks minimum	
Miconazole	Oral gel	Apply to affected area 3–4 times/day	Occasional mild local reactions Also has antibacterial activity
	Cream	Apply twice/day and continue for 10–14 days after lesion heals	Theoretically the best antifungal to treat angular cheilitis Interacts with anticoagulants (warfarin), terfenadine, cisapride, and astemizole Avoid in pregnancy and liver disease
Ketoconazole	Tablets	200–400 mg tablets taken once or twice/day with food for 2 weeks	May cause nausea, vomiting, rashes, pruritus, and liver damage Interacts with anticoagulants, terfenadine, cisapride, and astemizole Contraindicated in pregnancy and liver disease
Fluconazole	Capsules	50–100 mg capsules once/day for 2–3 weeks	Interacts with anticoagulants, terfenadine, cisapride, and astemizole Contraindicated in pregnancy and liver and renal disease May cause nausea, diarrhea, headache, rash, and liver dysfunction
Itraconazole	Capsules	100 mg capsules daily taken immediately after meals for 2 weeks	Interacts with terfenadine, cisapride, and astemizole Contraindicated in pregnancy and liver disease May cause nausea, neuropathy, or rash

predisposing factors and for systemic candidiasis. Some suggested regimes for the treatment of local and systemic *Candida* infections are outlined in Table 4-8.

Prognosis of oral candidiasis is good when predisposing factors associated with the infection are reduced or eliminated. Persistent chronic plaque type and nodular candidiasis have been suggested to be associated with an increased risk for malignant transformation compared with leukoplakia not infected by candidal strains. Patients with primary candidiasis are also at risk if systemic predisposing factors emerge. For example, patients with severe immunosuppression, as seen in conjunction with leukemia and AIDS, may encounter disseminating candidiasis with a fatal course.[13]

Oral Hairy Leukoplakia

Oral hairy leukoplakia (OHL) is the second most common HIV-associated oral mucosal lesion. OHL has been used as a marker of disease activity, since the lesion is associated with low $CD4^+$ T lymphocyte counts.[14] It is caused by concurrent infection with the Epstein–Barr virus (EBV). The lesion is strongly associated with HIV disease, but other states of immune deficiencies, such as those caused by immunosuppressive drugs and cancer chemotherapy, have also been associated with OHL.

Etiology and Pathogenesis

OHL appears to be an EBV-induced lesion in patients with low levels of $CD4^+$ T lymphocytes. Antiviral medication, which prevents EBV replication, is curative and lends further support to EBV as an etiologic factor. There is also a correlation between EBV replication and a decrease in the number of $CD1a^+$ Langerhans cells, which, together with T lymphocytes, are important cell populations in the cellular immune defense of the oral mucosa.[15]

Epidemiology

The prevalence figures for OHL depend on the type of population investigated and vary around the world. Prior to the ART era, the mean prevalence was 25% of people living with HIV, but this figure has decreased considerably after the introduction of more effective therapies.[16] In contrast, patients who develop AIDS have an increased prevalence of greater than 50%. The prevalence in children is lower compared with adults and has been reported to be around 2%.[17] The condition is more frequently encountered in men, but the reason for this predisposition is not known. A correlation between smoking and OHL has also been observed.[18]

Clinical Findings

OHL is frequently encountered bilaterally on the lateral borders of the tongue (Figure 4-18), but may also be observed on the dorsum and in the buccal mucosa.[19] The typical clinical appearance is vertical white folds oriented as a palisade along the borders of the tongue. The lesions may also be seen as white and somewhat elevated plaque, which cannot be scraped off. OHL is asymptomatic, although symptoms may be present when the lesion is superinfected with candidal strains. As OHL may present in different clinical forms, it is important always to consider this mucosal lesion whenever the border of the tongue is affected by white lesions, particularly in immunocompromised patients.

Diagnosis

A diagnosis of OHL is usually based on clinical characteristics, but histopathologic examination and detection of EBV can be performed to confirm the clinical diagnosis (Table 4-9). It may most easily be confused with chronic trauma to the lateral borders of the tongue, but in that instance the corrugations are horizontal, not vertical.

Figure 4-18 Hairy leukoplakia at the left lateral border of tongue in an AIDS patient showing vertical keratotic corrugations.

Pathology

The histopathology of OHL is characterized by hyperkeratosis, often with a chevron-pattern surface and acanthosis. Hairy projections are common, which is reflected in the name given to this disorder. Koilocytosis, with edematous epithelial cells and pyknotic nuclei, is also a characteristic histopathologic feature. The complex chromatin arrangements may mirror EBV replication in the nuclei of koilocytic epithelial cells. Candidal hyphae surrounded by polymorphonuclear granulocytes are a common feature. The number of Langerhans cells detected by immunostaining is considerably reduced. Mild subepithelial inflammation may also be observed. EBV can be detected by in situ hybridization or by immunohistochemistry. Exfoliative cytology may be of value and can serve as an adjunct to biopsy.

Management

OHL can be treated successfully with antiviral medication, but this is not often indicated, as this disorder is not associated with adverse symptoms. In addition, the disorder has also been reported to show spontaneous regression. OHL is not related to increased risk of malignant transformation. Medication with ART has reduced the number of OHL to a few percent in HIV-infected patients.[20]

ORAL POTENTIALLY MALIGNANT DISORDERS

Oral Leukoplakia

Definitions

Leukoplakia is defined as a white plaque of questionable risk for malignant transformation having excluded other known white lesions or disorders that carry no increased

Table 4-9 Features of the diagnosis of oral hairy leukoplakia.

Provisional diagnosis
Characteristic gross appearance of bilateral vertical corrugations on sides of tongue, with or without responsiveness to antifungal therapy
Presumptive diagnosis
Light microscopy of histologic sections revealing hyperkeratosis, koilocytosis, acanthosis, and absence of inflammatory cell infiltrate, or light microscopy of cytologic preparations demonstrating nuclear beading and chromatin margination
Definitive diagnosis
In situ hybridization of histologic or cytologic specimens revealing positive staining for Epstein–Barr virus DNA, or electron microscopy of histologic or cytologic specimens showing herpesvirus-like particles

risk for cancer. Leukoplakia is thus a diagnosis of exclusion. Erythroplakia is a fiery red patch that cannot be characterized clinically or pathologically as any other definable disease. Both those diagnoses thus require exclusion of other similar-looking lesions of known causes or mechanisms before being applied.[21]

By far the majority of white and red lesions are benign. However, the two conditions with the greatest malignant potential in the oral cavity are leukoplakia (white plaque) and erythroplakia (red plaque). The relative importance of one versus the other is that leukoplakia is very common and can sometimes transform into cancer, whereas erythroplakia is rather uncommon but frequently represents a precursor to cancer. There is also a term erythroleukoplakia (nonhomogeneous, speckled leukoplakia), which has both white and red areas, and the sinister nature of erythroleukoplakia and erythroplakia should be considered alike.

Etiology and Pathogenesis

By definition, leukoplakia is idiopathic, having excluded white patches of known etiology. The exception to this rule is that smoking is recognized as an etiological or exacerbating factor and smoker's keratosis may regress when the irritant is removed (see later).[22] As smoking cessation can effectively reverse many tobacco-associated leukoplakia, appreciating its etiology and acting appropriately form the best approach to prevent oral cancer.[22]

Hairy leukoplakia is not considered a true leukoplakia, since the etiology and infective agent (EBV) are known and the risk of malignant transformation appears to be almost nonexistent.

The development of oral leukoplakia and erythroplakia as potentially malignant lesions involves different genetic events. This notion is supported by the fact that markers of genetic defects are differently expressed in different leukoplakias and erythroplakias.[23–25] Activation of oncogenes and deletion and injuries to suppressor genes and genes responsible for DNA repair will all contribute to a defective functioning of the genome that governs cell division. Following a series of mutations, a malignant transformation may occur. For example, carcinogens such as tobacco may induce hyperkeratinization, with the potential to revert following cessation, but at some stage mutations will lead to unrestrained proliferation and cell division.

Epidemiology

The prevalence of oral leukoplakia varies among scientific studies. A comprehensive global review points at prevalences between 1.5% and 2.6%.[26] Most oral leukoplakias are seen in patients beyond the age of 50 and are infrequently encountered below the age of 30. In population studies, leukoplakias are more common in men, but a slight majority for women has been found in some studies.[27]

Clinical Findings

Oral leukoplakia is defined as a white plaque of questionable risk having excluded (other) known diseases or disorders that carry no increased risk for cancer. This disorder can be further divided into a homogeneous and a nonhomogeneous type. The typical homogeneous leukoplakia is clinically characterized as a white, often well-demarcated plaque with a similar reaction pattern throughout the lesion (Figure 4-19). Some lesions are uniformly presented in the entire area, but the surface texture can vary, even in a single case, from smooth and thin to a leathery appearance with surface fissures sometimes referred to as "cracked mud." Thus, different thicknesses and textures can, in the absence of red areas and frank verruciform parts, still allow styling leukoplakia as homogeneous. The demarcation is usually distinct, which is different from an oral lichen planus (OLP) lesion, where the white components have a more diffuse transition to the normal oral mucosa. Another difference between these two lesions is the lack of a peripheral erythematous zone in homogeneous oral leukoplakia. The lesions are asymptomatic.

The term "nonhomogeneous" is somewhat less precise. The term is ascribed to lesions with two different features, usually having both red and white areas (Figure 4-20A), but also to all those without redness but containing verruciform exophytic elements. Due to the combined appearance of white and red areas, the nonhomogeneous oral leukoplakia has also been called erythroleukoplakia and speckled leucoplakia (Figure 4-20B). The clinical manifestation of the white component may vary from large white verrucous areas to small nodular structures. If the surface texture is homogeneous but contains verrucous, papillary (nodular), or exophytic components, the leukoplakia is also regarded as nonhomogeneous.

It should be stressed that there is a marked difference in malignant potential between those two subtypes of nonhomogeneous leukoplakia. Those with red areas should be considered

Figure 4-19 Clinical variations of homogeneous leukoplakias. (A) A homogeneous leukoplakia at the left buccal mucosa, (B) right side of tongue, and (C) upper buccal sulcus, which transformed into a squamous cell carcinoma two years later.

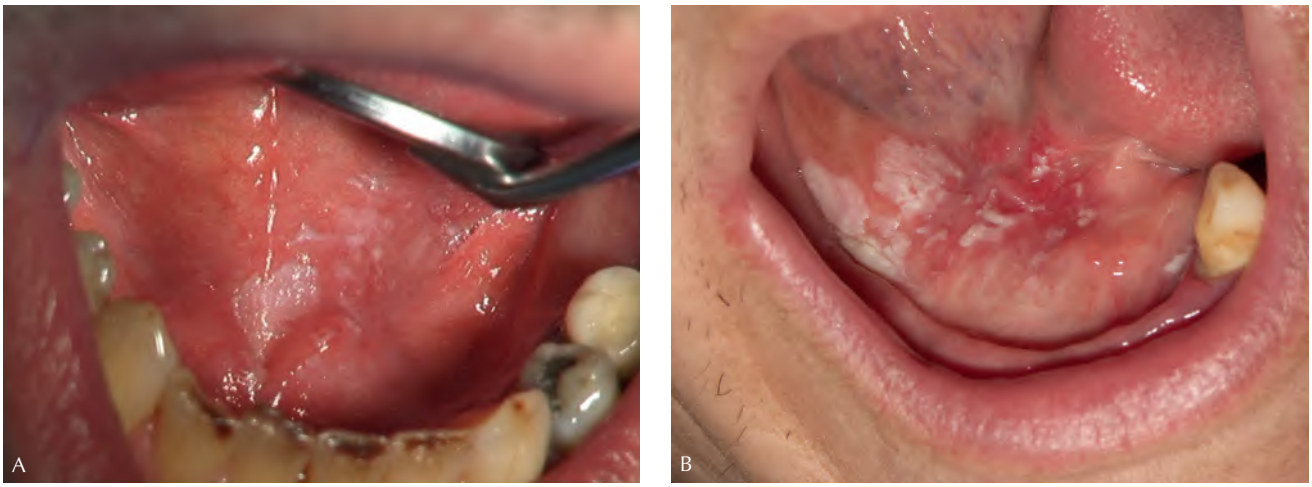

Figure 4-20 Nonhomogeneous leukoplakias of the floor of the mouth, which both transformed into squamous cell carcinomas.
(A) Nonhomogeneous leukoplakia in a heavy smoker at the floor of the mouth. The left part of the lesion has a speckled appearance.
(B) Nonhomogeneous leucoplakia showing a speckled appearance centrally, which transformed into squamous cell carcinoma over two years.

as an early cancer unless histopathologically proven otherwise. Those without red areas still have potential for malignant transformation, but less so. Oral leukoplakias, where the white component is dominated by papillary projections, similar to oral papillomas, are referred to as verrucous or verruciform leukoplakias.[28]

Oral leukoplakia may be found at all sites of the oral mucosa. The floor of the mouth and the lateral borders of the tongue are high-risk sites for malignant transformation (Figure 4-21). These sites have also been found to have a higher frequency of loss of heterozygosity compared with low-risk sites. However, the size of the lesion and the homogeneous/nonhomogeneous pattern are also decisive characteristics for the prognosis, whatever the site.

Proliferative Verrucous Leukoplakia

Proliferative verrucous leukoplakia (PVL) is an uncommon and serious condition where the pattern of clinical behavior does not match the histologic features. Diagnosis cannot usually be established at a single consultation. Histologically the lesion may appear benign, but clinically it behaves as a malignancy with gradually spreading leukoplakia, often gingivally. Oral leukoplakias with this clinical appearance but with a more aggressive proliferation pattern and high recurrence rate are designated as PVL (Figure 4-22).[29] This lesion may start as a homogeneous leukoplakia, but over time develops a verrucous appearance containing various degrees of dysplasia. PVL is usually encountered in older women, and the lower gingiva is a predilection site. The malignant potential is very high, and verrucous carcinoma or squamous cell carcinoma may be present at the primary examination. As the reaction pattern is similar to what is seen in oral papillomas, PVL has been suspected to have a viral etiology, although an association has not been confirmed.[30]

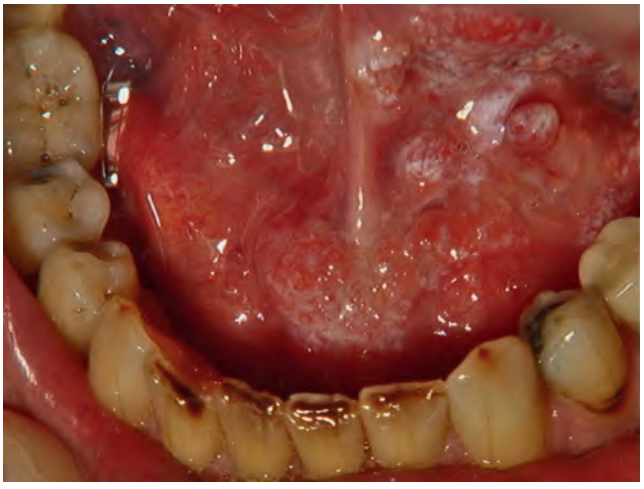

Figure 4-21 The patient with floor-of-mouth nonhomogeneous leukoplakia (Figure 4-20A) did not attend follow-up visits for three years and developed a squamous cell carcinoma.

Figure 4-22 A proliferative verrucous leukoplakia progressively extending from the buccal mucosa, across the gingiva to the ventral surface of the tongue in a 48-year-old female.

Erythroplakia

Epidemiology

Oral erythroplakia is not as common as oral leukoplakia, and the prevalence in adults has been estimated to be in the range of 0.02% to 0.1%. The sex distribution is reported to be equal.

Oral erythroplakia has not been studied as extensively as oral leukoplakia, presumably because it is less common. Erythroplakia is initially a clinical diagnosis. It is defined as a red lesion of the oral mucosa that excludes other known pathologies (Figure 4-23). It comprises an irregular red lesion that is frequently observed with a distinct demarcation against the normal-appearing mucosa, sometimes with velvety granular surface texture.[31–33] Clinically, erythroplakia is different from erythematous OLP, as the latter has a more diffuse border and is surrounded by white reticular or papular structures. Erythroplakia is usually asymptomatic, although some patients may experience a burning sensation in conjunction with food intake.

It has been reported that 91% of histologically assessed homogeneous erythroplakias showed invasive carcinoma or carcinoma in situ, and in 9% there was moderate to severe dysplasia.[31] Another study showed severe dysplasia and frank carcinoma in 75% and mild to moderate dysplasia in 25%.[33] Thus, all erythroplakias should be considered as sinister. Any red mucosal lesion without an apparent local cause or not fitting into other known red lesions, and not regressing following removal of possible cause or two weeks of

Figure 4-23 An erythroplakia on the upper alveolar ridge. Later on the patient developed a squamous cell carcinoma.

treatment, should be considered a cancer unless histologically proven otherwise.

A special form of erythroplakia has been reported that is related to reverse smoking of *chutta*, predominantly practiced in India. The lesion comprises well-demarcated red areas in conjunction with white papular tissue structures. Ulcerations and depigmented areas may also be a part of this particular form of oral lesion.

Diagnosis

The diagnostic procedure of oral leukoplakia and erythroplakia is identical. The provisional diagnosis is based on the clinical observation of a white or red patch that is not explained by a definable cause, such as trauma. If trauma is suspected, the cause, such as a sharp tooth or restoration, should be eliminated. If healing does not occur in two weeks, a tissue biopsy is essential to rule out malignancy. Realistically, differential diagnosis often requires considerable experience. As can be observed from referrals, clinicians not trained in an oral medicine specialty will rarely be able to perform clinical "fine print" distinction between various white lesions. Any similar white mucosal area will likely be initially indiscriminately proclaimed as "leukoplakia" instead of what it really may be (frictional hyperkeratosis, plaque-like lichen planus, habitual cheek biting, etc.). Sometimes there are cases when even specialists struggle with a final diagnosis, or change it over time.

Biopsies

Excisional biopsy is generally recommended if the leukoplakia diameter is less than 30 mm and the location allows (e.g., out of fine sublingual structures or not associated with marginal gingiva). Otherwise, in larger lesions incisional biopsies should be undertaken, sometimes from several sites. Selecting the appropriate site that will best represent the most severe aspect is of paramount importance, as underdiagnosing the lesion may be dangerous. New biopsies should be taken if new clinical features emerge. Following five years of no relapse, self-examination may be a reasonable approach.

Oral Leukoplakia and Erythroplakia: Pathology

The clinical appearance is a poor predictor of the histologic characteristics or behavior of oral leukoplakia, with the exception of the nonhomogeneous (speckled, erythroleukoplakia) type, which often displays a spectrum of occurrences from any degree of dysplasia to cancer. The biopsy should include representative tissue of the different clinical patterns. Hyperkeratosis without any other features of a definable diagnosis is compatible with homogeneous oral leukoplakia. If the histopathologic examination leads to another definable lesion, the definitive diagnosis will be changed accordingly. However, there is no uniform depiction of an oral leukoplakia and the histopathologic features of the epithelium may include hyperkeratosis, atrophy, and hyperplasia with or without dysplasia. When dysplasia is present, it may vary from mild to severe. Dysplasia may be found in homogeneous leukoplakias, but is much more frequently encountered in nonhomogeneous leukoplakias and in erythroplakias.

Epithelial dysplasia is defined in general terms as a precancerous lesion of stratified squamous epithelium characterized by cellular atypia and loss of normal maturation short of carcinoma in situ (Figure 4-24). Carcinoma in situ is defined as a lesion in which the full thickness of squamous epithelium shows the cellular features of carcinoma without stromal invasion.[34] A more detailed description of the features of epithelial dysplasia is presented in Table 4-10. The prevalence of dysplasia in oral leukoplakias varies from 1% to 30%, presumably due to various lifestyle factors involved and due to subjectivity in the histopathologic evaluation. The majority of erythroplakias display an atrophic epithelium with dysplastic features. The significance of epithelial dysplasia for predicting future development of oral cancer is not always clear.

Oral Leukoplakia and Erythroplakia: Management

There are two key unanswered questions that clinicians would consider the most challenging regarding management of oral leukoplakia. The first is how to estimate the risk of a particular case transforming into oral squamous cell carcinoma; that is, to assess the likelihood of malignant transformation and how soon it may happen. Clinical and histopathologic features are somewhat helpful, but the information obtained from them has limitations. In spite of major scientific efforts, universal markers that reliably and efficiently identify lesions with higher risk and that could predict their malignant transformation have not been discovered.[35,36]

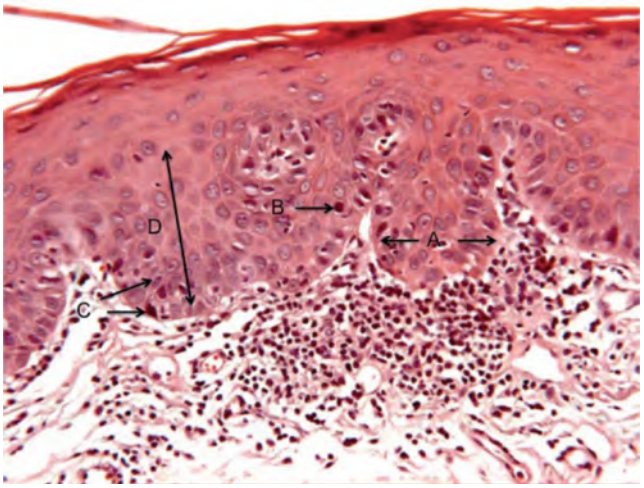

Figure 4-24 Histopathology of a leukoplakia with several characteristics of dysplasia in the oral epithelium (Table 4-9): drop-shaped rete ridges, nuclear hyperchromatism, presence of more than one layer of cells having a basaloid appearance, and irregular epithelial stratification.

Table 4-10 Criteria used for diagnosis of epithelial dysplasia.

Loss of polarity of basal cells
Presence of more than one layer of cells having a basaloid appearance
Increased nuclear–cytoplasmic ratio
Drop-shaped rete ridges
Irregular epithelial stratification
Increased number of mitotic figures
Mitotic figures that are abnormal in form
Presence of mitotic figures in the superficial half of the epithelium
Cellular and nuclear pleomorphism
Nuclear hyperchromatism
Enlarged nuclei
Loss of intercellular adherence
Keratinization of single cells or cell groups in the prickle cell layer

Since leukoplakias are asymptomatic, the main purpose of treatment is to prevent the development of cancer (or sometimes esthetics). Thus, a key question is whether anything can be done so that leukoplakia does not transform to cancer. Several approaches have been suggested, including chemoprevention with nonsteroidal anti-inflammatory drugs (NSAIDs) and metformin, but neither medications nor surgical approaches seem to be effective in preventing cancer development in patients with leukoplakia.[37–39]

As we do not have answers to those two pertinent questions, management of leukoplakia follows certain non-evidence-based protocols, but optimal management approaches are on a case-by-case basis and sometimes require numerous, lifelong, and frequent follow-up visits, including repeated biopsies.[40] Every oral health professional has a major role in identifying and diagnosing leukoplakia. Due to its unpredictable nature and the fact that even specialists find leukoplakia challenging, once it is suspected it is best referred to an oral medicine specialist. Oral medicine specialists will monitor patients closely and in a structured manner. Furthermore, specialists in hospitals have direct access to other clinicians, including head and neck surgeons, in case malignancy occurs and aggressive surgical intervention is required.

In contrast to leukoplakias, where close monitoring for years is a sensible alternative to surgical treatment, in erythroplakias biopsy and then excision constitute the normal recommended approach. Since such a high proportion of erythroplakias show severe dysplasia or carcinoma in situ on biopsy, excision usually follows. Usually, erythroplakias are not extensive, and thus neither will the surgery be.

In general, *clinical management* of leukoplakia relates to a combination of clinical (site, homogeneity, size, behavior) and histologic features (presence and degree of dysplasia and inflammation). While those leukoplakias that are homogeneous, stable, on lower-risk sites such as the buccal mucosa and show no dysplasia, can be reviewed annually (assuming no change in clinical characteristics), those showing clinical characteristics of mixed appearance, on high-risk sites, changing in size, in smokers, and histologically showing a degree of dysplasia will need to be reviewed more regularly. It can be deduced that a reproducible risk score from this combination of features would be very helpful for clinicians. An algorithm for management is shown in Figure 4-25.

If dysplasia is not present, follow up at six-month intervals is recommended. In case of dysplasia, the decision whether to surgically remove the whole lesion or not will depend upon its severity and the size and location of the lesion. Mild dysplasia may regress, and thus watchful waiting is appropriate. However, moderate to severe dysplasia is not likely to regress, but the rate of its progression cannot be estimated. In such cases, the premalignant site irrespective of surgical excision should be reexamined every three months, at least for the first year. If the lesion does not relapse or change in clinical pattern, the follow-up intervals may be extended to once every six months, with the patient advised with regard to self-examination. Oral leukoplakia is a lesion with an increased risk of malignant transformation, which has great implications for the management of this oral mucosal disorder (Figure 4-25). Since alcohol and smoking are well-established risk factors for the development of oral squamous cell carcinomas, measures should be taken to influence patients to modify or discontinue such habits.

Cold-knife surgical excision, as well as laser surgery, is widely used to eradicate leukoplakias and erythroplakias, but

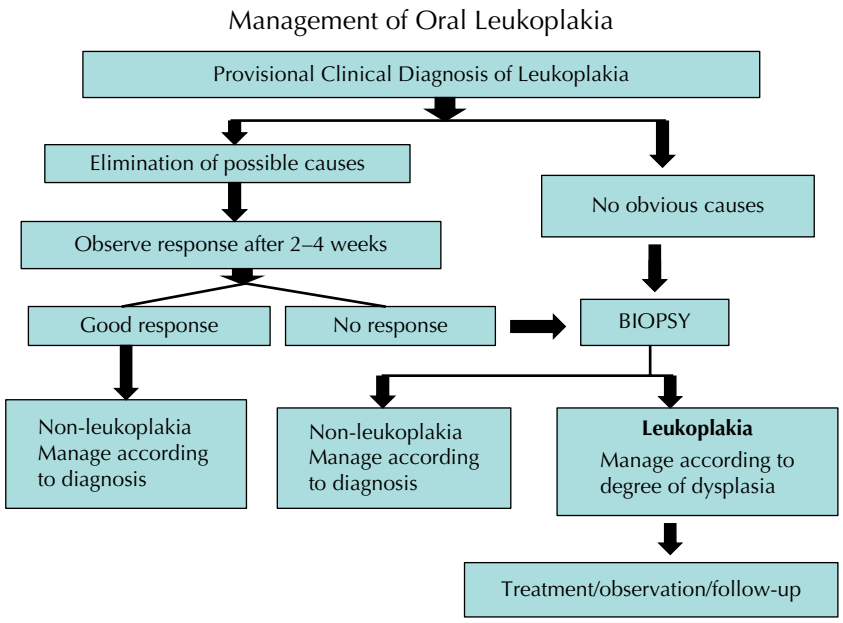

Figure 4-25 An algorithm for the management of oral leukoplakias.

will not prevent all premalignant lesions from malignant development. On the contrary, surgery has been strongly questioned, as squamous cell carcinomas are almost equally prevalent in patients subjected and not subjected to surgery.[41] This may be explained by genetic defects even in clinically normal mucosa surrounding the removed lesion and is supported by a concept referred to as field cancerization.[42] Field cancerization is caused by simultaneous genetic instabilities in the epithelium of several extralesional sites that may lead to squamous cell carcinomas. However, in the absence of evidence-based treatment strategies for oral leukoplakias, surgery will remain the treatment of choice for oral leukoplakias and erythroplakias where intervention is indicated. Such a treatment regimen is supported by the fact that serial sections of the total lesion after surgical removal have shown that as many as 7% of the lesions contained frank squamous cell carcinomas, which had not been revealed by an incisional biopsy.[37]

Malignant transformation of oral leukoplakias has been reported to be up to 20% over 30 years, depending on site and habits. According to available epidemiologic data, studies report an incidence that varies from less than 1% up to higher than 2% per year.[43] One study reported the incidence of malignant transformation of 2.6% per year among 144 cases. From that cohort, a total of 11% of cases transformed within the observation period of between two and seven years.[38] A recent meta-analysis of 23,498 pooled cases showed a mean malignant transformation rate of included studies of 9.7% over 2–10 years, with a slight preponderance in females, in patients followed up for a longer time, in older patients, and in lesions localized on the tongue and floor of the mouth.[44]

Over half of oral carcinomas have been reported to be associated with leukoplakias at the time of diagnosis, while in some countries such as India 80% of oral cancers were reported to be preceded by oral precancerous disorders. Until biomarkers are developed, management of oral leukoplakias and erythroplakias has to rely on traditional clinical and histopathologic criteria. Homogeneous oral leukoplakias are associated with a lower risk for malignant transformation than nonhomogeneous leukoplakias and erythroplakias, and lesions not exceeding 200 mm^2 appear to have a better prognosis than larger lesions

Oral Submucous Fibrosis

Oral submucous fibrosis (OSMF) is a chronic disease affecting the oral mucosa, as well as the pharynx and the upper two-thirds of the esophagus. There is substantial evidence that lends support to a critical role of areca nuts in the etiology behind OSMF.

Etiology and Pathogenesis

There is dose dependence between an areca quid chewing habit and the development of this oral mucosal disorder. Areca nuts contain alkaloids, of which arecoline seems to be a primary etiologic factor.[45] Arecoline has the capacity to modulate matrix metalloproteinases, lysyl oxidases, and collagenases, all affecting the metabolism of collagen, which leads to increased fibrosis.[46] During the development of fibrosis, a decrease in water-retaining proteoglycans will occur in favor of increased collagen type I production.[47] There is also evidence of a genetic predisposition of importance for the etiology behind OSMF. Polymorphism of the gene, which is coding for tumor necrosis factor α (TNF-α), has been reported to promote the development of the disorder. Fibroblasts are stimulated by TNF-α,

thereby participating in the development of fibrosis. Aberrations of other cytokines of importance are transforming growth factor β and interferon-γ, which may lead to increased production and decreased degradation of collagen.

Epidemiology

Areca nut–derived products are commonly used by several hundred million individuals in the southern parts of Asia. Regional variations exist regarding the preference for areca nut use, which also accounts for variation in the oral sites affected. Oral complications are most commonly observed on the lips, buccal mucosa, retromolar area, and soft palatal mucosa. The habit of chewing betel quid, containing fresh, dried, or cured areca nut and flavoring ingredients, is widespread in India, Pakistan, Bangladesh, and Sri Lanka and in emigrants from these regions. Tobacco is often used in conjunction with betel quid. The habit is more common among women in some geographic areas, which is also reflected in the sex distribution of oral submucous fibrosis.

The global incidence of OSMF has been estimated at 2.5 million individuals.[48] The prevalence in Indian populations is 5% for women and 2% for men. Individuals less than 20 years old are commonly affected by OSMF, probably reflecting the advertising of areca nut products, which is directed to younger age groups.

Clinical Findings

The first signs of OSMF are erythematous lesions, sometimes in conjunction with petechiae, pigmentations, and vesicles. These initial lesions are followed by a paler mucosa, which may comprise white marbling (Figure 4-26). The most prominent clinical characteristics will appear later in the course of the disease and include fibrotic bands located beneath an atrophic epithelium. Increased fibrosis eventually leads to loss of resilience, which interferes with speech and tongue mobility, and leads to a decreased ability to open the mouth. The atrophic epithelium may cause a smarting sensation and an inability to eat hot and spicy food. More than 25% of patients also exhibit oral leukoplakias.

Figure 4-26 Marble-like appearance of the right buccal mucosa in a patient with submucous fibrosis with restricted ability to open her mouth. Similar changes were present in the left buccal mucosa.

Diagnosis

The diagnosis of OSMF is based on the clinical characteristics and on the patient's report of a habit of betel chewing. An international consensus has been reached where at least one of the following characteristics should be present:

- Palpable fibrous bands.
- Mucosal texture that feels tough and leathery.
- Blanching of mucosa together with histopathologic features consistent with oral submucous fibrosis (atrophic epithelium with loss of rete ridges and juxtaepithelial hyalinization of lamina propria).

Pathology

The early histopathologic characteristics for OSMF are fine fibrils of collagen, edema, hypertrophic fibroblasts, dilated and congested blood vessels, and an infiltration of neutrophilic and eosinophilic granulocytes. This picture is followed by a downregulation of fibroblasts, epithelial atrophy, and loss of rete pegs, and early signs of hyalinization occur in concert with an infiltration of inflammatory cells. Epithelial dysplasia in OSMF tissues appeared to vary from 7% to 25% depending on the study population.[49]

Management

Products derived from areca nuts are carcinogenic, regardless of the concomitant use of tobacco products. Thus, treatment of OSMF should be focused on cessation of the chewing habit. If this is successfully implemented, early lesions have a good prognosis as they may regress. A plethora of treatment strategies have been tried, such as topical and systemic steroids, hyaluronic acid, interferon-γ, supplementation of vitamins and nutrients, repeated dilatation with physical devices, and surgery. None of these treatments has reached general acceptance and the long-term results are dubious.

Malignant transformation of OSMF has been estimated in the range of 0.7% to 1.3% per annum and the incidence over a 10-year period at approximately 8%.[50]

IMMUNOPATHOLOGIC DISEASES

Lichen Planus

This is a family of lesions with different etiologies and a common clinical and histologic appearance. Neither clinical nor histopathologic features enable reliable discrimination

between them, but may be used to distinguish any of them from other pathologic conditions of the oral mucosa. This group of reactions includes the following disorders:

- Oral lichen planus.
- Oral lichenoid contact reactions.
- Oral lichenoid drug eruptions.
- Oral lichenoid reactions of graft-versus-host disease.

OLCRs are included in the later section where allergic reactions are discussed, since these lesions represent a delayed hypersensitivity reaction to constituents derived from dental materials or flavoring agents in foods and other ingested substances.

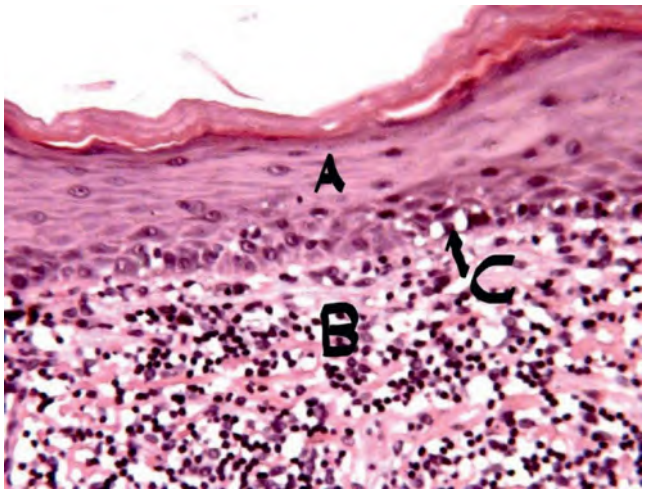

Figure 4-27 Lichenoid reaction with a subepithelial infiltrate of inflammatory cells and apoptosis of epithelial cells in the basal cell layer. (A) Epithelium, (B) subepithelial infiltrate, and (C) apoptopic epithelial cells.

Oral Lichen Planus

OLP is a chronic inflammatory cell-mediated immune disease of unknown etiology. Skin and mucous membranes are most commonly involved. In addition to oral mucosa, other mucous membranes (e.g., genitals in women, esophagus, rectal area) as well as scalp and nails can be affected. Several sites may be involved, consecutively or simultaneously. Typically, OLP is bilateral (symmetric) and can appear both white and red, depending on disease activity. It is striking because of its versatile presentation between individual patients. Some have long periods of remission, while others have frequent exacerbations and are not very responsive to treatment.

Etiology and Pathogenesis

The precise etiology of OLP is not known, but something is known about its pathogenesis.[51] The immune system has a primary role in the development of this disease and it is now considered to be an autoimmune cell-mediated disease targeted against epithelial cells, mainly in the basal layer. This is supported by the histopathologic characteristics of a subepithelial band–formed infiltrate dominated by T lymphocytes and macrophages and apoptosis of basal cells (Figure 4-27). There is no evidence that antibodies play a role.

A diagrammatic representation of the disease mechanism in lichen planus is shown in Figure 4-28. Cytotoxic $CD8^+$ T lymphocytes are responsible for apoptosis of the keratinocytes in the basal cell layer. These lymphocytes are a major component of the subepithelial inflammatory infiltrate in the mucosal lamina propria. The tissue destruction originates from the lymphocytic infiltrate and production of cytokines, characteristic of T-helper type 1 immune cellular response (IL-12, TNFα, interferons). They activate keratinocytes for increased expression of ICAM1 and the class II major histocompatibility complex (MHC) antigens. Other cells participating are CD4 cells, dendritic cells, natural killer (NK) cells, and mast cells. B cells and antibodies are not contributory. Activation of the autoreactive T lymphocyte is a process that may arise in other parts of the body than the oral mucosa and may not even occur in concert with the onset of the mucosal lesion. Autoantibodies do not appear to be involved in the pathogenic process.

The antigen that would trigger the onset of OLP is still unknown. Most likely, it is not one single peptide that has the potential to evoke the inflammatory response but several, depending on the specificity of the autoreactive T lymphocytes (Figure 4-28). It has not been possible to identify a single etiologic factor behind OLP, especially to explain the bilateral and symmetric nature of the clinical presentation. Other factors, such as stress, may also be of importance in establishing this inflammatory process. It is not unusual for patients to report that they have been exposed to negative social events months before the onset of the disease. Altogether, this makes the etiology behind OLP a multifactorial process comprising events that may take place at different time points and therefore difficult to investigate.

The exact influence of possibly associated etiologic factors remains controversial. Studies have found associations with hepatitis C virus (HCV), but this appears to relate to a small proportion of cases of OLP, possibly geographically based; OLP prevalence is also enhanced in those with thyroid diseases. However, at present the stimulus for cellular recognition of host antigens is unknown, so OLP remains in the idiopathic category.

Epidemiology

In the literature, a wide range of prevalence figures for OLP has been reported, but prevalence appears to be between

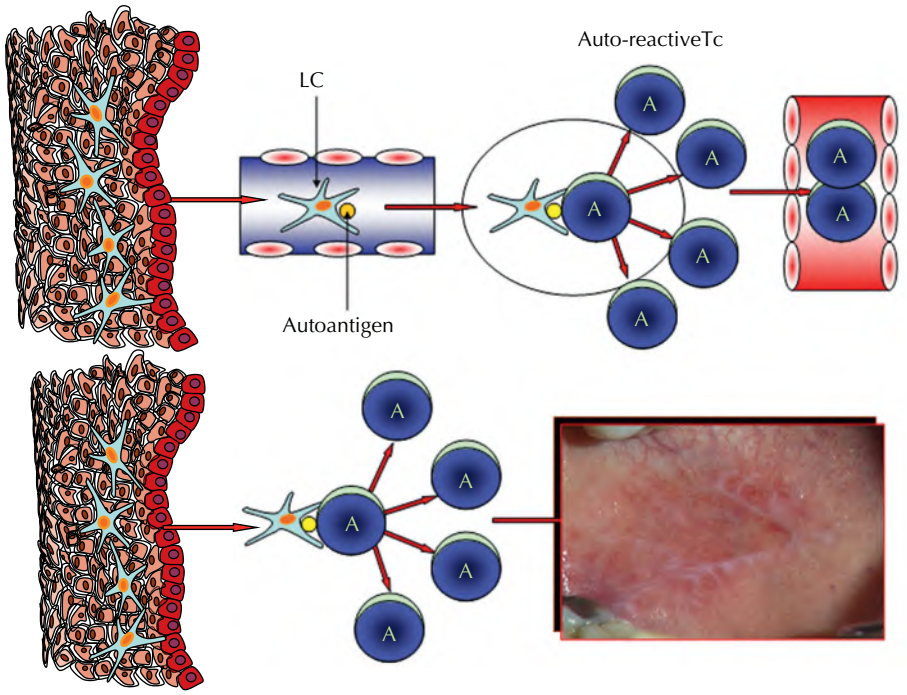

Figure 4-28 Diagrammatic representation of possible pathogenic mechanisms in oral lichen planus, a cell-mediated autoimmune disease where cytotoxic $CD8^+$ T lymphocytes are responsible for apoptosis of the keratinocytes in the basal cell layer. Autologous antigen peptides from basal cells or elsewhere are presented by Langerhans cells (Lc) to autoreactive T cells (Tc), which clonally expand and induce apoptosis in the basal cell layer and lead to the clinical lesions of oral lichen planus.

0.5% and 2% in different populations.[52] Oral lesions occur in around 50–60% of patients with cutaneous lichen planus. Conversely, cutaneous lesions occur in 10–15% of persons with OLP. The proportion of women is higher than that of men, with a ratio of 3:2. The condition usually occurs in people older than 40 years, the mean age of onset being 53 years. It is very rarely encountered in children, and does not seem to have a hereditary predisposition.

Clinical Findings

OLP may contain both red and white elements and these, together with the different textures, provide the basis for the clinical classification of this disorder. Oral lesions are typically multifocal, bilaterally distributed, most commonly symmetrically on the buccal mucosa, on lateral sites of the tongue, and on gingiva. However, they may appear anywhere in the mouth, including the lip vermilion. Palatal lesions are less common. The white and red components of the lesion can be a part of several clinical phenotypes:

- Reticular (and papular as its close clinical variant).
- Erythematous (also referred to as atrophic).
- Ulcerative (also referred to as erosive).
- Plaque-like.
- Bullous—very uncommon and usually associated with one of the other phenotypes.

The explanation of the different clinical manifestations of OLP is presumably related to the magnitude of the subepithelial inflammation. A mild degree of inflammation may provoke the epithelium to produce hyperkeratosis, whereas more intense inflammation will lead to partial or complete deterioration of the epithelium, histopathologically perceived as atrophy, erosion (thinning), or ulceration. This corroborates the fact that most erythematous and ulcerative lesions are surrounded by white reticular or papular structures. An inflammatory gradient may be formed where the central part comprises an intense inflammatory process, whereas the periphery is less affected and the epithelial cells are able to respond with hyperkeratosis.

Of the listed phenotypes, OLP most commonly presents in three of them: reticular/papular, erythematous/atrophic, or ulcerative/erosive forms.[53–56]

In the *reticular* form, hyperkeratotic white striations ("Wickham's striae"), which are a hallmark of the condition, form an interlacing or net-like (Latin "rete"; hence the name) pattern of linear white areas (Figure 4-29). This type is frequently present without symptoms. The reticular pattern tends to diminish with the duration of the condition.

The *papular* type of OLP is usually present in the initial phase of the disease (Figure 4-30). Small and densely distributed hyperkeratotic papules are present. These papules may coalesce and form a more reticular type, which is a variant of

Figure 4-29 Reticular form of oral lichen planus at the right buccal mucosa with an almost identical clinical appearance in the left buccal mucosa.

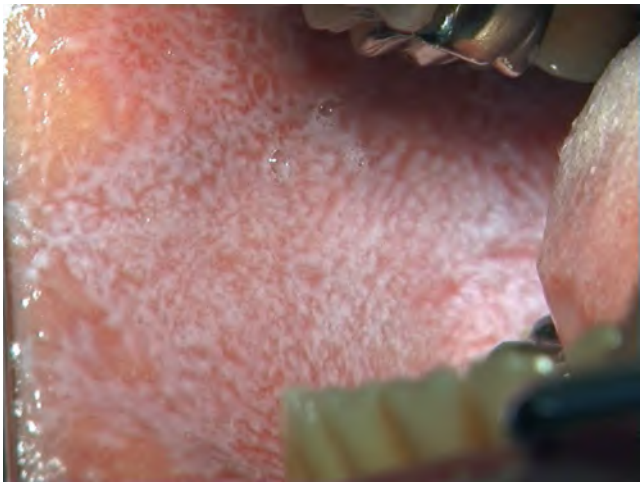

Figure 4-30 Papular oral lichen planus with dense cover of papules at the right buccal mucosa. The lesion has started to form a more reticular pattern on the anterior aspect. Bilateral presentation.

the other, since papular elements merge into striae as part of the natural course of OLP.

In *erythematous* (or *atrophic*) OLP, frank red lesions of atrophic mucosa appear as a result of hyperemia, reflecting clinical inflammation as well as some thinning of the epithelium. These usually affect the buccal mucosa, but may also be present on lateral parts of tongue and any other oral site. Although thinned and atrophic, the epithelium is not completely disrupted. Erythematous patches may be concomitant with hyperkeratotic lesions. However, erythematous lesions frequently occur with only discrete and gentle features typical of OLP, which may be unnoticed by the less experienced clinician, making clinical diagnosis more difficult.

When this type of OLP is present in the buccal mucosa or palate, striae are frequently seen in the periphery of the lesion. Some patients may display erythematous OLP exclusively affecting the attached gingiva (Figure 4-31). This form of lesion may occur without any papules or striae and presents as desquamative gingivitis (in more detail later). Therefore, erythematous OLP may require a histopathologic examination in order to arrive at a correct diagnosis and to distinguish it from mucous membrane pemphigoid.

The *ulcerative form* is characterized by grayish/yellowish fibrin pseudomembranes overlying breaches of the mucosa (ulceration). It is assumed that damage or loss of basal epithelial cells leads to loss of integrity of the epithelium above, which manifests as single or multiple lesions that are ulcers (ulcerative lichen planus) and often incorrectly described as erosions (erosive lichen planus). Ulcerative lesions are the most disabling form of OLP (Figures 4-32 and 4-33). Clinically, the fibrin-coated ulcers are surrounded by an erythematous zone with white striae in the periphery. This appearance may reflect a gradient of the intensity of subepithelial inflammation that is most prominent at the center of the lesion. The affected patient complains of chronic sensitivity, increased in conjunction with food intake. In the absence of treatment, clinical phenotypes appear to be relatively stable, but in time, inflammatory activity wanes and keratosis may become more prominent.

In addition to the three main clinical OLP presentations, there is *a plaque-like* form, which often represents a clinical challenge, as it is not easy to differentiate from homogeneous leukoplakia. In those lesions, solid hyperkeratotic patches are present instead of net-like striations and are usually bilateral. Plaque type OLP shows a homogeneous, well-demarcated white plaque that occurs in conjunction with striae (Figure 4-34).

One typical presentation of OLP is on the dorsal tongue, in the form of bilateral hemilunar whitish plaque areas, substituting for lost filiform papillae (Figure 4-35). These hemilunar areas can meet or involve much of the dorsum of the tongue. This large depapillated area may form perpendicular fissures, giving it a pattern resembling tiles (Figure 4-36). This typical presentation helps diagnose OLP if only the dorsal tongue is involved.

To distinguish plaque type lesions from homogeneous oral leukoplakias, it is often possible to identify reticular or papular structures besides plaque-like lesions in OLP (at least histologically), as well as the fact that they are usually bilateral. Some scientific reports lend support to the premise that a proportion of leukoplakias are derived from "burnt-out" lichen planus, supporting the view that OLP has an increased malignant transformation rate. Plaque type OLP is more often encountered in smokers, presumably reflecting the increased smoke-induced keratosis, and following cessation the plaque may disappear and convert into the reticular type of OLP.

Figure 4-36 Tongue lichen planus showing bilateral depapillation with mild fissures, giving rise to a clinical picture resembling tiles.

The *bullous* form of OLP is very unusual. While sporadic case reports describe rare cutaneous lesions of bullous OLP, it is possible that this form does not exist at all as a separate phenotypic entity, but rather that occasionally bullae may be seen in the ulcerative or erythematous forms. Several contributory conditions may be misinterpreted as bullous OLP, including a clinically thick fibrin pseudomembrane of ulcerative OLP that resembles a wheal as it sticks out above the mucosal level, the small superficial mucoceles that frequently occur in mucosa affected by OLP, and a very rare condition called lichen planus pemphigoides,

Desquamative Gingivitis as a Manifestation of Oral Lichen Planus

OLP may appear as diffusely erythematous fragile gingiva that easily erodes. Gingival erythema with epithelial atrophy yields painful areas. It also may contain whitish, hazy, or lichenoid

Figure 4-37 Classic desquamative gingivitis of lichen planus, with apparent absence of any striae.

lace-like epithelial film, but the presentation is usually just red. Frequently, gingival lesions are present in addition to other oral mucosal sites, but they also can be restricted to the gingivae alone in up to 10% of cases, meaning that no other more typical features of OLP are present (Figure 4-37). In those patients, a solid amount of caution and even clinical experience is required not to miss the diagnosis.

For these lesions, we use the term *desquamative gingivitis*. This is a clinical descriptive term for a non-biofilm-related, immune-mediated inflammatory condition affecting marginal, attached, and free gingivae. It is more prominent on the vestibular surface. Desquamative gingivitis is not a specific diagnosis. It most frequently represents OLP (typically indicating multimucosal disease, see later), but differentially it may be a consequence of several blistering diseases, most important among them a mucous membrane pemphigoid (MMP). Less probably, it may occur as a consequence of pemphigus vulgaris (PV), other subepithelial autoimmune blistering conditions (e.g., linear immunoglobulin A [IgA] disease), and hypersensitivity reactions (plasma-cell gingivitis).

Most commonly, it is mistaken for biofilm-related simple gingivitis. Misdiagnosis as such may lead to inadequate and too aggressive mechanical periodontal treatment, resulting in inadvertent exacerbation.

Extraoral Clinical Manifestations of Oral Lichen Planus

Patients with OLP may develop or already have lesions in extraoral locations. One or more sites can be involved, either sequentially or concomitantly, without a specific order or pattern. Cutaneous lesions may be encountered in approximately 15% of patients with OLP. The classic appearance of skin lesions consists of pruritic erythematous to violaceous papules that are flat topped. The predilection sites are the trunk and flexor surfaces of arms and legs (Figure 4-38). The papules may be discrete or coalesce to form plaques. Patients report

Figure 4-38 Cutaneous lichen planus on the flexor side of the forearm of a 45-year-old male.

relief following intense scratching of the lesions, but trauma may aggravate the disease, which is referred to as a Koebner phenomenon.

This phenomenon may also be of relevance for OLP, which is continuously exposed to physical trauma during mastication, toothbrushing, and denture wearing. Unlike OLP, cutaneous lichen planus is of short duration and, according to dermatologists, even untreated achieves full remission within a year or two, as opposed to OLP, which is long-lasting, frequently throughout life. It is very peculiar that the same disease acts so differently depending on the epithelial site it affects. If desquamative gingivitis is present in OLP, clinicians should be alert to ascertain if the patient has disease elsewhere.

Vulvovaginal-Gingival Syndrome

The most frequent extraoral mucosal site involved is the genital mucosa. Close to 25% of women presenting with OLP also have genital involvement, though not always symptomatic, and frequently misdiagnosed. Within this cohort is a distinct group of patients with a specific presentation of gingival, vulval, and vaginal lichen planus with genital and oral (usually buccal mucosa) scarring and loss of sulcular depth, known as vulvovaginal-gingival (VVG) syndrome.[57] The rare equivalent in men is peno-gingival syndrome. Symptoms in female patients include burning, pain, vaginal discharge, and dyspareunia, which are frequently noted, especially with the erythematous or ulcerative forms of the disease. No relationship seems to exist between the degree of severity in oral and genital sites.

Genital lichen planus has been reported in men, but the association with OLP is not as frequent as for women. In addition to standard treatment of oral lesions, erosions or desquamation of vulval and vaginal mucosae require timely therapeutic measures for preservation of vulval architecture in order to minimize vaginal stenosis. Cases of women with undiagnosed lichen planus undergoing inappropriate vulvovaginal surgery are not uncommon. OLP is an immune-mediated inflammatory condition, and any surgical approach should not be entertained until attempts to control the disease medically have been exhausted.

In up to 5% of OLP patients three or more sites are involved. In addition to the genital region, potential locations include skin, conjunctival mucosa, ears, scalp (causing alopecia), nails, and esophagus (causing dysphagia). All these associations will be revealed by a good medical history.

Diagnosis

Although OLP is a common disease, its diagnosis can be challenging due to overlapping clinical as well as histopathologic features with other oral conditions. Papules or reticular components have to be present in order to establish a correct clinical diagnosis. These pathognomonic components may exist together with plaque-like, erythematous, or ulcerative lesions. In patients with gingival erythematous lesions, it may be difficult to find striae or papules. A biopsy is usually required for an accurate diagnosis of this type of OLP and indeed for all cases of OLP, except those that have a low disease severity score, both to confirm the diagnosis and to exclude any early dysplasia. It is important that the biopsy is taken as far as possible from the gingival pocket to avoid inflammatory changes due to periodontal disease.

Conditions that need to be considered in a differential diagnosis for OLP include oral lichenoid lesions (see later). There are reactions to dental restorative materials, mainly amalgam, called oral lichenoid contact reactions (OLCR), which are frequently encountered; and drug reactions to medications, called oral lichenoid drug eruptions (OLDE), which are very rare although strongly represented in textbooks and literature. They both are likely to represent type IV immune delayed hypersensitivity reactions.

OLP can often be clinically separated from OLCRs to dental materials, which are most often detected on the buccal mucosa and the lateral borders of the tongue. OLP, on the other hand, usually displays a more general involvement. OLP is universally bilateral and frequently symmetrically distributed on oral mucosa, while OLCR is in close topographic contact with dental material and usually unilaterally present.

OLDEs have been reported to have similar histopathologic characteristics as OLP. The patient's disease history may give some indication as to which drug is involved, but OLP may not start when the drug is first introduced. Withdrawal of the drug and rechallenge are the most reliable ways to diagnose OLDEs, but may not be possible to carry out. OLP should also be distinguished from oral chronic graft-versus-host disease (GVHD) and discoid and systemic lupus erythematosus (DLE and SLE, respectively), and the medical history normally will guide the diagnosis.

Oral GVHD has the same clinical appearance as OLP, but the lesion is usually more generalized. The lichenoid reactions are frequently seen simultaneously with other characteristics, such as xerostomia and the presence of localized skin involvement and liver dysfunction, even if an oral lichenoid reaction may emerge as the only clinical sign of GVHD (see later).

DLE shows white radiating striae, sometimes resembling those of OLP but with a brush border of short striae. The striae present in DLE are typically more prominent, with a more marked hyperkeratinization, and may abruptly terminate against a sharp demarcation (Figure 4-39). Histopathologic criteria for lupus erythematosus (LE) have been reported to discriminate against OLP with a sensitivity of 92% and a specificity of 96% (see "Diagnosis" in the "Lupus Erythematosus" section). Direct immunofluorescence for IgM on biopsies of the clinically normal oral mucosa (lupus band test) may also be used, although it is only positive in about 45% of SLE cases.

Several other conditions need to be included in differential diagnosis of OLP. Erythematous OLP of the gingiva exhibits a similar clinical presentation to MMP. Thus, in cases of desquamative gingivitis, MMP should also be suspected. In pemphigoid lesions, the epithelium is easily detached from the connective tissue by a probe or a gentle searing force (Nikolsky's phenomenon). A biopsy for routine histology and direct immunofluorescence are required for an accurate differential diagnosis. Plaque-form OLP can be clinically similar to homogeneous oral leukoplakia, especially from the early stage of PVL (see earlier).

As was discussed in Chapter 3, "Ulcerative, Vesicular, and Bullous Lesions," in more severe ulcerative OLP cases, differential diagnosis should also include MMP and chronic ulcerative stomatitis (a rare condition in which stratified epithelium-specific antinuclear antibodies develop). PV and erythema multiforme may be included in a broader list of differential diagnoses of erosive OLP, but more precise assessment of their clinical features and the acute nature of erythema multiforme will allow even clinical distinction in most cases. Furthermore, the former lesions do not typically appear with reticular or papular elements in the periphery of the ulcerations.

Figure 4-39 Unilateral lesion of discoid lupus erythematosus of the left buccal mucosa showing the typical brush border.

Immunofluorescence is useful in distinguishing lichen planus from the extremely rare chronic ulcerative stomatitis, as well as from vesiculo-bullous immune-mediated diseases. Histopathologic and immunofluorescence investigations combined with finer assessment of clinical presentation provide the most precise diagnosis (see Chapter 5).

Investigations

Routine Investigations

The presence of bilateral white and red areas of mucosa, often with the typical clinical presentation of some reticular and/or ulcerative component, is diagnostic for OLP. However, frequently and in less typical cases, biopsy is needed for histopathologic confirmation. Biopsy is also advised if red lesions persist despite treatment.

The most prominent and important histopathology feature is "interface mucositis" around the basement membrane, characterized by a dense "band-like," predominantly T-lymphocytic subepithelial infiltrate in the lamina propria (upper corium; see Figure 4-27).[58] T lymphocytes from the lamina propria penetrate epithelium and cause apoptosis of epithelial basal cells, which is sometimes described as vacuolar (hydropic) degeneration and lysis of basal cells, seen under a microscope as scattered cytoid (hyaline, colloid) Civatte bodies along the epithelial interface. Eosinophils and fibrin may be seen just beneath the basement epithelial layer covering the lamina propria. The basal epithelium may display "sawtooth" rete pegs, but this feature, although typical for cutaneous lichen planus, is not so frequently present in OLP.

The epithelium shows hyperorthokeratosis and hyperparakeratosis (stratum corneum), often with a thickening of the granular cell layer and acanthosis (thickening of stratum spinosum). In addition, melanin "incontinence" and melanophages also may be seen, especially in postinflammatory hyperpigmentation, but are not specific to OLP.

Depending on the nature of the clinical lesion and the site selected for biopsy, atrophy and ulceration may be seen. However, biopsy samples should be taken from the nonulcerated adjacent full-thickness epithelium, including basement membrane and subepithelial connective tissue, so that pathologic changes around the basement membrane can be identified, which may be lacking if the biopsy is taken from ulcerated areas.

There is very high but not always absolute clinico-pathologic agreement in OLP. Histopathology findings can (1) be confirmatory for clinical diagnosis; (2) be compatible with diagnosis (fitting in its spectrum); or (3) be considered not to have histologic features of OLP. Since pathologic diagnoses should not be made in a vacuum, clinicians must provide the pathologist with all clinical details available including the behavior, site, and size of the lesion, as well as a provisional and differential diagnosis. In the case of a mismatch, the clinical diagnosis prevails, but the case should be more closely monitored and reviewed in the future.

Some pathologists, less experienced in oral and mucosal pathology, may describe the inflammatory changes in OLP as cellular atypia, especially if the sectioning has not been performed perpendicular to the mucosal surface, but the changes only mimic it. Conversely, real cellular atypia in dysplastic and even malignant lesions is sometimes described as "lichenoid." "Interface mucositis" is also seen in oral LE and other lichenoid lesions, complicating histologic interpretation.

Histopathologic examination alone is of modest diagnostic value in the differentiation between OLP and the other four types of oral lichenoid lesions—that is OLCRs, OLDEs, oral lichenoid reactions of GVHD, and oral DLE or SLE—since all five lesions display similar histopathologic features. The diagnosis is dependent on the combination of clinical and histologic features. However, histopathology is a valuable tool when lichenoid reactions are to be discriminated from other mucosal lesions. Explicit guidelines on the necessity of a biopsy to arrive at an accurate diagnosis of OLP have not been universally approved, but most clinicians would accept the need for biopsies when the disease severity is moderate or severe or when the diagnosis is uncertain.

Special Investigations

Direct immunofluorescence (DIF), otherwise essential for vesiculobullous diseases (see Chapter 3), is rarely performed in OLP, as it is nonspecific. However, DIF helps us in differentiating OLP from MMP or PV in cases of desquamative gingivitis, or it can help differentiate OLP from lupus. In OLP, DIF can be positive in about two-thirds of cases. DIF shows accumulation of shaggy fibrinogen along the basement membrane zone (BMZ) and in approximately one-third of cases it reveals granular deposits of IgM, IgA, complement c4, and fibrinogen, corresponding to apoptotic Civatte corpuscles (a consequence of apoptosis and degeneration of epithelial cells due to an autoimmune T lymphocyte reaction). Shaggy deposition of fibrinogen along the BMZ is not restricted to OLP, and can also be seen in other premalignant and malignant oral lesions.

Epicutaneous patch testing can be useful for identifying causative allergens if OLCR is suspected, which can then be avoided. Standard series of allergens (e.g., the European series) ensure consistency of preparations, but training is needed for application, reading, and interpretation of positive results. Skin tests represent delayed (contact) hypersensitivity and are most frequently conducted in dermatology departments. Positive skin tests can be helpful, but lesions may resolve after replacement of dental materials even if the test is negative.

Hematological investigations are sometimes performed in OLP not to make a diagnosis, but to screen for possibly associated systemic diseases, especially hematologic. Since OLP is considered an idiopathic condition, there are no specific hematologic tests to confirm the diagnosis, but deficiency of iron and other hematinics may contribute to exacerbation of symptoms. There are reports of potentially relevant associations between OLP thyroid disease and also hepatitis B or C virus infection. Therefore, liver function tests—aspartate transaminase (AST), alanine transaminase (ALT), and gamma-glutamyl-transpeptidase (GGT)—and thyroid hormones are sometimes performed in OLP patients. However, repeated hematologic investigations are rarely justified.

Photographic records of lesions can be very helpful to assist in the determination of any response to therapy and can become part of the evidence of clinical outcomes (see later).

Management

Current therapies are directed largely against (1) the presumed immune mechanisms using immunosuppressives; (2) the cellular inflammatory response using anti-inflammatories; and (3) reducing or eliminating symptoms.[59]

Careful oral hygiene to reduce biofilm-associated supplementary inflammation is extremely important in OLP patients with symptoms.[60] Therefore, training patients in gentle, careful oral hygiene procedures is recommended. Physical trauma to the gingival tissue should be reduced to avoid pain and exacerbation of gingival lesions.

Preventive therapies are lacking, and no sound strategy at present exists for their development. Pain as a symptom in OLP has a major role in deciding whether to treat or to observe. Typically, the reticular, papular, and plaque-like forms of OLP are asymptomatic, although the patient may experience a feeling of roughness when touched by the tongue or increased sensitivity to spicy or hot foods. However, pain is a very relevant symptom in the ulcerative (erosive) and erythematous (atrophic) forms of OLP. At the mild end of the spectrum, pain appears as burning in contact with irritating agents, acidic, coarse and hot foods and beverages, alcohol, and so on, but intense and persistent pain can be found in the ulcerative forms, directly related to the degree of ulceration. Pain is thus a relevant element in quantification of the intensity of the condition.

The decision about whether to prescribe local or systemic therapy depends on the disease severity, the extent of pain, and the individual patient's needs and ability to cope.

Oral Disease Severity Scoring

Disease severity scoring systems are tools that can help clinicians assess both the severity of objective clinical findings as well as the subjective features of a disease, including its impact on patients' lives. There are three essential aspects that are important in defining the intensity of a disease: (1) a clinical score measuring the level of inflammation, area, and specific clinical features (e.g., ulceration); (2) subjective reporting of pain that the disease is inflicting; and (3) a questionnaire relating to how the condition affects patients' functioning and their lives, or oral health-related quality of life (OHRQoL). There are now several validated and universally used tools for oral diseases that should be used at every patient visit.

It is a sad truism and a reflection on the field that few oral medicine treatments are evidence based, even those regarded as standard therapies. Until the last few years, there had been a lack of any method to routinely assess disease severity and thus of quantifying responses to therapies. This led to the obvious need to devise and validate oral disease severity scores for a variety of conditions seen in routine clinical practice that could also be used for assessing treatment responses.

The benefits of a scoring system for mucosal disease severity are that (1) they can indicate the severity of disease; (2) they are needed to indicate the efficacy of any treatments; (3) they may distinguish between or reveal subgroups of activity; (4) they may assist in deciding to implement or withhold treatment; and (5) they are a routine clinical audit tool that can also be used for research. Any such oral disease scoring system must be objective, reproducible, easy to use, and widely applicable. Fortunately, such scoring systems have been created and validated and are in use for recurrent aphthous ulceration, OLP, pemphigus, MMP, orofacial granulomatosis, and dry mouth assessment.

Oral Disease Severity Score for Oral Lichen Planus

The Oral Disease Severity Score (ODSS) is a comprehensive oral scoring system previously validated for OLP (Figure 4-40).[61,62] In the ODSS, the oral cavity is divided into 17 sites. These sites include outer and inner lips, buccal mucosae, soft and hard palates, oropharynx, floor of the mouth, and the gingivae in sextants. Each site receives a *site score* of 1 if disease is present, with larger sites such as the buccal mucosa, tongue, and palate being doubled if greater than 50% of the area is involved or if lesions are bilateral. An *activity score* between 0 and 3 is assigned to describe the severity of disease at each site, for example no activity = 0 (keratosis only), mild inflammation (erythema or healing areas) = 1, marked erythema = 2, and ulceration = 3. If the site score is 2 (i.e., affecting >50%), the activity score is doubled. A *pain score* (subjective score provided by the patient between 0 and 10) is then added to provide the *total score*. The theoretical maximum total score is 106; however, more than 95% of patients have scores between 0 and 60, representing a clinical range from remission to severe disease. The ODSS takes an average of 90 seconds to complete.

OLP is not only the most common oral mucosa disease affecting approximately 1–2% of the adult population at any one time, but can also present in a wide variety of clinical appearances. The ODSS or any scoring system needs to be able to embrace this wide variety of appearances. The 17 individual sites are examined and assessed for the presence of disease, the disease severity at each site, along with a subjective pain score, and these three scores give an overall ODSS for lichen planus (Figure 4-40). Different clinical phenotypes appear to be relatively consistent over many years and clinical photographs form an additional tool for recording outcomes (Figure 4-41).[63]

Pain Score

The most widely used tool for pain is the numeric pain rating scale (NPRS), which lets the patient subjectively relate their current perception of pain on a scale from 0 to 10, if 0 is "No pain" and 10 represents "Worst imaginable pain." Similar, and perhaps more sensitive, is the visual analogue scale (VAS), which is a straight line on a piece of paper, usually 100 mm in length, with only two extremes listed: "No pain" to the left of the line and "Worst imaginable pain" to the right. The patient marks their current pain level on the line with a pen.

Oral Health-Related Quality of Life

OHRQoL is assessed by using validated questionnaires that measure a patient's oral health self-perception of their capability for daily activities.[64] The Oral Health Impact Profile (OHIP-14) is a widely accepted tool in the form of a questionnaire (it is a short version of the original OHIP-49), showing good sensitivity to any improvement of OHRQoL in relation to clinical improvement (e.g., due to treatment). OHIP-14 is the most commonly used instrument for assessing OHRQoL. It should be noted that OHIP is generic for any oral, dental, or denture-related condition that may impair quality of life, and thus it was not intended only for mucosal diseases. An OHRQoL questionnaire specific for oral mucosal diseases would provide more precise and relevant information, as reported by our patients. Therefore, a questionnaire specific for mucosal diseases, the Chronic Oral Mucosal Diseases Questionnaire-15 (COMDQ-15), was recently devised.[65] Patients respond to 15 questions (Figure 4-42) by selecting one of the answers from a 5-point scale (from "not at all" to "extremely"). Scores are then added and may range from 0 to 60.

Both COMDQ-15 and NPRS/VAS are considered valuable tools for quantifying what are called "patient-related outcome measures" (PROMs). It has been observed that the clinical severity of any medical condition and a response to treatment

Site	Site Score	Activity score (0–3), Double if site = 2
L Buccal mucosa <50% = 1, >50% = 2		
R Buccal Mucosa (1 or 2)		
Outer lips (1)		
Inner lips (1)		
Gingivae (1 each segment)		
Lower R (distal)		
Lower central		
Lower L (distal)		
Upper R (distal)		
Upper central		
Upper L (distal)		
Dorsum tongue (1 or 2)		
R lateral tongue (1)		
L lateral tongue (1)		
Floor of mouth (1 or 2)		
Hard palate (1 or 2)		
Soft palate (1 or 2)		
Oropharynx (1 or 2)		

Activity Score

- 0 = keratosis only
- 1 = mild erythema. (e.g., on gingivae, papillae only, or less than 3 mm along margins)
- 2 = marked erythema (e.g., full thickness on gingivae, extensive with atrophy, or edema on nonkeratinised mucosa)
- 3 = ulceration at this site

Site score

- 0 if no lesion at site
- 1 if less than 50% of area affected,
- 2 if greater than 50% of area affected. Not defined anatomically

Pain score

- Analogue scale from 0 (no discomfort) to 10 (unbearable pain).

Figure 4-40 Oral disease scoring for site and activity elements for oral lichen planus. The Oral Disease Severity Score for an individual patient visit is the sum of sites, activity at each site, and a pain score. Site score = 1 for each site affected, 2 for large sites. Activity score = 0–3 at each site. Pain = average pain over last week, from 0 (no discomfort) to 10 (unbearable/the most severe pain imaginable). *Source:* Reproduced with permission from Challacombe SJ, McParland H, Proctor G, et al. How cross-disciplinary research has increased our understanding of oral mucosal diseases. In: Meurman JH (ed.), *Translational Oral Health Research*. Berlin: Springer International; 2018: 1–12.

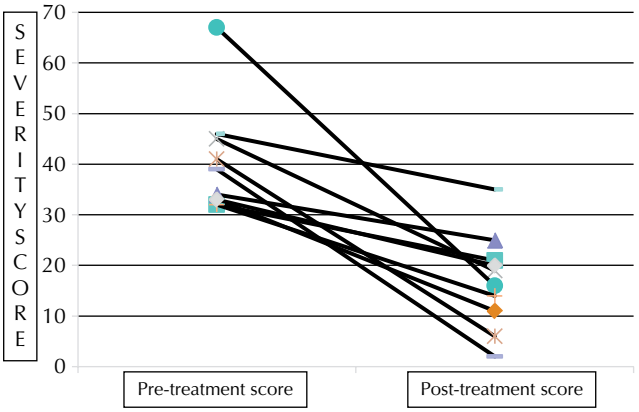

Figure 4-41 Example of an Oral Disease Severity Score (ODSS) of oral lichen planus (OLP) before and after treatment with mycophenolate in 10 vulvovaginal-gingival-OLP patients. Total ODSS for each patient before and after treatment includes disease activity, sites affected, and pain score. *Source:* Reproduced with permission from Wee J, Shirlaw PJ, Challacombe SJ, Setterfield JF. Efficacy of mycophenolate mofetil in severe mucocutaneous lichen planus: a retrospective review of 10 patients. *Br J Dermatol*. 2012;167:36–43.

does not always reflect a patient's subjective feeling. Thus, the addition of complementary PROMs in the assessment of the complexity of diseases is a mandatory part of a responsible clinical approach. Additionally, it is valuable feedback information on our therapeutic approaches.

Treatment

Treatment depends on the severity of the case and on the mucosal area involved. Most cases of OLP are not symptomatic and do not require active treatment. The area affected by hyperkeratosis may increase over time, but as long as there is no pain, only reassurance and regular follow-up are needed. Explanation of the condition along with information leaflets is important for wellbeing and for future compliance with follow-up. Patients need to understand that treatment is not curative, but rather serves to alleviate the inflammation and symptoms when needed, and that it may take even a week before response to therapy is observed. Additionally, patients must comprehend that the condition is chronic and that

Chronic Oral Mucosal Disease Questionnaire-15 (COMDQ-15)

Instructions: Please answer the following questions by ticking one of the following boxes for each.

Physical discomfort	**Not at all**	**Slightly**	**Moderately**	**Considerably**	**Extremely**
How much do certain *types of food/drink* cause you discomfort (spicy food, acidic food)?	0	1	2	3	4
How much do certain *food textures* cause you discomfort (rough food, crusty food)?	0	1	2	3	4
How much does the *temperature of certain foods/drinks* cause you discomfort?	0	1	2	3	4
How much does your oral condition lead to discomfort when *carrying out your daily oral hygiene routine* (brushing, flossing, mouthwash usage)?	0	1	2	3	4
How much do you feel you *need medication* to help you with activities of daily life (talking, eating etc.)?	0	1	2	3	4
Medication and Treatment					
How concerned are you about the possible *side effects of the medications* used to treat your oral condition?	0	1	2	3	4
How much does it frustrate you that there is *no single standard medication* to be used in your oral condition?	0	1	2	3	4
How much does *the use of the medication limit* you in your *every day life* (routine / the way you apply or take your medications)?	0	1	2	3	4
Social and Emotional					
How much does your oral condition get you *down*?	0	1	2	3	4
How much does your oral condition cause you *anxiety*?	0	1	2	3	4
How much does the *unpredictability* of your oral condition bother you?	0	1	2	3	4
How much does your oral condition make you *pessimistic about the future*?	0	1	2	3	4
How much does your oral condition *disrupt social activities* in your life (social gatherings, eating out parties)?	0	1	2	3	4
Patient Support					
How satisfied are you with the *level of support and understanding* shown to you by *family* regarding this oral condition?	4	3	2	1	0
How satisfied are you with the *level of support and understanding* shown to you by *friends/work colleagues* regarding your oral condition?	4	3	2	1	0

Figure 4-42 Chronic Oral Mucosal Diseases Questionnaire-15. *Source:* Reproduced with permission from Wiriyakijja P, Porter S, Fedele S, et al. Development and validation of a short version of Chronic Oral Mucosal Disease Questionnaire (COMDQ-15). *J Oral Pathol Med.* 2020;49(1):55–62.

long-term treatment or follow-up is sometimes necessary. Patients with symptomatic OLP will usually require active treatment, but if mild then the question of whether to treat or not may depend on whether symptoms are induced only while eating (see Figure 4-42).

Topical Treatment

Several topical drugs have been suggested, including steroids, calcineurin inhibitors (cyclosporine and tacrolimus), retinoids, and ultraviolet phototherapy. Among these, topical steroids (ointment, adhesive paste, gel, spray, or rinse) are widely used and accepted as the primary treatment of choice (Figure 4-43). Although systematic reviews of treatment modalities for OLP have not strongly confirmed several accepted standard therapies, OLP can usually be very successfully treated.[66–68] There is an evidence base for significant reduction in disease severity (reducing and stopping pain) using high- or moderate-potency topical corticosteroids (e.g., clobetasol propionate, fluocinonide, betamethasone, and triamcinolone acetonide).[66]

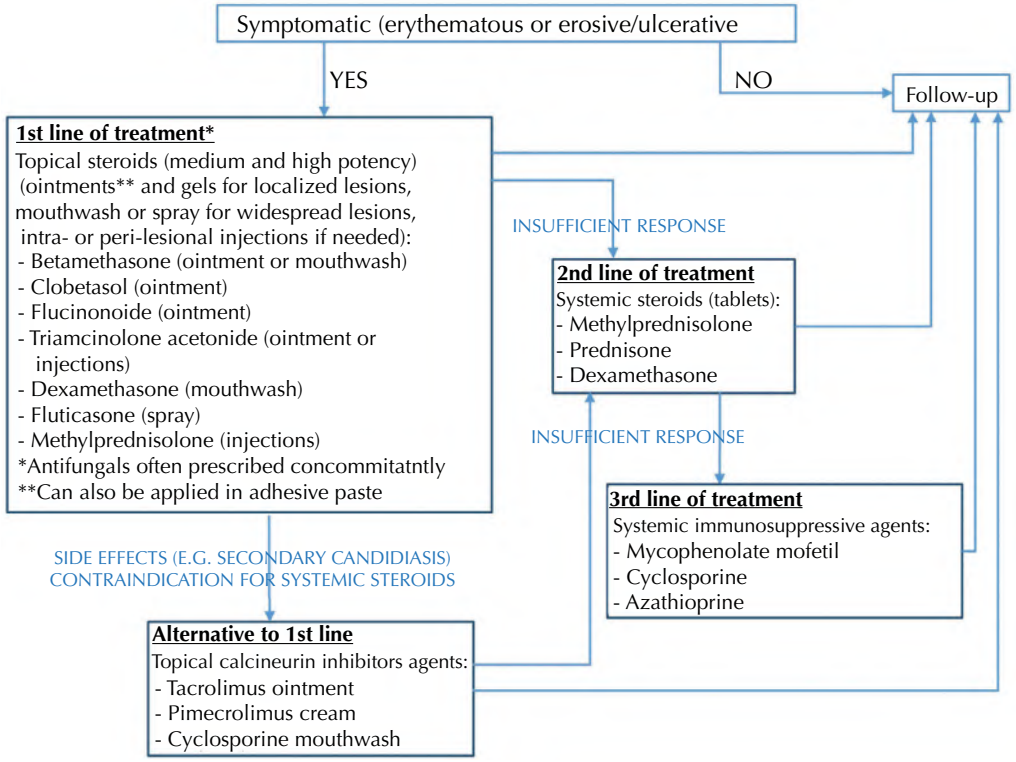

Figure 4-43 Algorithm for the management of oral lichen planus. Treatment is dependent on symptoms, the oral disease severity score, and previous response to therapy.

Although no systematic studies have compared different frequencies of application, a reasonable approach may be to apply the drug two to four times a day for one to two months, followed by tapering during the following eight weeks until a maintenance dose of two to three times a week is reached. For specific lesions, treatment with betamethasone dipropionate 0.5 mg/g ointment or triamcinolone acetonide 1 mg/g in adhesive paste or steroid sprays is appropriate. For more widespread lesions, betamethasone mouthwash is more useful. Adhesive pastes consisting of pectin, gelatin, and carboxymethyl cellulose containing topical steroids (e.g., triamcinolone) have been formulated for use on moist oral mucosal surfaces. Ointments containing steroids can also be effective, but as they are hydrophobic they require drying of the mucosal surface before application.

It should be noted that extended application of topical steroids to mucosa does not appear to result in adrenal suppression. However, since OLP is a chronic condition with alternating episodes of remissions and flare-ups, patients can self-regulate according to symptoms. In more severe rare cases, corticosteroids may need to be regularly applied over several months. In the absence of considerable clinical improvement after four weeks (e.g., marked pain reduction and significant reduction in severity score), higher-potency topical corticosteroid clobetasol propionate 0.5 mg/g ointment can be applied twice a day, and only occasionally three times a day. Gingival OLP lesions appear to be more resistant to treatment, and if there is no response to improved oral hygiene[60] clobetasol is usually the first line of topical therapy. However, no randomized clinical trials exist where different formulas, strengths, and classes of topically applied steroids have been compared. In the case of widespread lesions, dexamethasone 0.5 mg/5 mL rinse can be applied three times a day for three minutes, gradually decreasing the number of applications following the improvement as already described.

Topical application of cyclosporine and tacrolimus has been suggested as a substitute topical therapy in OLP patients who develop candidiasis regardless of antimycotic therapy. Cyclosporine has been reported to be less effective than clobetasol propionate and not significantly better than 1% triamcinolone paste. No adverse effects related to these two drugs have been reported, except for a temporary burning sensation following the use of cyclosporine. Topical tacrolimus 0.1% ointment has been reported to have a better initial therapeutic response than triamcinolone acetonide 0.1% ointment.[69–71] However, there are concerns about extended use of tacrolimus in OLP due to the increased risk of malignancy (squamous cell carcinoma and lymphoma).[72] These agents should therefore be used in limited circumstances,

and patients made aware of such concerns.[73] Current data are reassuring and show acceptable safety for short-term use of tacrolimus or pimecrolimus.[74,75]

In conclusion, topical steroids should be used as the primary therapeutic choice for symptomatic OLP (see the algorithm for OLP treatment in Figure 4-43). Cyclosporine may be considered a second choice, although the efficacy has been questioned. Tacrolimus should only be used by experts when symptomatic OLP lesions are recalcitrant to topical steroids or cause side effects related to the use of steroids. Relapses are common, and the general approach should be to use steroids at the lowest level to keep the patient free of symptoms. This approach necessitates an individual amendment of the steroid therapy to each patient. When potent topical steroids are used, a fungal infection may emerge, and a parallel treatment with antifungal drugs may be necessary when the number of applications exceeds one a day; antifungal treatment itself may result in significant improvement of symptoms and clinical features. Since half of OLP lesions exhibit candidal infection, antifungal treatment may be used concurrently with steroids. More routine assessment of outcome measures using disease severity scoring would enable a more robust evidence base for many of the therapies discussed.

Systemic Therapy

Although topical steroids are usually able to keep OLP patients free of symptoms, systemic steroids are justified to control symptoms from recalcitrant lesions. A dose of 0.5–1 mg/kg prednisolone daily for seven days has been suggested, followed by a reduction of 5 mg each subsequent day. A maintenance dose with topical steroids may be commenced during tapering of systemic steroids.

However, before switching to systemic steroids, the use of peri- or intralesional steroids should be considered. Usually, 0.2–0.5 mL of 40 mg/mL methyl prednisolone or triamcinolone suspension is injected around and under the erosive lesion of OLP. This treatment is usually a sufficient supplement to regain control of OLP with topical steroids, even if performed once, but can be occasionally repeated (weekly or bi-weekly) if required.[76] Mycophenolate mofetil or azathioprine can be used in very severe OLP or in VVG syndrome, as seen in Figure 4-41.

Erythematous (desquamative) OLP of the gingiva constitutes a therapeutic challenge. It is critical to remove both sub- and supragingival plaque and calculus (Figure 4-31). If microbial plaque–induced gingivitis is present, it seems to work in concert with gingival lichen planus and make the latter more resistant to pharmacologic treatment. Thus, oral hygiene should be optimized together with commencement of steroid treatment. Some patients experience a decrease in or even elimination of symptoms with oral hygiene and steroid treatment is no longer necessary. If symptoms persist, steroid gels in prefabricated plastic trays may be used for 30 minutes at each application to increase the concentration of steroids in the gingival tissue.

As part of OLP lesions, ulcerative areas may be found in close contact with dental materials, similar to what is observed in OLCRs. This only accounts for cases in which amalgam restorations are in direct contact with lesions, but not in those where OLP lesions were not in close contact with the restorations. When symptomatic ulcerations of this kind are present as part of the OLP lesion, replacement of the dental material, usually amalgams, may convert a symptomatic to a nonsymptomatic lesion.

Prognosis

Patients have periods of remission and exacerbation. These may correspond to psychologic factors and stress levels, but the topic is not well investigated. There have been few very long-term follow-up studies of OLP, but those that have been done suggest that a proportion of OLP "burn out" and turn into leukoplakia-like lesions without underlying mucosal inflammation.

OLP is considered to be a potentially premalignant disorder with an increased risk of malignant transformation at some site of the oral mucosa, not necessarily associated with a preexisting lesion (Figure 4-44). It is widely accepted that patients with OLP are predisposed to develop oral carcinomas. A recent systematic review pooled 7806 OLP patients from 16 follow-up studies on the risk of malignant transformation in OLP.[77] The mean was 0.4% per year, with a wide variation (0.03% to 1.3%) against age-matched controls of 0.02% per year. Patients thus need to be realistically informed about a small but increased risk of developing oral carcinoma. No clear relationship with the clinical phenotype has emerged, and the site as well as the severity appears to be important.

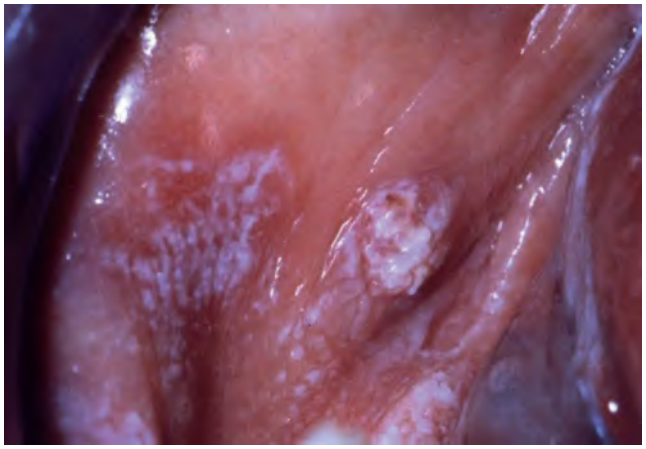

Figure 4-44 An exophytic squamous cell carcinoma developed in reticulo-papular oral lichen planus in the right buccal mucosa. The contralateral side showed only lichen planus.

We cannot clinically or histologically predict the malignant potential of any particular OLP case. Long-lasting inflammation of OLP may lead to secondary cellular atypia, which might be histopathologically interpreted as mild to moderate dysplasia. There is a quest for the discovery of molecular markers that would ideally help identify the premalignant nature of a lesion before the development of the corresponding clinical and pathologic alterations. With such information, we would be able to select patients who would undergo closer follow-up for secondary prevention. Many specific molecular features of OLP are being studied as potential markers for increased risk of malignant transformation. Among them, genetic (p53 mutation), epigenetic (DNA methylation, histone modification, miRNAs), and cytogenetic (loss of heterozygosity) occurrences were postulated and are still being investigated.[78] There is no current reliable risk marker for malignant transformation of OLP. While DNA aneuploidy (i.e., abnormal genetic content in the form of changes in chromosome number and structure) might be a promising predictor for oral lesions in a broader sense, it is rarely observed in OLP tissues and is not a consistent predictor of a lesion's behavior. Nevertheless, when DNA aneuploidy is performed on "high-risk" OLP lesions, around a third with positive findings will develop oral cancer.

Albeit the risk for patients with OLP of contracting oral squamous cell carcinomas is low (0.4% per annum), a minimum of annual monitoring has been suggested in conjunction with routine dental examination by the general dental practitioner. For patients with symptomatic OLP, examination for malignancies will be a part of treatment. In countries with limited healthcare resources, it may be difficult to conduct annual monitoring, but at the time of diagnosis, patients need to be properly educated on the malignant potential of OLP.

Oral Lichenoid Drug Eruptions

Etiology and Pathogenesis

In certain individuals, it has been reported that OLDE develops secondary to the use of medications. The mechanisms behind OLDEs are poorly understood. As the clinical and histopathologic appearances resemble a delayed hypersensitivity reaction, it has been hypothesized that drugs or their metabolites, with the capacity to act as haptens, trigger a lichenoid reaction. Penicillin, gold, NSAIDs, and sulfonamides are examples of drugs that have been related to the development of OLDEs. However, sulfonamides are much more relevant as a factor behind the development of erythema multiforme (see Chapter 5). Penicillin and gold may bind directly to self-proteins, which will be presented by antigen-presenting cells (APCs) and perceived as foreign by specific T lymphocytes, similar to a delayed hypersensitivity reaction. Drugs such as sulfonamides haptenate self-proteins indirectly, through the formation of reactive metabolites, which will covalently bind to proteins present in the oral mucosa.[79] It has been postulated that OLDEs may result from poor drug metabolism because of genetic variation of the major cytochrome P-450 enzymes.

Epidemiology

No prevalence figures are available for OLDEs; most likely, they are unusual and constitute a minority of cases. Some recent publications have questioned their existence, due to an extremely low occurrence and because only case reports are available.[80]

Clinical Findings

Our knowledge about oral OLDEs is limited and primarily based on case reports. It has been suggested that OLDEs are predominantly unilateral and present with an ulcerative reaction pattern. These characteristics are far from consistent and not useful to discriminate between OLP and OLDEs (Figure 4-45A). At present, OLDEs are often clinically indistinguishable from OLP[81] with hyperkeratotic striations and an erythematous base. They are frequently found in the form of a single oral lesion and are often unilateral. However, many oral drug reactions, such as nicorandil and lingual ulceration, do not present with any obvious lichenoid component. The history of any temporal relationship between taking medications and clinical manifestations is of paramount importance diagnostically.

Diagnosis

Although diagnostic testing methods exist, in general they are of limited clinical value. One major problem that affects the use of diagnostic tests for drug hypersensitivity is that the immune pathogenesis for most drugs, except for penicillin and gold, is virtually unknown. To be clinically classified as an OLDE, the oral lesions should comprise a white reticulum or papules. These characteristics may be observed concurrently with erythematous and ulcerative lesions. OLDEs are often a diagnostic challenge, as the condition has been associated with a large number of drugs (Table 4-11). A correct diagnosis is easier to establish when a patient develops OLDE after starting a new drug (see Figure 4-45A). Discontinuation of the offending substance is the mode of treatment and also of confirming the diagnosis. For practical reasons, it is difficult to conduct withdrawal unless a patient has a severe symptomatic case. An OLDE may not develop for several months after a new drug is started. It may also take several weeks before an OLDE disappears following withdrawal (Figure 4-45B). The delay between exclusion of the offending drug and regression of the lesion indicates that the molecule has sensitized the epithelium, which may persist regardless of drug withdrawal.

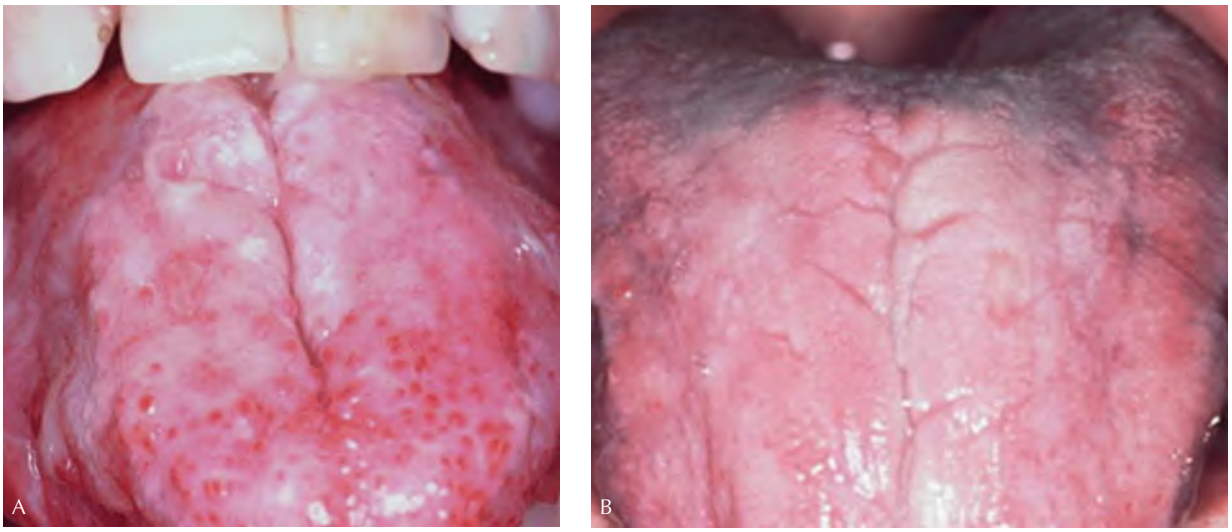

Figure 4-45 (A) Drug-induced lichenoid reaction at the dorsum of the tongue following one month of medication with a cholestyramine-containing drug. (B) Three weeks following withdrawal of the drug.

Table 4-11 Examples of drugs which have been associated with lichenoid reactions.

Angiotensin-converting enzyme inhibitors
Allopurinol
Antimalarials
Barbiturates
Chlorpropamide
Colchicine
Dapsone
Gold
Hydroxychloroquine
Metformin
Nonsteroidal anti-inflammatory drugs
Penicillamine
Phenothiazines
Phenylbutazones
Phenytoin
Propranolol
Protease inhibitors
Sulfonamide
Tetracyclines

Management

Discontinuance of the drug and symptomatic treatment with topical steroids would be sufficient. The patient should be properly educated about the responsible drug to prevent future OLDEs. Altering medication regimen requires communication with the patient's physician. Nevertheless, if a patient has idiopathic OLP and happens to take one of the allegedly lichenoid reaction-causing medications, we might needlessly try to substitute a suspect medication.

Lichenoid Reactions of Graft-versus-Host Disease

Etiology and Pathogenesis

The major cause of GVHD is allogeneic hematopoietic cell transplantation, even if an autologous transplant may also entail GVHD. In GVHD, it is the transplanted immunocompetent tissue that attempts to reject the tissue of the host. As a first step, conditioning of the host by chemotherapy and radiation will generate host cell damage, release of cytokines, and upregulation of adhesion and MHC molecules, which all facilitate recognition of alloantigens by donor T lymphocytes. A second step comprises an interaction between the recipient's APCs and the donor's T lymphocytes, which will perceive the histocompatibility antigens, expressed by APCs as foreign. This interaction may in fact be considered as the donor T lymphocytes recognizing the recipient's APCs as self-APCs expressing non-self-peptides. This interaction resembles the interaction between autoreactive T lymphocytes and APCs, hypothesized to play a role in the development of OLP. In a third step, the inflammatory cascade that follows the APC–T lymphocyte reaction will stimulate the proliferation of stromal cells, resulting in clinical features compatible with a lichenoid reaction.[82]

Epidemiology

Chronic GVHD occurs in 15–50% of patients who survive three months after transplantation and varies in incidence

from 33% of human leukocyte antigen (HLA)-identical sibling transplants to 64% of unrelated donor transplants. The risk for GVHD increases with the age of the marrow recipient. Chronic GVHD is defined as occurring more than 100 days post hematopoietic stem cell transplantation (HSCT), most commonly as a transition from acute GVHD. In 20–30% of patients, chronic GVHD may occur de novo.

Clinical Findings

Oral lichenoid reactions as part of GVHD may be seen both in acute and chronic GVHD, although the latter are more often associated with typical lichenoid features. The clinical lichenoid reaction patterns are indistinguishable from what is seen in patients with OLP—that is, reticulum, erythema, and ulcerations—but lichenoid reactions associated with GVHD are typically associated with a more widespread involvement of the oral mucosa (Figure 4-46).

Extraoral Clinical Manifestations

The skin lesions often present with a pruritic maculopapular and morbilliform rash, primarily affecting the palms and soles. Violaceous scaly papules and plaques may progress to a generalized erythroderma, bulla formation, and, in severe cases, a toxic epidermal necrolysis–like epidermal desquamation.[83]

Diagnosis

The presence of systemic GVHD facilitates the diagnosis of oral mucosal changes of chronic oral GVHD. However, the oral cavity may, in some instances, be the primary or even the only site of chronic GVHD involvement. Lichenoid eruptions are important in the diagnostic process of oral GVHD and have the highest positive predictive value of all reaction patterns. It is not possible to distinguish between OLP and oral GVHD based on clinical and histopathologic features. Although oral chronic GVHD is both clinically and histologically strikingly similar to OLP, a positive medical history of previous allogeneic HSCT will remove any doubt—that is, if the clinician asks the proper questions.

Management

The same treatment strategy as for OLP may be used for chronic oral GVHD; that is, topical steroid preparations, such as fluocinonide and clobetasol gel, or topical tacrolimus ointment or rinse. Intensive dexamethasone rinse (0.5 mg/5 mL) showed favorable results in a recent trial.[84] Opportunistic infections such as candidiasis should always be considered in immunosuppressed patients. The development of secondary malignancies has been recognized as a potentially serious complication of GVHD. Patients with a history of oral GVHD should therefore be examined for oral malignancies as part of the medical follow-up procedure.

Lupus Erythematosus

Etiology and Pathogenesis

LE represents the classic prototype of an autoimmune disease involving immune complexes. Both the natural and the adaptive parts of the immune system participate, with the latter involving both B and T lymphocytes.[85,86] Environmental factors are of importance such as sun exposure, drugs, chemical substances, and hormones, which all have been reported to aggravate the disease. A genetic predisposition is supported by an elevated risk for siblings to develop LE and by an increased disease concordance in monozygotic twins. More than 80 different drugs have been associated with the onset of SLE, including hydralazine, methyldopa, chlorpromazine, isoniazid, quinidine, and procainamide.[87]

Figure 4-46 Oral manifestations of graft-versus-host disease. (A) Irregular depapillation of the dorsusm of the tongue with apparently keratotic patches; and (B) nonremovable white patches of the hard and soft palate in the same patient.

Epidemiology

SLE predominantly affects women of reproductive age, and the prevalence decreases during the menopause. In the interval of 20–40 years, as much as 80% of cases have been reported to be women.[88] This predominance has lent support to the involvement of hormones in the pathogenesis of LE, as well as the fact that the disease can be precipitated by hormonal drugs. There are large variations in the distribution of the disease between different ethnic groups. In the United Kingdom, the prevalence of SLE among Asian individuals is 40 per 100,000; for Caucasians, it is 20 per 100,000 individuals.

Clinical Findings

The oral lesions observed in SLE and DLE are similar in their characteristics, both clinically and histopathologically.[89] The typical clinical lesion comprises white striae with a distinctive radiating orientation, and these may sharply terminate toward the center of the lesion, which has a more erythematous appearance (see Figure 4-39). However, several clinical manifestations of oral LE exist. The most affected sites are the hard palate (Figure 4-47A), buccal mucosa (Figure 4-47B), and gingiva. The tongue also can be involved. Lesions in the palatal mucosa can be dominated by erythematous lesions, and white structures may not be observed (Figure 4-48). Oral mucosa lesions compatible with LE may be the first sign of the disease. Approximately 20% of patients with LE have been reported to display oral lesions, although the figures vary from 9% to 45%.

Clinical Manifestations

The classic categorization of LE into SLE and DLE has during recent years been supplemented with acute cutaneous LE and subacute cutaneous LE.[90] SLE may also occur in concert with other rheumatologic diseases such as secondary Sjögren's syndrome and mixed connective tissue disease. An SLE diagnosis requires that four or more of the diagnostic criteria displayed in Table 4-12 should be present at each time point of the disease. The typical DLE diagnosis comprises well-demarcated cutaneous lesions with round or oval erythematous plaques with scales and follicular plugging. These lesions may form butterfly-like rashes over the cheeks and nose, known as a malar rash. The typical oral DLE lesion is a well-demarcated lesion with a mixed center and with a brush border of fine striae around the lesion (Figure 4-39). They are usually asymmetric or scattered, in contrast to OLP.

Laboratory Findings

Antinuclear antibodies are frequently found in patients with SLE and can be used to indicate a systemic involvement, but patients with other rheumatologic diseases, such as Sjögren's syndrome and rheumatoid arthritis, may be positive as well. Moderate to high titers of anti-DNA and anti-Smith antibodies are almost pathognomonic of SLE.

Pathology

The clinical picture of LE varies, which also is reflected in the histopathology. Variable histopathology is depending on the duration and mucosal site, but the pattern overlaps with OLP and other lichenoid lesions, causing it to be very challenging to differentiate between them. Some distinction may be represented by more common histopathologic features of LE: (1) hyperkeratosis with keratotic plugs; (2) atrophy of the rete processes; (3) deep inflammatory infiltrate; (4) edema in the lamina propria; and (5) thickening of basement membrane, which may show patchy or continuous periodic acid–Schiff (PAS)-positive deposits. Perivascular infiltrate may be present.

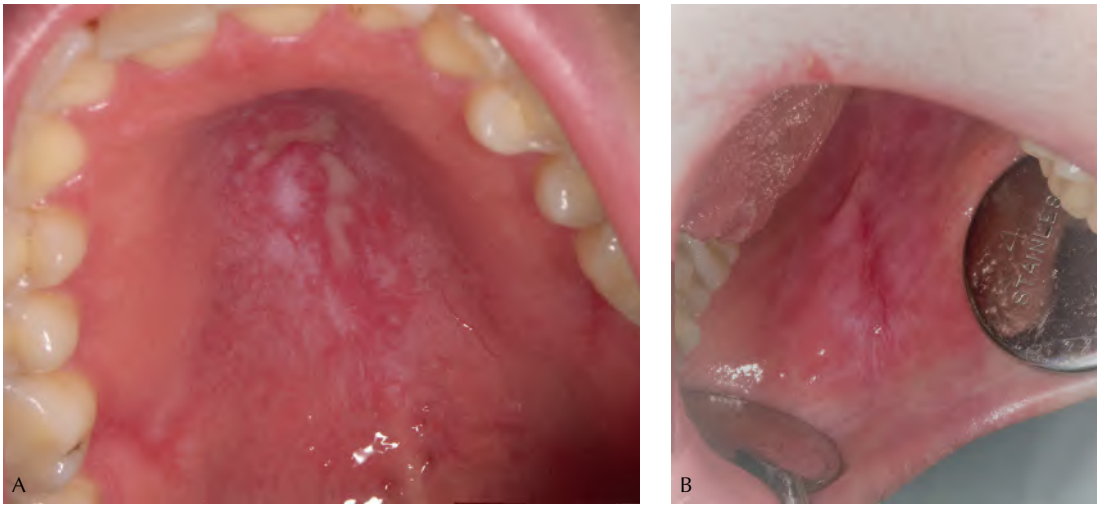

Figure 4-47 Discoid lupus erythematosus lesions in (A) the palate and (B) the left buccal mucosa in the same 47-year-old female. The pale lesions are a mixture of irregular ulcers and white patches with a keratotic appearance.

Figure 4-48 Systemic lupus erythematosus oral lesions on the hard palate showing irregular erythematous patches.

Table 4-12 American college of rheumatology criteria for systemic lupus erythematosus.*

1	Malar rash
2	Discoid lesions
3	Photosensitivity
4	Presence of oral ulcers
5	Nonerosive arthritis of two joints or more
6	Serositis
7	Renal disorder
8	Neurologic disorder (seizures or psychosis)
9	Hematologic disorder (hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia)
10	Immunologic disorder (anti-DNA, anti-Smith, or antiphospholipid antibodies)

*Systemic lupus erythematosus diagnosis with 4 or more of 10 criteria present at any time.

Diagnosis

Oral mucosal lesions seen in conjunction with different types of LE are clinically and histopathologically indistinguishable. Liquefaction degeneration may also be present, which may result in diagnostic problems in relation to OLP. The criteria mentioned earlier were tested among clinically atypical cases of DLE and the other groups of mucosal lesions, with a sensitivity of 92% and a specificity of 96% against both OLP and leukoplakia for the presence of two or more of the five criteria. DIF of the lesion is conducted to reveal granular, homogeneous, shaggy, lumpy, linear, or fibrillar deposition of IgG, IgA, IgM, and c3 in the BMZ (in all SLE and 70% of DLE cases), unlike in OLP where fibrinogen may be seen there.

Oral LE lesions would respond less rapidly than OLP to the usual topical steroid treatment. This also may be helpful in distinguishing between LE and OLP. If we are having doubts about differential diagnosis between the two and if we do not get a steady improvement following steroid treatment, we should consider LE "ex iuvantibus" (see the "Treatment" section).

A lupus band test is DIF performed on uninvolved skin or mucosa in order to differentiate between SLE and DLE. The extralesional oral mucosa in SLE patients has a positive reaction to IgM in 45% of cases in combination with variable deposits of IgG, IgA, and c3. DLE is accompanied by a positive antibody reaction in as few as 3% of patients.

Management

No randomized clinical trials with acceptable quality considering outcome measures have been conducted in regard to the treatment of oral mucosal LE lesions.[91] The oral lesions may respond to systematic treatment used to alleviate the systemic disease in SLE. Not all lesions are symptomatic, and many do not therefore require topical therapy. When symptomatic intraoral lesions are present, topical steroids may be considered (Table 4-13). It takes much longer and more frequent applications of topical steroids to show improvement of oral LE lesions compared to OLP. Prolonged use over several months is necessary to obtain observable effects. To obtain relief of symptoms, potent topical steroids such as clobetasol propionate gel 0.05% should be used, but also other steroids, such as betamethasone dipropionate 0.05%, fluticasone propionate spray 50 µg aqueous solution,

Table 4-13 Topical therapy for oral lesions of lupus erythematosus.

Topical Steroid Therapy*	Directions for Use†
0.05% fluocinonide gel	Place on affected area(s) 2 times/day for 2 weeks
0.05% clobetasol gel	Place on affected area(s) 2 times/day for 2 weeks
Dexamethasone elixir (0.5 mg/mL)	Swish and spit 10 mL 4 times/day for 2 weeks
Triamcinolone acetonide (5 mg/mL)	Intralesional injection
Topical antifungal therapy (10 mg clotrimazole troches)	Dissolve in mouth 5 times/day for 10 days
Nystatin suspension (100,000 U/mL)	Swish and spit 5 mL 4 times/day for 10 days
Chlorhexidine rinse (0.12%)	Swish and spit 10 mL 2 times/day until lesions resolve

* Fungal infections are a side effect of topical steroids.
† If lesions do not respond appropriately to topical steroids in 2 weeks, consider systemic therapy such as antimalarials, steroids, thalidomide, clofazimine, and methotrexate.
Source: Adapted from Brennan MT, Valerin MA, Napenas JJ, et al. Oral manifestations of patients with lupus erythematosus. *Dent Clin North Am.* 2005;49:127–141.

betamethasone valerate 0.1% cream, or triamcinolone acetonide 0.1% ointment may be used. Calcineurin inhibitors, such as tacrolimus 0.03–0.1% ointment or pimecrolimus 1% cream, showed some efficacy as well.[92] The treatment may begin with applications two to three times a day followed by tapering during the next six to nine weeks. When topical steroids are ineffective, antimalarial drugs are the treatment of choice (hydroxychloroquine has a success rate of 85%). Other immunosuppressive drugs (and their success rates) include azathioprine (59%), dapsone (41%), thalidomide (35%), and pulse steroids (27%).[93] Immunosuppressive drugs used to treat LE may precipitate opportunistic fungal and viral infections. Opportunistic oral infections can also originate from the immunologic defects that are part of the pathogenesis. In SLE, oral mucosal lesions often mirror the disease activity. They may regress spontaneously, but can also persist for months or even years.

ALLERGIC REACTIONS

Oral Lichenoid Contact Reactions

OLCR is considered to be due to a delayed (contact) hypersensitivity reaction to constituents derived from dental materials. The majority of patients, but not all, are patch test positive to mercury (Hg), which lends support to OLCR being allergic in nature. Although Hg is usually considered the primary etiologic factor, other amalgam constituents may also initiate OLCR, and other filling materials such as gold, composites, and glass ionomers may also generate reactions.

Etiology and Pathogenesis

The pathogenesis of OLCR is considered to be a type of delayed hypersensitivity reaction to constituents derived from dental materials, predominantly amalgam fillings. The pathogenesis of OLCR is not fully elucidated, but based on the knowledge of delayed hypersensitivity, the following probably occurs (Figure 4-49). Hg is a hapten and cannot be recognized by T lymphocytes, as the T-cell receptor (TCR) is primarily limited to the identification of peptides. However, Hg ions are highly reactive and may bind to self-proteins of the oral epithelium, which will induce transformation changes of the protein. This assembly between Hg and protein will be perceived as non-self and, following pinocytosis by APCs, such as the Langerhans cells of the oral epithelium, these cells will degrade the protein complex to oligopeptides. The activated APCs will mature through migration to regional lymph nodes and start to express Hg-containing peptides together with class II molecules on the cell surface. Class II molecules represent a subset of glycoproteins derived from the MHC, which is critical for the APC–T lymphocyte interaction. The process of antigen presentation is therefore considered to be class II molecule restricted.

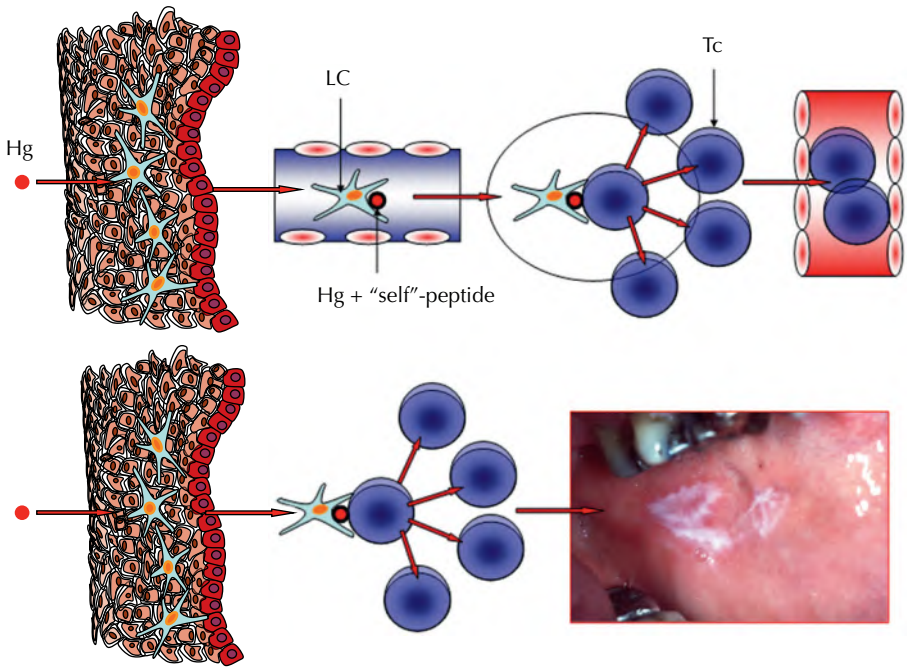

Figure 4-49 Diagrammatic representation of the mechanisms of sensitivity to dental materials leading to lichenoid contact reactions. Mercury ions (Hg) combined with host peptides are presented by Langerhans cells (LC) to cytolytic T cells (Tc). Sensitized Tc cells amplify and in the presence of further Hg^{+} self-peptide cause a localized lesion.

Within the lymph node, an interaction between the assembly of class II molecule–Hg-containing peptide on the APC and the TCR expressed on the antigen-specific T lymphocyte will occur. This interaction is known as the first signal in the antigen-presenting process. The second signal comprises further cellular interactions, which are decisive for the clonal expansion of the Hg peptide-specific T lymphocytes to take place. These cells will migrate into the bloodstream to reach and patrol all peripheral tissues of the body. At this stage, the patient is considered to be sensitized against Hg.

Once the oral mucosa of a sensitized individual is re-exposed to Hg, the Langerhans cells in the oral epithelium are able to present peptide-conjugated Hg to peripheral T lymphocytes with an appropriate TCR. Thus, in a sensitized individual, the Langerhans cells are able to fulfill their mission in situ and do not have to migrate to the regional lymph node to encounter an appropriate T lymphocyte. The interaction between the cells instigates cytokine production, which will lead to the attraction of inflammatory cells necessary to mount a local immune response in the Hg-exposed oral mucosa, and eventually also lead to healing once Hg exposure is eliminated. The cytokine profile produced is most likely responsible for the stimulation of inherent cells of the oral mucosa, which gives rise to the clinical reaction pattern of OLCR.

Epidemiology

No prevalence figures for OLCR have been reported in the literature. The sex distribution seems to be different from OLP, with a higher proportion of women among patients affected by OLCR. No significant differences regarding general diseases, drugs, or history of allergy between OLCR and OLP have been reported.

Clinical Findings

Clinically, OLCR displays the same reaction patterns as seen in OLP; that is, reticulum, papules, plaque, erythema, and ulcers (Figure 4-50). The most apparent clinical difference between OLP and OLCR is the extension of the lesions and proximity to restorations, and the fact that OLCR are asymmetric and usually unilateral, making this a dominant differential distinction.[94] In a case when a patient has silver amalgam fillings bilaterally, and if symmetrically distributed lichenoid reactions develop, it will not be possible to easily discriminate between a lichenoid reaction and idiopathic OLP. Unfortunately, histopathology findings of lichenoid reactions are very similar to those of OLP, and thus performing biopsy for that reason is usually not helpful. The majority of OLCRs are confined to sites that are regularly in contact with dental materials, such as the buccal mucosa and the border of the tongue. Lesions are hardly ever observed in sites as the gingiva, palatal mucosa, floor of the mouth, or dorsum of the tongue. Most OLCRs are asymptomatic, but when erythematous or ulcerative lesions are present, the patient may experience discomfort from spicy and warm food constituents. The duration with which the material is in contact with the oral mucosa has a decisive influence on the development of OLCR. The clinical implication of this is that some lesions, especially those on the lateral border of the tongue, may extend somewhat beyond the direct contact of dental material.

Figure 4-50 Oral lichenoid contact reaction. This lesion in the left buccal mucosa is immediately adjacent to a large amalgam restoration. No other lesions were present and it regressed on replacement of the amalgam.

Lichenoid reactions in contact with composites have been observed on the mucosal side of both the upper and lower lips.[95] The majority of this type of OLCR improve following treatment with chlorhexidine, possibly indicating a role for plaque in exacerbating symptoms. Further studies have to be conducted to substantiate a true lichenoid nature of these lesions.

Diagnosis

There are no dependable investigations that could help discriminate between idiopathic OLP and OLCR. The diagnosis is primarily based on the topographic relationship to dental materials. OLP may display similar characteristics, and clinical improvement after replacement of the culprit dental material may assist to discriminate between OLCR and OLP (Figure 4-51). However, OLP lesions in close contact with amalgam may also improve following the replacement, but to a lesser extent compared to OLCR. Cutaneous patch tests (CPTs), if well done, may be helpful.[96,97] It should be noted that many patients with OLCR may test negative to relevant test compounds, although the lesions may resolve following replacement of the dental material. A CPT may not relate directly to mucosal sensitization, since the concentration of antigen to elicit a positive reaction in the oral mucosa needs

Figure 4-51 (A) Widespread lichenoid reactions in the buccal mucosa and tongue in relation to extensive amalgam restorations. (B) Removal and replacement of the amalgams resulted in almost complete remission of the lesions within three months.

to be 5–12 times higher than in skin.[98] Thus, CPT results, though more sensitive, may not reliably identify patients in whom amalgam replacement will achieve healing of the lesion.[99,100] There are also reported OLCRs to gold and composites, with resolution on their replacement, and to most restorative materials except palladium, titanium, and zirconium. Histopathology will not normally be of much assistance in discrimination between OLP and OLCR, but may be useful in identifying dysplasia and any risk of malignant transformation.

Management

Replacement of dental materials in direct contact with OLCR will result in cure or considerable improvement in at least 90% of cases (Figure 4-51B).[99] Most lesions should be expected to heal within one to two months. There is no need for replacement of restorative materials that are not in direct contact with the OLCR. Healing does not seem to depend on what type of dental material is used for replacement. A malignant potential of OLCR has been suggested in some large case series, but no prospective studies have been conducted to support this hypothesis.[101]

Reactions to Dentifrice and Chlorhexidine

Delayed hypersensitivity reactions to toothpastes (Figure 4-52) and mouthwashes have been reported, but such reactions are rare.[102] The compounds responsible for the allergic reactions may include flavor additives such as carvone and cinnamon aldehyde, eugenol, menthol, or preservatives. These flavoring constituents may also be used in chewing gum and produce similar forms of plasma-cell gingivitis. The clinical manifestations include fiery red edematous gingiva, which may include both erosions and white lesions. Similar lesions may involve other sites, such as the labial, buccal, and tongue mucosae. The clinical manifestations are characteristic and form the basis of the diagnosis, which is supported by healing of the lesions after withdrawal of the allergen-containing agent.[102] Dentifrice may also cause a disturbed desquamation, which clinically can be observed as thin veils of scaling keratin (Figure 4-53).

TOXIC REACTIONS

Reactions to Smokeless Tobacco

Smokeless tobacco represents a nonhomogeneous group of compounds used with different intraoral application methods. Three different geographic areas are of special interest: South Asia, the United States, and Scandinavia. In India, tobacco is often used in combination with betel leaf, sliced areca nut, and powdered slaked lime, which increases the toxicity of the compound. There is a definitive association between this form of smokeless tobacco and oral cancer (see the earlier section "Oral Submucous Fibrosis").

Smokeless tobacco in the United States and Scandinavia can be divided into three different groups: chewing tobacco,

Figure 4-52 Immune delayed hypersensitivity response (allergy) to components of dentifrice resulting in gingival erythema, particularly the attached gingivae in the upper right anterior region.

Figure 4-53 Hypersensitivity reaction to dentifrice resulting in desquamation of the superficial epithelial layers.

moist snuff, and dry snuff.[103] All three are different regarding composition, manufacturing procedures, and type of consumers. In Scandinavia, moist snuff is the most popular compound, but is different in the manufacturing process from the moist snuff used in the United States.[104] The latter contains higher concentrations of tobacco-specific nitrosamines and nitrite.

The clinical picture varies in relation to the type, brand, frequency, and duration of use of moist snuff.[105] In its mildest form, the lesion may just be noted as wrinkles at the site of application, whereas high consumers may display a white and leathery lesion (Figure 4-54), which sometimes contains ulcerations. Hyperkeratinization, acanthosis, and epithelial vacuolizations are common histopathologic features together with different degrees of subepithelial inflammation. Gingival retraction is the most common adverse reaction seen in conjunction with a smokeless tobacco habit. These retractions are irreversible, whereas the mucosal lesion usually regresses within a couple of months. Oral mucosal lesions are less

Figure 4-54 Oral mucosal reaction to moist snuff held in contact in the central part of the maxillary vestibulum, displaying both wrinkles at the site of application and a white and leathery lesion. Generalized hyperkeratinization overlies apparent edema of the mucosa.

frequently observed in association with chewing tobacco compared with moist snuff.

There is a distinct difference between lesions caused by smokeless tobacco and oral leukoplakia with respect to the presence of epithelial dysplasia, which is more frequently found in the latter. Furthermore, the degree of dysplasia is also milder. The carcinogenic potential of smokeless tobacco has been a subject of considerable debate, and no global consensus has been reached. However, it is undisputable that smokeless tobacco products contain nitrosamines, polycyclic hydrocarbons, aldehydes, heavy metals, and polonium 210, which all have the potential to cause harm.[106,107] Some studies conclude that there is a higher risk of oral cancer and pancreatic cancer, results that have not been confirmed by others. The World Health Organization International Agency for Research on Cancer established in its report from 2004 that "overall, there is sufficient evidence that smokeless tobacco causes oral cancer and pancreatic cancer in humans, and sufficient evidence of carcinogenicity from animal studies." In a recent comprehensive review, it was concluded that the use of moist snuff (Figure 4-54) and chewing tobacco imposes minimal risks for cancers of the oral cavity and other upper respiratory sites, with relative risks ranging from 0.6 to 1.7. The use of dry snuff imposes higher risks, ranging from 4 to 13, and the risks from smokeless tobacco, unspecified as to type, are intermediate, from 1.5 to 2.8.[106]

Smoker's Keratosis

Moderate to heavy tobacco smoking, especially cigarettes but also cannabis, can give rise to reactive keratosis anywhere in

the oral cavity, but especially in the palate (see later) and sublingually (Figure 4-20). Sublingual keratosis can be clinically indistinguishable from sublingual leucoplakia, except that cessation of the habit and removal of the irritant may lead to regression of the lesion(s). Persistence of the lesion after cessation of smoking confirms a sublingual leucoplakia, which must be biopsied due to the high risk of malignant transformation.

Smoker's Palate

The most common effects of smoking are presented clinically as dark brown pigmentations of the oral mucosa (smoker's melanosis) and as white leathered lesions of the palate, usually referred to as nicotine stomatitis or smoker's palate. In smoker's palate, an erythematous irritation is initially seen, and this lesion is followed by a whitish palatal mucosa reflecting a hyperkeratosis (Figure 4-55). As part of this lesion, red dots can be observed representing orifices of accessory salivary glands, which can be enlarged and display metaplasia. Histopathologically, smoker's palate is characterized by hyperkeratosis, acanthosis, and a mild subepithelial inflammation.[108]

The prevalence of smoker's palate has been reported in the range of 0.1–2.5%. Smoker's palate is more prevalent in men and is a common clinical feature in high consumers of pipe tobacco and cigarettes and among individuals who practice inverse smoking. The etiology is probably more related to the high temperature rather than the chemical composition of the smoke, although there is a synergistic effect of the two.[109]

Figure 4-55 Classic appearance of smoker's palate showing widespread reactive keratosis, and enlarged, inflamed minor salivary glands with obvious ductal orifices.

REACTIONS TO MECHANICAL TRAUMA

Morsicatio (Mucosal Nibbling)

Morsicatio is instigated by habitual chewing (Figure 5-56). This parafunctional behavior is done unconsciously and is therefore difficult to bring to an end. Morsicatio is most frequently seen in the buccal and lip mucosa and is never encountered in areas that it is not possible to traumatize by habitual chewing.[110,111] Typically, morsicatio does not entail ulcerations, but encompasses an asymptomatic shredded area. In cases of more extensive destruction of oral tissues by habitual chewing, a psychiatric disorder should be suspected. The prevalence has been reported to be in the range of 0.5–1.0%. Morsicatio is three times more common among women.

Morsicatio has a very typical clinical appearance, and the diagnosis is relatively easy to establish, with one exception. If the lesion affects the borders of the tongue, it may mimic hairy leukoplakia. This also has bearing for the histopathologic picture, which is characterized by hyperkeratosis and acanthosis. A careful disease history will assist in the discrimination between the two conditions. The management is limited to reassurance, and the patient should be informed about the parafunctional behavior. There is no malignant potential.

Frictional Hyperkeratosis

Oral frictional hyperkeratosis is typically clinically characterized by a white lesion without any red elements. The lesion is observed in areas of the oral mucosa subjected to increased friction caused by, for example, food intake (Figure 4-57).

Figure 4-56 Morsicatio lesions in the left buccal mucosa in a 33-year-old female, caused by habitual chewing of the cheek. Chewing has resulted in shredding of the mucosa and reactive keratosis.

Figure 4-57 Frictional keratosis of the lower left alveolar ridge, caused by chewing solid foods directly on the ridge in the absence of a denture.

Etiology and Pathogenesis

Frictional hyperkeratosis is observed in areas subjected to increased abrasion, which stimulates the epithelium to respond with increased production of keratin. The reaction can be regarded as a physiologic response to minor trauma. Smoking and alcohol consumption have been reported as predisposing factors.[112] Thus, the development of frictional hyperkeratosis is facilitated when the oral mucosa is exposed to these factors.

Epidemiology

In population studies, the prevalence has been reported to be in the range of 2–7%. Predisposing factors such as smoking and alcohol will increase the prevalence of frictional hyperkeratosis, and it is the most common mucosal lesion in individuals with these habits.

Clinical Findings

Frictional hyperkeratosis is often seen in edentulous areas of the alveolar ridge, but may also be observed in other parts of the oral mucosa exposed to increased friction or trauma. The lesions are asymptomatic, although they can cause anxiety to the patient as they can be perceived as malignant or premalignant.

Diagnosis

For most lesions, the diagnosis can be established based on clinical features. As frictional hyperkeratosis does not carry any symptoms and is caused by comparatively common habits, it may be difficult to relate the lesions to increased friction. If the diagnosis is doubtful, biopsy is mandatory to exclude premalignant lesions. The histopathologic picture is characterized by hyperkeratosis without dysplasia and no or mild subepithelial inflammation. Differential diagnosis against homogeneous leukoplakia is clinically based on a combination of features such as the affected site and a more diffuse demarcation. The ultimate way to differentiate between the two is to reduce or eliminate predisposing factors and await a remedy.

Management

No surgical intervention is indicated. Information about the nonmalignant nature of the lesions and attempts to reduce predisposing factors are sufficient.

OTHER RED AND WHITE LESIONS

Benign Migratory Glossitis (Geographic Tongue)

Geographic tongue is an annular lesion affecting the dorsum and margin of the tongue. The lesion is also known as erythema migrans or benign migratory glossitis. The typical clinical presentation comprises a white, yellow, or gray, slightly elevated peripheral zone (Figure 4-58) surrounding an erythematous patch. Since several layers of tongue epithelium can be desquamated per day, the clinical appearance can alter from day to day.

The occurrence of geographic tongue makes people worried and prone to self-observation of the tongue. It creates a disproportional level of stress. Additionally, it may cause symptoms while eating certain types of food. Sometimes people discover it during self-examination of the tongue if they have burning mouth syndrome.

Etiology and Pathogenesis

Although geographic tongue is one of the most prevalent oral mucosal lesions, there are virtually no studies available with the objective of elucidating the etiology behind this disorder. Heredity has been reported, suggesting the involvement of genetic factors in the etiology.

Epidemiology

The prevalence of geographic tongue varies considerably between different investigations, which may reflect not only geographic differences but also patient selection procedures and diagnostic criteria. The most frequently reported prevalence is in the range of 1.5–2.5%.[113] The sex distribution appears to be equal.

Clinical Findings

Geographic tongue is circumferentially migrating and leaves an erythematous area behind, reflecting atrophy of the filiform papillae. The peripheral zone disappears after some time, and healing of the depapillated and erythematous area starts. The lesion may commence at different starting points,

Figure 4-58 Benign migratory glossitis showing typical appearance of apparently atrophic areas of the dorsum of the tongue surrounded by gray-white keratotic margins.

the peripheral zones fuse, and the typical clinical features of a geographic tongue emerge. Depending on the activity of the lesion, the clinical appearance may vary from single areas to multiple lesions occupying the entire dorsum of the tongue.[114] Disappearance of the peripheral zone may indicate that the mucosa is recovering. Geographic tongue is characterized by periods of exacerbation and remission, with different durations over time. The disorder is usually nonsymptomatic, but some patients experience a smarting sensation. Typical of this condition is that patients experience symptoms only upon eating certain foods. These include walnuts and other nuts, as well as kiwi fruit, citric flavors, and tomatoes. In these cases, a parafunctional habit, revealed by indentations at the lateral border of the tongue, may be a contributing factor to the symptoms. Patients often report that their lesions are aggravated during periods of stress.[114,115] Geographic tongue may be followed by a fissured tongue and sometimes the two lesions are observed simultaneously (Figure 4-59).

The appearance of the tongue dorsum may vary greatly, from a mild presentation to a very dramatic one. A geographic appearance can be observed at sites of the oral mucosa other than on the dorsum of the tongue, and is then denoted geographic stomatitis (sometimes called "ectopic geographic tongue"). The information about geographic stomatitis is sparse and relies on case reports. A similar clinical presentation as for geographic stomatitis may be seen as part of Reiter's disease. This disease is characterized by arthritis, uveitis or conjunctivitis, and urethritis. Reiter's disease is considered to be a reaction that originates from a gastroenteral or urogenital infection.[116,117]

An increased prevalence of geographic tongue has been observed in patients with generalized pustular psoriasis. In psoriasis in general, no such association has been revealed. No

Figure 4-59 Fissured tongue associated with concurrent benign migratory glossitis (BMG). Fissures can appear in the apparent absence of BMG.

studies have demonstrated that patients with geographic tongue are at increased risk of acquiring psoriasis. Atopy has also been associated with geographic tongue, but this was not confirmed by a recently conducted study in the United States.

Diagnosis

The clinical features of this mucosal disorder are quite characteristic, and histopathologic confirmation is not needed. If biopsy is considered, it should involve the peripheral zone to capture the lesion's typical histopathologic features. These include parakeratosis, acanthosis, subepithelial inflammation of T lymphocytes, and transepithelial migrating neutrophilic granulocytes. These cells may be a part of microabscesses formed near the surface, similar to those found in pustular psoriasis (Monro's microabscesses).

Management

Since the etiology is unknown, no causal treatment strategy is available.[114] Symptoms are rarely present, and management is confined to reassurance and proper information about the disorder's benign character. It is important to emphasize that it is not a pathologic lesion, but rather a morphologic variation of generally health mucosa, as well as that patients may eat anything except walnuts, kiwi fruit, tomatoes, and citric foods. It is helpful to have an information

sheet ready for patients to read about the benign nature of the condition. No special treatment is required, although many approaches have been tried. If symptoms are reported, topical anesthetics may be used to obtain temporary relief. Other suggested treatment strategies include antihistamines, anxiolytic drugs, or steroids, but none of these has been systematically evaluated.

Geographic tongue may regress, but it is not possible to predict when and to which patient this may happen. The prevalence of the disease seems to decrease with age, which supports spontaneous regression over time.

Leukoedema

Leukoedema is defined as edematous mucosa with a whiteish, often apparently translucent appearance.

Etiology and Pathogenesis

The etiology of leukoedema is not clear.

Epidemiology

The prevalence of areas of leukoedema in Caucasians has been estimated at 50%. The lesion is even more prevalent in the black population. The distribution between sexes has been found to be equal.[112]

Clinical Findings

Leukoedema is a white and veil-like alteration of the oral mucosa that is merely considered a normal variant. The condition is often encountered bilaterally in the buccal mucosa (Figure 4-60) and sometimes at the borders of the tongue. Leukoedema is less clinically evident after stretching the mucosa, but reappears after this manipulation is discontinued.

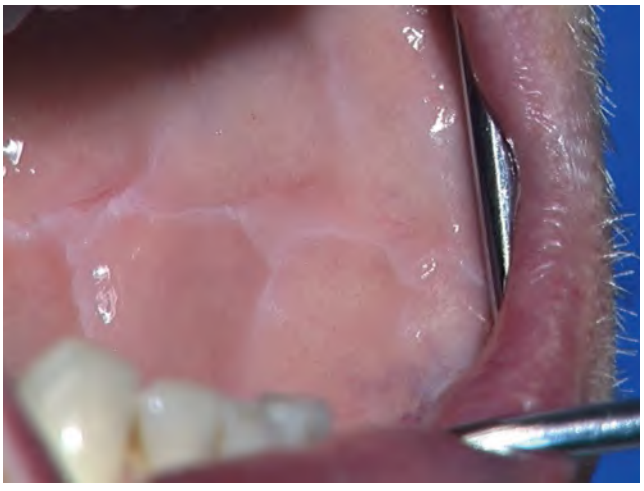

Figure 4-60 Leukodema in the left buccal mucosa showing an apparent edematous mucosa with a whiteish, translucent appearance associated with parafunctional behavior.

In more pronounced cases, leukoedema is accompanied by mucosal folds. The condition is asymptomatic and has no malignant potential.

Diagnosis

The clinical features of leukoedema are quite different from oral keratosis, such as leukoplakia, as the demarcation is diffuse and gentle stretching results in a temporary disappearance. The histopathology is characterized by parakeratosis and acanthosis together with intracellular edema in epithelial cells of stratum spinosum.

Management

There is no demand for treatment as the condition is asymptomatic and has no complications, including premalignant features.

White Sponge Nevus

Etiology and Pathogenesis

White sponge nevus is initiated following mutations in those genes that are coding for epithelial keratin of types K4 and K13. In K4-deficient mice, epithelial disturbances have been reported that are compatible with white sponge nevus.[118]

Epidemiology

White sponge nevus has been listed as a rare disorder by the US National Institutes of Health, which implicates a prevalence below 1 in 200,000. In a population study of 181,338 males between 18 and 22 years of age, two cases of white sponge nevus were identified. The clinical appearance usually commences during adolescence, and the sex distribution has been reported to be equal.

Clinical Findings

White sponge nevus is an autosomal dominant disorder with high penetrance. The typical clinical appearance is a white lesion with an elevated and irregular surface comprising fissures or plaque formations (Figure 4-61). The most affected sites are the buccal mucosa, but the lesion may be encountered in other areas of the oral cavity covered by parakeratinized or nonkeratinized epithelium. The disorder may also involve extraoral sites, such as the esophagus and anogenital mucosa. Although the lesion does not entail any symptoms, it may cause dysphagia when the esophagus is involved.

Diagnosis

White sponge nevus may constitute a differential diagnostic problem, as this disorder may be taken for other oral dyskeratoses, for example oral leukoplakia and plaque type candidiasis. The hallmark microscopic feature of this disorder is pronounced intracellular edema of the superficial epithelial

Figure 4-61 White sponge nevus in the left buccal mucosa.

cells, predominantly located within the stratus spinosum. Cells with pyknotic nuclei are present, and these cells may imitate the koilocytosis observed in viral infections. Deep fissures in the nondysplastic epithelium may reach just above the basal layer, but the lower portions of the epithelium are not involved. No or only mild infiltrations may be seen in the subepithelial tissue.

Management

White sponge nevus does not entail any symptoms, and no treatment is therefore required. Systemic antibiotics have been used in an attempt to resolve the disorder, but with inconsistent results. When a positive effect is obtained, the recurrence rate is considerable. White sponge nevus is a totally benign condition.

Hairy Tongue

Hairy tongue is characterized by an impaired desquamation of the filiform papillae, which leads to the hairy-like clinical appearance.[119,120] The tongue frequently becomes stained through tea or coffee drinking, smoking, or resident bacteria, and is then designated *black hairy tongue*.

Etiology and Pathogenesis

The etiology of hairy tongue is unknown in most cases. A number of predisposing factors have been related to this disorder, including decreased tongue motility and subsequent lack of physiologic exfoliation of filiform papillae (oral inactivity), neglected oral hygiene, a shift in the microflora, antibiotics and immunosuppressive drugs, oral candidiasis, excessive alcohol consumption, and prolonged use of chlorhexidine. The impact of oral inactivity and ignored oral hygiene is supported by the high prevalence of hairy tongue in hospitalized patients, who are not able to carry out their own oral hygiene. An example of this is a patient thrusting the tongue against an unstable upper denture, causing a lack of exfoliation of papillae. Hairy tongue is also associated with smoking habits.

Epidemiology

The reported prevalence varies between different geographic areas, diagnostic criteria, and frequencies of predisposing factors. In studies from the United States and Scandinavia, the prevalence of hairy tongue is reported at below 1%.

Clinical Findings

The elongation of the filiform papillae has to reach lengths in excess of 3 mm to be classified as "hairy," although lengths of more than 15 mm have been reported in hairy tongue. The lesion is commonly found in the posterior third of the tongue, but may involve the entire dorsum (Figure 4-62).

Figure 4-62 Clinical appearances of "hairy" tongue. (A) Central yellow-white appearance of the dorsum of the tongue caused by elongation of the filiform papillae. (B) Black hairy tongue caused by bacterial and food staining on the greatly elongated filiform papillae.

Hairy tongue may adopt colors from white to black depending on food constituents and the composition of the oral microflora. Patients with this disorder may experience both physical discomfort and esthetic embarrassment related to the lengths of the filiform papillae.

Diagnosis

The diagnosis is based on clinical appearance, and microbiologic examinations do not give any further guidance.

Management

The treatment of hairy tongue is focused on reduction or elimination of predisposing factors and removal of the elongated filiform papillae. Patients should be instructed on how to use devices developed to scrape the tongue. Food constituents with an abrasive effect may also be used to prevent recurrences. Attempts have been made with tretinoin, but this treatment has not reached any widespread acceptance. Patients should be informed about the benign and noncontagious nature of hairy tongue.

Pigmented Lesions of the Oral Mucosa

Alfredo Aguirre, DDS, MS
Faizan Alawi, DDS
Jose Luis Tapia, DDS, MS

Healthy oral soft tissue presents a typical pink to red hue that reflects the degree of keratinization, quantity and activity of melanocytes, vascularization, and type of submucosal tissue of distinct topographic areas.[1] Although oral and perioral pigmentation may be physiologic in nature, particularly in individuals with a darker complexion, throughout the course of disease it is possible for the oral mucosa and perioral tissues to assume a variety of discolorations, including brown, blue, gray, and black. Such color changes are often attributed to the deposition, production, or increased accumulation of various endogenous or exogenous pigmented substances. However, although an area may appear pigmented, the discoloration may not be related to actual pigment, but rather to the deposition or accumulation of organic or inorganic substances, including various metals and drug metabolites.[2]

Hemoglobin, hemosiderin, and melanin represent the most common endogenous sources of mucosal color change (Table 5-1). A submucosal collection of hemoglobin or hemosiderin, produced by extravasation and/or lysis of red blood

cells, may impart a red, blue, or brown ephemeral appearance to the oral mucosa. Melanin, which is synthesized by melanocytes and nevus cells, may appear as brown, blue, or black, depending on the amount of melanin and its spatial location within the tissue (i.e., superficial vs. deep).

Exogenous pigmentations are usually associated with traumatic or iatrogenic events resulting in the deposition of foreign material directly into the mucosal tissues (Table 5-2).[3] In some cases, the substances may be ingested, absorbed, and distributed hematogenously into connective tissues, particularly in areas subject to chronic inflammation, such as the gingiva. In other instances, these ingested substances can stimulate melanin production, thus precipitating a color change. Chromogenic bacteria can produce discoloration of the dorsal tongue. Certain foods, drinks, and confectionery can also result in exogenous pigmentation that, in most cases, is reversible.

Clinically, oral pigmentations can range from a solitary macule to large patches and broad, diffuse tumefactions. The specific hue, duration, location, number, distribution, size, and shape of the pigmented lesion(s) may be of diagnostic importance. In addition, recording extensive social, family, medical, and dental histories, various diagnostic procedures (e.g., colonoscopy), and laboratory tests (including biopsy) may be necessary. Thus, an understanding of the various disorders and substances that can contribute to oral and perioral pigmentation is essential for the appropriate evaluation, diagnosis, and management of the patient.

Table 5-3 lists additional lesions that may be associated with oral mucosal discoloration. Each of these lesions is discussed in more detail elsewhere in this textbook. Similarly, vascular lesions such as hemangioma, lymphangioma, angiosarcoma, and Kaposi's sarcoma, which are frequently considered in the differential diagnosis of macular and mass-forming pigmented lesions, are shown in Table 5.1, but otherwise excluded from this chapter.

ENDOGENOUS PIGMENTATION

Melanin is the pigment derivative of tyrosine and is synthesized by melanocytes, which typically reside in the basal cell layer of the epithelium.[4] Investigations into normal melanocyte homeostasis led to the discovery that keratinocytes control melanocytic growth.[5] Yet the mechanisms by which melanocytes are stimulated to undergo cell division remain poorly understood. Their presence in the skin is thought to protect against the damaging effects of actinic irradiation. They also act as scavengers, protecting against cytotoxic intermediates.[6] However, the role of melanocytes in oral epithelium is unclear.

Melanin is not commonly observed in routine biopsies of the oral mucosa, unless the tissues were obtained from non-Caucasoid individuals. Oral melanocytic pigmentation in Caucasians is almost always considered pathologic in origin, although the pathology or pigment itself may be of no clinical significance.

Melanin is synthesized within specialized structures known as melanosomes. It is composed of eumelanin, a

Lipoma	Yellow
Granular cell tumor	Yellow

brown-black pigment, and pheomelanin, a pigment of red-yellow color.[4] The term *melanosis* is used to describe diffuse hyperpigmentation. Cutaneous overproduction of melanin may be associated with a variety of mechanisms, but most commonly with increased sun exposure. However, intraorally, hyperpigmentation is more typically a consequence of physiologic, idiopathic sources, neoplasia, medications, high serum concentrations of pituitary adrenocorticotropic hormone (ACTH), postinflammatory changes, and genetic or autoimmune disorders. Therefore, the presence or absence of systemic signs and symptoms, including cutaneous hyperpigmentation, is of great importance to elucidate the genesis of oral pigmentations. If the etiology of the oral pigmentation cannot be clinically established, a tissue biopsy is warranted for definitive diagnosis. This is critical, because malignant melanoma may present with a deceptively benign clinical appearance.

In addition to biopsy and histologic study, various laboratory and clinical tests, including diascopy, radiography, and blood tests, may be necessary for the definitive diagnosis of oral pigmentations. Recently, two noninvasive tests, which were originally developed to study cutaneous pigmentation, have been applied to evaluate oral melanosis. The first, dermoscopy (also known as epiluminescence microscopy), uses a handheld surface microscope, incident light, and oil immersion. This technique has been successfully used for the evaluation of selected oral pigmented lesions.[7] The second, reflectance confocal microscopy (RCM), allows the in vivo microscopic visualization of the skin and mucosa, which provides high-resolution horizontal views with an approximate depth of 200–300 μm.[8] This procedure can assist in the diagnosis and management of benign and malignant pigmented lesions of the lips.[9] Because prospective and controlled studies detailing the predictive value and efficacy of dermoscopy and RCM for the diagnosis of oral pigmented lesions have not been performed, the practitioner should be wary of their use in common clinical dental practice.

In summary, melanin pigmentation may be physiologic or pathologic, and may clinically present with focal, multifocal, or diffuse patterns. Figures 5-1 and 5-2 show algorithms that can assist the clinician in associating these patterns with selected pigmented conditions.

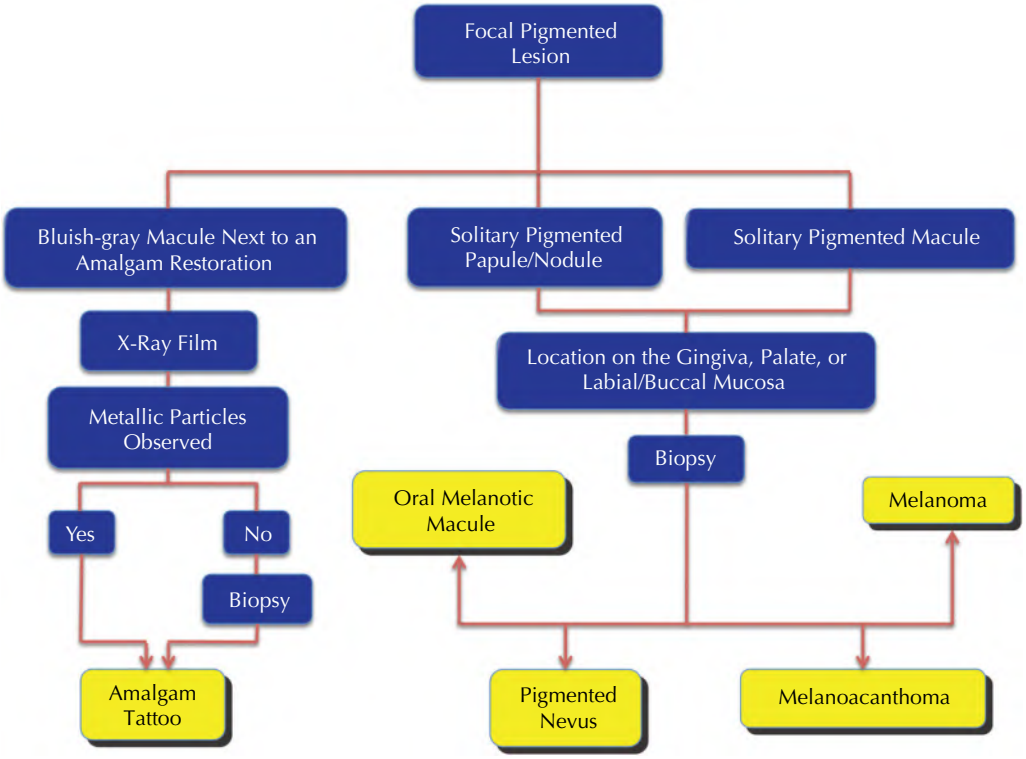

Figure 5-1 Focal pigmented lesions. Algorithm illustrating clinical procedures needed to segregate and diagnose common focal pigmented lesions.

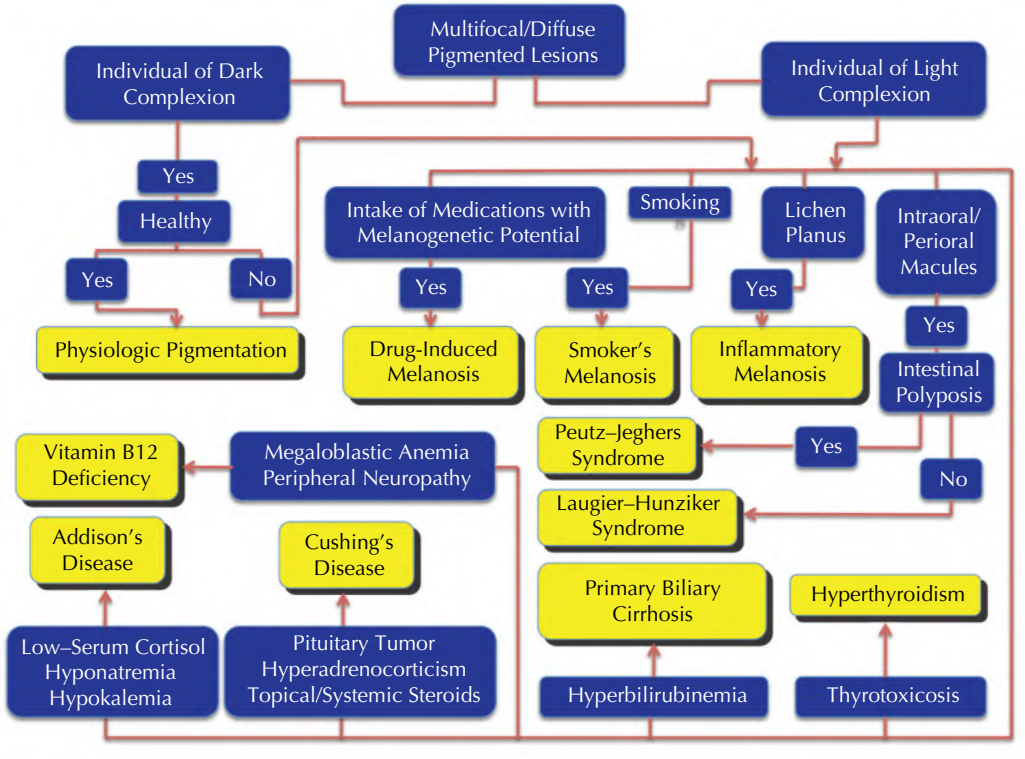

Figure 5-2 Multifocal and diffuse pigmented lesions. Algorithm illustrating the clinical presentation of pigmented lesions with accompanying habits, endoscopic features, and systemic/laboratory findings that allow their segregation.

FOCAL MELANOCYTIC PIGMENTATION

Freckles/Ephelis

Freckles is the lay term for ephelis and lentigines, which are commonly occurring, asymptomatic, well-circumscribed, tan- or brown-colored macules often seen on sun-exposed regions of the skin (Figure 5-3). Ephelides are most commonly observed in light-skinned individuals and are quite prevalent in red- or light blond-haired individuals. Freckles are thought to be developmental in origin. A number of genes have been shown to participate in their formation.[10]

Ephelides are usually more abundant in number and darker in intensity during childhood and adolescence. They tend to become darker during periods of prolonged sun exposure (e.g., spring, summer) and fade during the autumn and winter months. However, the increase in pigmentation is solely related to an increase in melanin production without a concomitant increase in the number of melanocytes. With increasing age, the number of ephelides and color intensity tend to diminish. In contrast, the number of lentigines tends to increase. In general, no therapeutic intervention is required.

Oral/Labial Melanotic Macule

Etiology and Pathogenesis

The melanotic macule is a unique, benign, pigmented lesion that has no known dermal counterpart. Melanotic macules are the most common oral lesion of melanocytic origin. In one large-scale retrospective study, melanotic macules made up over 85% of all solitary melanocytic lesions.[11] Although the etiology remains elusive, trauma has been postulated to play a role. Sun exposure is not a precipitating factor.

Figure 5-3 Ephelis of the lower vermilion border. Brown pigmented macule with circumscribed borders on the left lower vermilion border.

Clinical Features

Melanotic macules develop more frequently in females, usually in the lower lip (labial melanotic macule) and gingiva. However, any mucosal site may be affected. Although the lesion may develop at any age, it generally tends to present in adulthood. Congenital melanotic macules have been described, occurring primarily in the tongue.[12] Overall, melanotic macules tend to be small (<1 cm), well-circumscribed, oval or irregular in outline, and often uniformly pigmented (Figure 5-4). Once the lesion reaches a certain size, it does not tend to enlarge further. Unlike an ephelis, a melanotic macule does not become darker with continued sun exposure. Overall, the oral melanotic macule is a relatively innocuous lesion, and in general will not recur following surgical removal. However, an apparent association between oral melanotic macule and melanoma has been documented.[13]

Pathology

Microscopically, melanotic macules are characterized by the presence of abundant melanin pigment in the basal cell layer without an associated increase in the number of melanocytes (Figure 5-5). Pigmentation is often accentuated at the tips of the rete pegs, and melanin incontinence into the subjacent lamina propria is commonly encountered. Melanocytic hyperplasia is an ominous microscopic finding that may herald the development of malignant melanoma.

Differential Diagnosis

The differential diagnosis includes melanocytic nevus, malignant melanoma, amalgam tattoo, and focal ecchymosis. If such pigmented lesions are present after a two-week period, ecchymosis can usually be ruled out.

Management

A biopsy specimen should be obtained to secure a definitive diagnosis. Once the microscopic diagnosis is obtained, no further treatment is necessary. Since oral mucosal malignant melanomas have no defining clinical characteristics, a biopsy of any persistent solitary pigmented lesion is always warranted.

Oral Melanoacanthoma

Etiology and Pathogenesis

Oral melanoacanthoma is an innocuous melanocytic lesion that may spontaneously resolve, with or without surgical intervention.[14] Although the term *melanoacanthoma* may imply a neoplastic process, the oral lesion is actually reactive in nature. Most patients report a rapid onset, with acute trauma or a history of chronic irritation preceding the development of the lesion. A biopsy is always warranted to confirm the diagnosis, but once rendered, no further treatment is required. The biopsy procedure itself may lead to spontaneous regression of the lesion. If it has been identified, the underlying source of the irritation should be eliminated in order to minimize recurrence.

Clinical Features

Oral melanoacanthoma usually presents as a rapidly enlarging, ill-defined, darkly pigmented flat or slightly elevated lesion with a predilection for black females. Although lesions may present over a wide age range, the majority occur between the third and fourth decades of life. Typically, melanoacanthoma presents as a solitary lesion; nevertheless, bilateral and multifocal lesions have been reported.[15]

Oral melanoacanthomas are generally asymptomatic; however, pain may be present.[14] Although any mucosal surface may be involved, close to 50% of melanoacanthomas arise on the buccal mucosa.[15] The size of the lesion is variable, ranging from small and localized to large, diffuse areas of involvement, measuring several centimeters in diameter. The borders are typically irregular in appearance, and the pigmentation may be uneven (Figure 5-6).

Although there is a recognized cutaneous melanoacanthoma,[16] it is clear that the similarities with oral melanoacanthoma lie solely in the nomenclature. Cutaneous melanoacanthoma represents a pigmented variant of seborrheic keratosis and typically occurs in older Caucasian patients. Dermatosis papulosa nigra is a relatively common facial condition that typically manifests in older black patients, often female, and represents multiple pigmented seborrheic keratoses.[17] These small papules are often identified in the malar and preauricular regions of the face.

Figure 5-6 Melanoacanthoma. Pigmented macule on the attached and marginal gingiva displaying irregular borders. *Source:* Reproduced from Tapia JL, Quezada D, Gaitan L, et al. Gingival melanoacanthoma: case report and discussion of its clinical relevance. *Quintessence Int.* 2011;42(3):253–258, with permission from Quintessence International.

Pathology

Microscopically, oral melanoacanthomas are characterized by a proliferation of benign, dendritic melanocytes throughout the full thickness of an acanthotic and spongiotic epithelium (Figure 5-7).[14] A mild lymphocytic infiltrate with exocytosis is also characteristic. Occasional eosinophils may be observed.

Differential Diagnosis

Pigmented nevus, melanotic macule, and melanoma should be included in the differential diagnosis.

Management

A biopsy is warranted to obtain a definitive diagnosis. No further treatment is indicated.

Melanocytic Nevus

Etiology and Pathogenesis

Melanocytic nevi include a diverse group of clinically and/or microscopically distinct lesions.[18] Unlike ephelides and melanotic macules, which result from an increase in melanin pigment synthesis, nevi arise as a consequence of melanocytic growth and proliferation.[11] In the oral cavity, the intramucosal nevus is most frequently observed, followed by the common blue nevus.[19] Compound nevi are less common, and the junctional nevus and combined nevus (a nevus composed of two different cell types) are infrequently identified. Rare reports of congenital nevus, Spitz nevus, balloon cell nevus, and the cellular, epithelioid, and plaque type variants of blue nevus have also been described. However, the list of morphologically distinct nevi continues to expand.

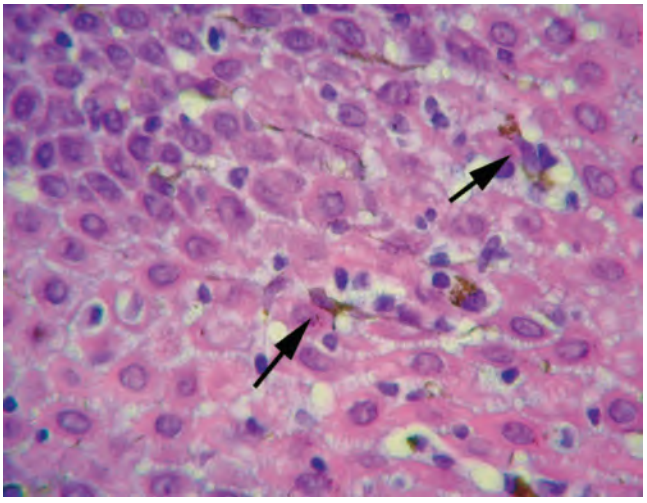

Figure 5-7 Melanoacanthoma. Dendritic-shaped, pigmented melanocytes (arrows) are noted throughout the full thickness of a spongiotic and acanthotic epithelium (hematoxylin-eosin stain; ×400 original magnification).

Relatively little is known about the pathogenesis of the various melanocytic nevi. In fact, there is still debate as to whether "nevus cells" are a distinct cell type derived from the neural crest or if they are simply a unique or immature form of melanocyte.[4] Nonetheless, the lesional nevus cells are cytologically and biologically distinct from the melanocytes that colonize the basal cell layer of the epidermis and oral epithelium. Whereas native melanocytes tend to have a dendritic morphology, most nevic cells tend to be round, ovoid, or spindle shaped.[20] Additional differences include the tendency for nevus cells to closely approximate one another, if not aggregate in clusters, and their ability to migrate into and/or within the submucosal tissues.

In general, both genetic and environmental factors are thought to play a role in nevogenesis. The effect of sun exposure on the development of cutaneous nevi is well recognized. However, there are also age- and location-dependent differences in the presentation, number, and distribution of nevi. Although most melanocytic nevi are acquired, some may present as congenital lesions (including those in the oral cavity). Moreover, there are several examples of increased nevus susceptibility in various inherited diseases, thus confirming the role of genetics. To illustrate: familial atypical multiple mole and melanoma syndrome is characterized by the formation of histologically atypical nevi,[21] blue nevus may be associated with the Carney complex,[22] markedly increased numbers of common nevi are characteristic in patients with Turner's syndrome[23] and Noonan's syndrome,[24] and congenital nevi are typical of neurocutaneous melanosis.[25] Thus, these findings also bring into question whether nevi are true benign neoplasms or hamartomatous or developmental in nature, as they have been historically characterized. A study by Pollock and colleagues demonstrated that up to 90% of dermal melanocytic nevi exhibit somatic, activating mutations in the *BRAF* oncogene.[26] Mutations in the *HRAS* and *NRAS* oncogenes have also been identified.[27,28] This lends further credence to the notion that cutaneous melanocytic nevi are neoplastic. It is currently unknown whether oral melanocytic nevi also harbor any of these same mutations.

Clinical Features

Cutaneous nevi are common. The average Caucasian adult may have several nevi; some individuals may have dozens. The total number of nevi occurring in males tends to be higher than that seen in females. In contrast, oral melanocytic nevi are rare solitary lesions that are more common in females.[6]

Oral melanocytic nevi have no distinguishing clinical characteristics. Lesions are usually asymptomatic and often present as a small (<1 cm), solitary, brown or blue, well-circumscribed nodule or macule (Figure 5-8). Up to 15% of

Figure 5-8 Intramucosal nevus of the right buccal mucosa.

oral nevi may be amelanotic. Once the lesion reaches a given size, its growth tends to cease and may remain static indefinitely. In rare cases, multifocal lesions have been described.[29] Whereas some studies suggest a greater prevalence of oral nevi in black patients, other studies have not identified any significant racial predilection. Oral nevi may develop at any age; however, most are identified in patients over the age of 30. The hard palate represents the most common site, followed by the buccal and labial mucosae and gingiva.

Pathology

Nevus cells initially maintain their residency at the basal layer, as cellular clusters at the junction of the epithelium and the underlying connective tissue (Figure 5-9). These junctional nevi are usually small (<5 mm), macular, and tan to brown in color. Over time, the clustered melanocytes are thought to proliferate down into the connective tissue, often in the form of variably sized nests of relatively small, rounded cells. Nonetheless, some nevus cells may still be seen at the epithelial–connective tissue interface. Such nevi often assume a dome-shaped appearance and are referred to as compound nevi. As the lesion further matures, the nevus cells completely lose their association with the epithelial layer and become confined to the lamina propria, often with an associated decrease in the amount of pigmentation. At this point, the lesion is given the designation of intramucosal nevus and, clinically, may appear brown, tan, or may even resemble the color of the surrounding mucosa.

Blue nevi are characterized by a variety of microscopic features. The "common" blue nevus, which is the most frequent histologic variant seen in the oral cavity, is characterized by a stromal proliferation of pigment-laden, spindle-shaped melanocytes. The blue nevus is described as such because the melanocytes that reside deep in the connective tissue and the overlying fibrous connective tissue often conceal the brown color of melanin, resulting in a blue tint. The less frequently occurring cellular blue nevus is characterized by a stromal proliferation of both spindle-shaped and larger round or ovoid-shaped melanocytes. It should be noted that histologic differentiation of the two forms is not merely academic. Whereas the common blue nevus usually has an innocuous

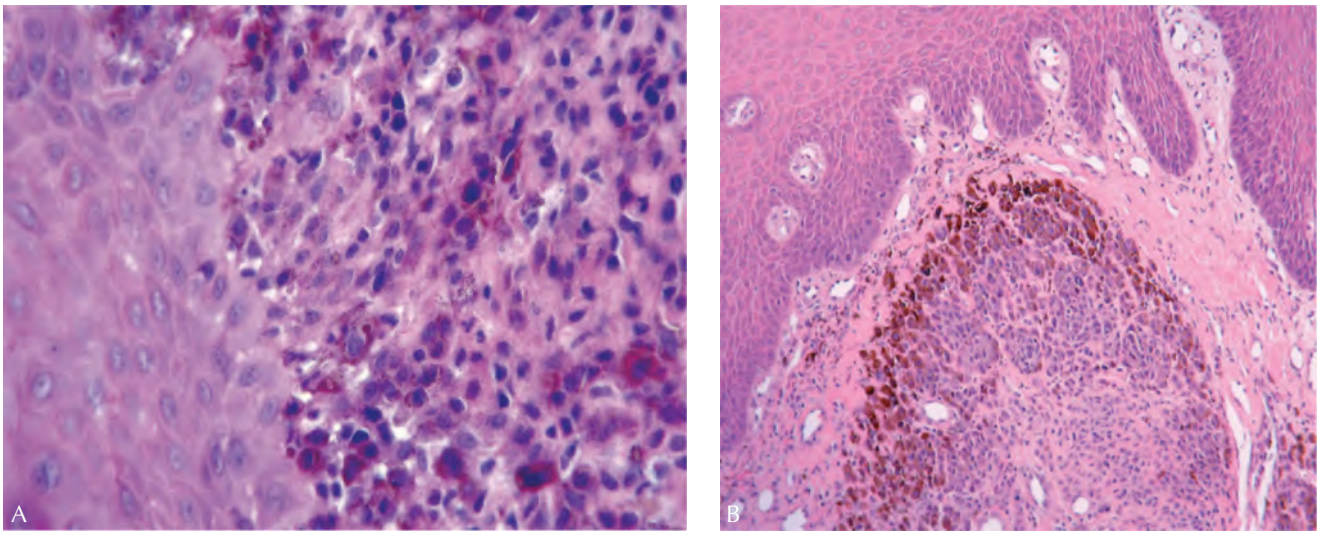

Figure 5-9 (A) Compound nevus: nevus cells are located at the junction of the epithelium and connective tissue and within the submucosal tissue. The cells are variably pigmented (hematoxylin-eosin stain; ×400 original magnification). (B) Intramucosal nevus: the nevus cells are located within the lamina propria, with no evidence of any junctional component. The superficial melanocytes are heavily pigmented. Melanin is less evident in the remaining cells (hematoxylin-eosin stain; ×100 original magnification).

clinical course, the cellular blue nevus may behave more aggressively and exhibit a greater rate of recurrence.[30] Rare reports of malignant transformation have also been associated with the cellular cutaneous variant.

While cutaneous acquired nevi and dysplastic nevi may represent precursors of malignant melanoma, there is no evidence of an increased malignant transformation rate for melanocytic nevi of the mouth. Nonetheless, it is advised that all oral nevi, regardless of histologic type, should be completely removed.[31]

Differential Diagnosis

The differential diagnosis includes a variety of other focally pigmented lesions, including malignant melanoma. Various vascular lesions and exogenous pigmentations may also be considered in the differential diagnosis.

Management

Biopsy is necessary for diagnostic confirmation of an oral melanocytic nevus. Complete but conservative surgical excision is the treatment of choice for oral lesions. Recurrence has only rarely been reported. Laser and intense pulse light therapies have been used successfully for the treatment of cutaneous nevi.[32] However, their value in the treatment of oral nevi is unknown.

Malignant Melanoma

Etiology and Pathogenesis

Malignant melanoma is the least common but most deadly of all primary skin cancers. Similar to other malignancies, extrinsic and intrinsic factors play a role in its pathogenesis. A history of multiple episodes of acute sun exposure, especially at a young age; immunosuppression; the presence of multiple cutaneous nevi; and a family history of melanoma are all known risk factors for the development of cutaneous melanoma.[33] Melanoma-prone families have a high incidence of germline mutations in the tumor suppressor genes, *CDKNA2/p16*^{INK4a} or, less commonly, *CDK4*.[34] Similar to melanocytic nevi, melanomas also frequently exhibit mutations in the *BRAF*, *HRAS*, and *NRAS* proto-oncogenes.[27,35] Other recurrent molecular findings, including *MC1R* polymorphisms and alterations or loss of PTEN function, have also been described.[36,37] This suggests that several distinct genetic changes are required for the molecular evolution of melanoma.

Clinical Features

Cutaneous melanoma is most common in white people living in sunbelt regions of the world. However, mortality rates are higher in black and Hispanic people. Epidemiologic studies suggest that its incidence is increasing in patients, especially males, over the age of 45.[38] In contrast, the incidence is decreasing in patients under the age of 40. Despite an overall predilection for males, melanoma is one of the most commonly occurring cancers in women of child-bearing age.[39]

Melanomas may develop either de novo or, less commonly, from an existing melanocytic nevus.[33] The malar region is a common site for melanoma because this area is subject to significant solar exposure. In general, the clinical characteristics of cutaneous melanoma are best described by the ABCDE criteria: asymmetry, irregular borders, color variegation, diameter greater than 6 mm, and evolution or surface elevation. These criteria are very useful (although not absolute) in differentiating cutaneous melanoma from other focal, pigmented melanocytic lesions.[40]

There are four main clinicopathologic subtypes of cutaneous melanoma: superficial spreading melanoma, lentigo maligna melanoma, acral lentiginous melanoma, and nodular melanoma (Figures 5-10 and 5-11).[33] In the first three subtypes, the initial growth is radial, where the melanocytic tumor cells spread laterally and therefore superficially. These lesions have a good prognosis if they are detected early and treated before the onset of nodular lesions, which would indicate invasion into the deeper connective tissue (i.e., a vertical growth phase). The development of nodularity in a previously macular lesion is an ominous sign.

The prognosis of melanoma can be ascertained by Breslow's tumor thickness criteria, or Clark's level of invasion. Microscopic findings such as surface ulceration, vascular or lymphatic invasion, neurotropism, high mitotic index, and absence of lymphocytes infiltrating the tumor are all associated with a poor prognosis.[6] Additionally, various clinical parameters, including tumor site, age of the

Figure 5-10 Cutaneous macular melanoma fulfilling the ABCDE criteria. *Source:* Courtesy of Dr. Gyorgi Paragh, Department of Dermatology, Roswell Park Comprehensive Cancer Center, Buffalo, NY, USA.

patient (>60 years), sex (male), and regional or distant metastasis, also are predictive of poor prognosis. The 5-year survival rate of patients with metastatic melanoma is less than 15%.[33]

Awareness of the epidemiologic and biologic properties of cutaneous melanoma is necessary for the clinical practitioner. However, these factors have little bearing on the clinical, histologic, demographic, and biologic profiles associated with primary mucosal malignant melanoma. In brief, mucosal melanomas are very distinct neoplasms.[41,42]

Primary mucosal melanomas comprise less than 1% of all melanomas.[41,43] The majority develop in the head and neck, mainly in the sinonasal tract and oral cavity. The prevalence of oral melanoma appears to be higher among black and Japanese people than in other populations.[41,44] The tumor presents more frequently in males than in females. Unlike the cutaneous variant, which has distinct and well-recognized risk factors associated with its development, the etiology of oral melanoma remains unknown. *BRAF* mutations are rarely observed in mucosal melanomas.[42]

Oral melanoma may develop at any age, but is most prevalent over the age of 50.[44,45] Any mucosal site may be affected; however, the palate represents the most common site of involvement, followed by the maxillary gingiva/alveolar crest.[46] Oral melanomas have no distinctive clinical features. They may present as macular, plaque like, or as a mass, well-circumscribed or irregular, and may exhibit focal or diffuse areas of brown, blue, or black pigmentation (Figure 5-12). Up to one-third of oral melanomas exhibit little or no clinical evidence of pigmentation (amelanosis).[47] In some cases, oral melanomas may display multifocal areas of pigmentation. This phenomenon most likely represents both melanotic and amelanotic areas.[44,47]

Additional signs and symptoms that may be associated with oral melanoma are nonspecific and similar to those observed with other malignancies. Ulceration, pain, tooth mobility or spontaneous exfoliation, root resorption, bone loss, and paresthesia/anesthesia may be evident. However, in some patients the tumors may be completely asymptomatic.[43] Thus, the clinical differential diagnosis may be quite extensive and could include melanocytic nevus, oral melanotic macule, and amalgam tattoo, as well as various vascular lesions and other soft tissue neoplasms. It is for this reason that a biopsy of any persistent solitary pigmented lesion is always warranted.[48]

(B) Malignant melanoma presenting as a mass on the maxillary gingiva. Courtesy of Dr. Rocio Fernandez, National Autonomous University of Mexico, Mexico City, Mexico.

Oral mucosal malignant melanoma is associated with a very poor prognosis. Studies have demonstrated 5-year survival rates of 15–40%.[43,44] Involvement of the palate is predictive of the worst prognosis compared to other intraoral sites.[49] Regional lymphatic metastases are frequently identified and contribute to the poor survival rate.[50] Less than 10% of patients with distant metastases survive after 5 years.[44] The 10-year survival rate is 0%.[51]

Pathology

Microscopically, oral mucosal melanomas (like cutaneous melanomas) may exhibit radial or vertical growth patterns. The radial or superficial spreading pattern is often seen in macular lesions, where clusters of pleomorphic melanocytes exhibiting nuclear atypia and hyperchromatism proliferate within the basal cell region of the epithelium. Upward spreading of abnormal melanocytes (pagetoid spread) and superficial invasion of the papillary lamina propria are evident (Figure 5-13).[3] Once vertical growth into the connective tissue is established, the lesions become clinically tumefactive.

Owing to its rare occurrence, even the most renowned clinical cancer centers do not have a large enough cohort of oral melanoma cases to reliably and significantly correlate the histologic findings with prognosis.[44] Thus, apart from tumor thickness greater than 5 mm and the presence of lymphovascular invasion, many of the histologic prognostic parameters of cutaneous melanoma (i.e., Breslow's classification and Clark's level of invasion) do not apply to oral melanoma.[3,6,47]

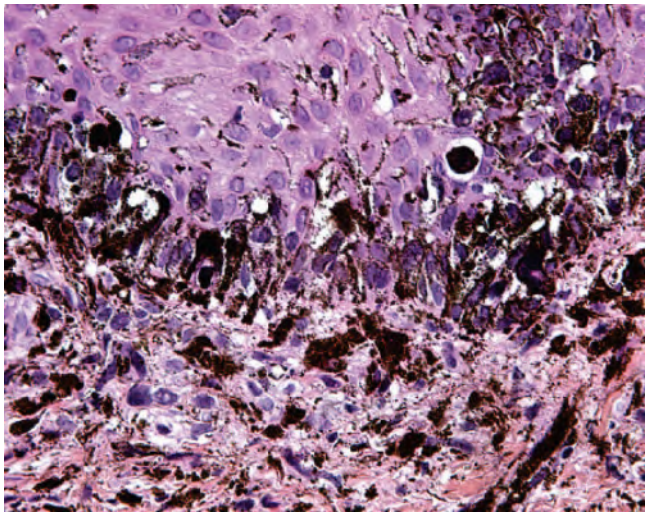

Figure 5-13 Heavily pigmented malignant melanoma exhibiting a primarily radial growth phase with pagetoid spread of tumor cells (hematoxylin and eosin stain; ×400 original magnification). *Source:* Photomicrograph courtesy of Dr. Julien Ghannoum.

Diagnosis

One of the main clinical and microscopic challenges in diagnosing oral melanoma is determining whether the lesion is a primary neoplasm or a metastasis from a distant site. This is not a semantic distinction, since confirming the primary site will dictate the patient's clinical stage and the type of therapy they will undergo. A history of a previous melanoma, sparing of the palate and gingiva, amelanosis, and microscopic features such as a lack of junctional activity and pagetoid spread are findings that may be more suggestive of a metastatic tumor.[6]

Management

For primary oral melanomas, ablative surgery with wide margins remains the treatment of choice.[3,44] Adjuvant radiation therapy may also be necessary.[52] However, it remains unclear whether radiation therapy alone is beneficial for the treatment of oral mucosal melanoma.[53] Computed tomography and magnetic resonance imaging studies should be undertaken to explore metastases to the regional lymph nodes. A variety of chemo- and immunotherapeutic strategies are often used if metastases are identified or for palliation.[3]

Melanoma is one of the most immunogenic cancers, and there are several clinical immunotherapeutic trials currently being conducted to test the effects of various antitumor vaccines. Adjuvant interferon-α-2B therapy has already been approved for the treatment of primary cutaneous melanomas more than 4 mm in thickness.[54] Unusual side effects of chemo- and immunotherapy may include the onset of autoimmunity. The appearance of autoantibodies and clinical manifestations of autoimmune disease, including vitiligo, have been associated with statistically significant improvements in overall survival rates for patients with cutaneous melanoma.[55] The discovery of KIT and BRAF mutations and the development of novel immunotherapeutic agents that specifically target and inhibit these oncogenic pathways have provided new alternative treatments.[56] Small molecule targeted therapy (BRAF and MEK inhibitors) and immune checkpoint inhibitors (CTLA-4 and PD-1) have shown promising clinical outcomes. However, the adverse effects associated with BRAF and MEK inhibitors are extensive, ranging from inflammatory to malignant conditions. Similarly, immune checkpoint inhibitors may result in a number of adverse side effects including autoimmunity (e.g., bullous pemphigoid, lichen planus pemphigoid, dermatomyositis, etc.). Viral oncolytic therapies (using a modified herpes simplex virus-1) are now also available. Collectively, these novel therapeutic venues for the treatment of melanoma have improved overall survival.[57]

MULTIFOCAL/DIFFUSE PIGMENTATION

Physiologic Pigmentation

Physiologic pigmentation is the most common multifocal or diffuse oral mucosal pigmentation (Table 5-4). Dark-complexioned individuals, including black, Asian, and Latino people, frequently show patchy to generalized hyperpigmentation of the oral mucosal tissues. In many patients, the pigment is restricted to the gingiva; however, melanosis of other mucosal surfaces is not uncommon (Figure 5-14). The pigment is typically first observed during childhood and does not develop de novo in the adult. The sudden or gradual onset of diffuse mucosal pigmentation in adulthood, even in darker-skinned patients, should alert the clinician to contemplate a pathologic genesis. A wide differential diagnosis should be considered (i.e., drug-induced or smoking-induced melanosis, an endocrinopathy, or a syndromic condition). A thorough history and laboratory tests are necessary to obtain a precise diagnosis.

Microscopically, physiologic pigmentation is characterized by the presence of increased amounts of melanin within the basal cell layer. This pigmentation is considered a variation of normal. Nonetheless, the appearance of brown to black discoloration, even intraorally, can be esthetically displeasing to some patients. Thus, surgical intervention may be necessary. Gingivectomy, laser therapy, and cryosurgery can all effectively remove oral pigmentation.[58] However, with each of these modalities, there is a possibility that the pigmentation may eventually recur. The mechanism of such repigmentation remains unclear.

Drug-Induced Melanosis

Etiology and Pathogenesis

Medications may induce a variety of different forms of mucocutaneous pigmentation, including melanosis. Pigmentation that is caused by the soft tissue deposition of drug metabolites or complexes and pigment associated with deposition of lipofuscin or iron are discussed later in this chapter.

The chief drugs implicated in drug-induced melanosis are the antimalarials, including chloroquine, hydroxychloroquine, and quinacrine (Figure 5-15).[59] In the Western world, these medications are typically used for the treatment of autoimmune disease. Other common classes of medications that induce melanosis include the phenothiazines

Figure 5-15 Drug-induced pigmentation of the palate in a patient who was taking quinacrine for the treatment of discoid lupus erythematosus. *Source:* Lerman MA, Karimbux N, Guze KA, Woo S-B. Pigmentation of the hard palate. Oral Surg Oral Med Oral Pathol Oral Radiol Endod. 2009;107(1):8–12. Reproduced with permission from Elsevier.

(e.g., chlorpromazine), oral contraceptives, cytotoxic medications such as cyclophosphamide and busulfan, as well as tyrosine kinase inhibitors used for the treatment of chronic myeloid leukemia and gastric intestinal stromal tumor (imatinib) (Figure 5-16).[60]

Table 5-5 lists selected known melanin-inducing medications.

Clinical Features

It has been estimated that 10–20% of all cases of acquired melanocytic pigmentation may be drug induced. Intraorally, the pigment can be diffuse yet localized to one mucosal surface, often the hard palate, or it can be multifocal and involve multiple surfaces. Some drugs may even be associated with a specific pattern of pigmentation. Much like other forms of diffuse pigmentation, the lesions are flat and without any evidence of nodularity or swelling. Sun exposure may exacerbate cutaneous drug-induced pigmentation.[59]

Pathology

Microscopically, there is evidence of basilar hyperpigmentation and melanin incontinence without a concomitant increase in the number of melanocytes. Although the mechanisms by which melanin synthesis is increased remain unknown, it is possible that the associated drugs or drug metabolites may stimulate melanogenesis. Alternatively, some drugs, including chloroquine and chlorpromazine, have been shown to physically bind melanin.[61] This complexation of melanin and drugs within melanocytes may contribute to the adverse mucocutaneous effects.

Quinidine

Differential Diagnosis

A differential diagnosis includes other causes of diffuse mucosal pigmentation. Laboratory tests may be necessary to rule out an underlying endocrinopathy.

Management

If the onset of the melanosis can be chronologically and accurately associated with the initial use of a specific medication (frequently within several weeks or months before development of the pigmentation), then no further intervention is warranted. In most cases, the discoloration tends to fade within a few months after the drug is discontinued.[59] However, pigmentation associated with hormone therapy may tend to persist for longer periods of time, despite discontinuation of the medications.

Smoker's Melanosis

Diffuse melanosis of the anterior vestibular maxillary and mandibular gingivae, buccal mucosa, lateral tongue, palate, and floor of the mouth is occasionally seen among cigarette smokers.[15] Most smokers (including heavy smokers) typically

Figure 5-17 Smoker's melanosis. The attached mandibular left gingiva shows pigmented macules on the side where the patient places the cigarette to smoke.

fail to show such changes. However, in certain individuals, melanin synthesis may be stimulated by tobacco smoke products. Indeed, among dark-skinned individuals who normally exhibit physiologic pigmentation, smoking can stimulate a further increase in oral pigmentation.[62] These pigmented areas present as brown, flat, and irregular, with some even geographic or map-like in configuration (Figure 5-17).

The mechanism by which smoking induces pigmentation remains unknown. Smokeless tobacco (snuff) does not appear to be associated with an increase in oral melanosis.[63] Thus, it is possible that one or more of the chemical compounds incorporated within cigarettes, rather than the actual tobacco, may be causative. Another possibility is that the heat of the smoke may stimulate oral pigmentation. Interestingly, passive smoking in children may also result in increased gingival pigmentation.[64]

Epidemiologic studies suggest that the incidence of oral melanosis conspicuously increases during the first year of smoking.[63] A reduction in smoking may lead to fading of the pigmentation. Histologically, basilar melanosis and melanin incontinence are observed. Unlike other smoking-related oral conditions, smoker's melanosis is not a preneoplastic condition.[65]

Alcohol has also been associated with increased oral pigmentation of the posterior regions of the mouth, including the soft palate. It has been suggested that alcoholic melanosis may be associated with a higher risk of cancers of the upper aerodigestive tract.[66]

Diffuse or patchy melanotic pigmentation is also associated with oral submucous fibrosis. Unlike smoker's melanosis, oral submucous fibrosis is a preneoplastic condition caused by habitual chewing of the areca (betel) nut. This custom is common in some East Asian cultures. In cases of alcoholic melanosis, increased fibrosis of the oral soft tissues is characteristically present.

Postinflammatory (Inflammatory) Hyperpigmentation

Postinflammatory hyperpigmentation is a well-recognized phenomenon that tends to develop more commonly in dark-complexioned individuals. Most cases present as either focal or diffuse pigmentation in areas that were subjected to previous injury or inflammation.[67] The acne-prone face is a relatively common site for this phenomenon. Although unusual, postinflammatory pigmentation may also develop in the oral cavity.[68] In rare cases, the mucosa overlying a nonmelanocytic malignancy may become pigmented.[69]

Oral pigmentation has also been described in patients with lichen planus (lichen planus pigmentosus).[68] This phenomenon has been described in various races, including Caucasians (Figure 5-18). In addition to the typical microscopic features associated with lichen planus, there is also evidence of basilar hyperpigmentation and melanin incontinence. Upon resolution of the lichenoid lesion, in most cases the pigmentation eventually does subside. Although it may be mere semantics, it is unclear whether lichen planus–associated pigmentation should be appropriately characterized as postinflammatory or inflammatory pigmentation. In addition, spontaneous postsurgical healing pigmentation of palatal donor sites for free gingival grafts has been reported.[70]

Melasma (Chloasma)

Melasma is a relatively common, acquired symmetric melanosis that typically develops on sun-exposed areas of the skin and frequently on the face. More than 5 million people in the United States have this condition.[71] The forehead,

Figure 5-18 Lichen planus–associated pigment. Classic-appearing Wickham's striae and surrounding pigmentation are seen in this Caucasian patient with biopsy-proven lichen planus. *Source:* Courtesy of Dr. Carl Allen. The Ohio State University, Columbus, OH, USA.

Figure 5-19 Melasma. A 48-year-old Hispanic female with patchy pigmentation on the left side of her face that developed during her first pregnancy 15 years earlier.

cheeks, upper lips, and chin are the most commonly affected areas (Figure 5-19). There is a distinct female predilection, and most cases arise in darker-skinned individuals. Unlike other forms of diffuse melanosis, melasma tends to evolve rather rapidly over a period of a few weeks.

The term *melasma* has been used to describe any form of generalized facial hyperpigmentation, including that related to postinflammatory changes and medication use. However, the term is most appropriately used to describe the pigmentary changes associated with sun exposure and hormonal factors, including pregnancy and contraceptive hormones.[71] Both pregnancy and use of oral contraceptives have also been associated with oral mucosal melanosis.[72] Rare cases of idiopathic melasma have also been described in females and, much less commonly, in males.[73,74] In most cases, it is the combination of estrogen and progesterone that induces the pigment. Estrogen replacement therapy alone, without progesterone, does not precipitate melasma. In idiopathic cases, significantly elevated levels of luteinizing hormone have been identified in both sexes, with associated decreases in serum estradiol (in women) and testosterone (in males). Despite the existence of evidence on the hormonal pathogenesis of melasma, the available data is conflicting, which is perhaps due to the varied genetic background of the populations studied. In light of the findings from some research studies, it appears that hormones may play a role in some patients' melasma; however, the association is weaker than previously believed.[71] Various thyroid abnormalities, including hypothyroidism, also may play a role in the pathogenesis of pregnancy- and non-pregnancy-associated melasma.[75]

A biopsy typically reveals basilar melanosis with no increase in the number of melanocytes. However, the melanocytes that are present may be larger than those in the adjacent normally pigmented areas.[76] Melasma may spontaneously resolve after parturition, cessation of the exogenous hormones, or regulation of endogenous sex-hormone levels. A successful therapeutic approach for the treatment of melasma consists of the topical administration of a triple-combination product (4% hydroquinone, 0.05% tretinoin, and 0.01% fluocinolone acetonide) along with photoprotection (SPF 30 sunscreen).[77]

MELANOSIS ASSOCIATED WITH SYSTEMIC OR GENETIC DISEASE

Hypoadrenocorticism (Adrenal Insufficiency, Addison's Disease)

Etiology and Pathogenesis

Hypoadrenocorticism is a potentially life-threatening disease, as much for its systemic complications as its underdiagnosis. A variety of etiologies may precipitate adrenal insufficiency.[15] In adults, autoimmune disease represents one of the most common causes where the majority of patients show the presence of circulating autoantibodies to steroidogenic enzyme 21-hydroxylase. However, infectious agents, neoplasia, trauma, certain medications, and iatrogenic causes may also lead to adrenal destruction or an impairment of endogenous steroid production. In rare cases, adrenal insufficiency may also be a consequence of genetic disease.[78] Regardless of etiology, the end result is essentially the same: a decrease in endogenous corticosteroid levels.

As steroid levels decrease, there is a compensatory activation of ACTH secretion from the anterior pituitary gland. ACTH then acts on the adrenal cortex to stimulate steroid production and ACTH secretion stops. If low steroid levels persist, there will be a loss of feedback inhibition, resulting in persistent secretion of ACTH into the serum. Concurrently, the serum levels of α-melanocyte-stimulating hormone (α-MSH) will also increase. At the molecular level, this is explained by the fact that the precursor pro-opiomelanocortin gene contains the sequences of both the *ACTH* and *α-MSH* genes. During

processing of the progenitor hormone, the *ACTH* and *α-MSH* genes may be cleaved independently of one another, thus creating two distinct hormones. However, the *α-MSH* sequence is actually contained within a portion of the *ACTH* gene; in fact, the first 13 amino acids of the ACTH hormone are identical to α-MSH. Upon cellular processing of the ACTH messenger ribonucleic acid transcript, the sequence containing the α-MSH gene is cleaved and is further processed into its own secretable form. Apart from the wide array of tissues and organs that these hormones act upon, both α-MSH and ACTH are also thought to have stimulatory effects on melanocytes.[79] However, the exact mechanism by which melanin synthesis increases remains unclear.

Clinical Features

Weakness, poorly defined fatigue, and depression are some of the typical presenting signs of the illness. However, in some patients the first sign of disease may be mucocutaneous hyperpigmentation. Generalized bronzing of the skin and diffuse/patchy melanosis of the oral mucosa are hallmarks of hypoadrenocorticism. Any oral surface may be affected. In some patients, oral melanosis may be the first manifestation of adrenal disease (Figure 5-20).[15] Diffuse hyperpigmentation is more commonly associated with chronic rather than acute-onset disease.

Differential Diagnosis

The diagnosis of oral Addisonian pigmentation requires a clinicopathologic correlation. Endocrinopathic disease should be suspected whenever oral melanosis is accompanied by cutaneous bronzing. A biopsy of the area will typically reveal increased melanin in the basal cell layer with melanin incontinence. Therefore, the differential diagnosis will include other causes of diffuse pigmentation, including physiologic and drug-induced pigmentation. Laboratory tests, including the evaluation of serum cortisol and electrolyte levels, are necessary to make a diagnosis of Addisonian hyperpigmentation. Serum cortisol levels of less than 100 nmol/L at 9:00 a.m. are diagnostic of deficiency.[80] Hyponatremia and hyperkalemia are frequently associated with adrenal insufficiency.

Management

Treatment consists of exogenous steroid replacement therapy with glucocorticoids and mineralocorticoids. There is evidence supporting the use of adrenal androgens such as dehydroepiandrosterone (DHEA) to improve the quality of life of patients with Addison's disease.[80] With appropriate therapy, the pigmentation will eventually resolve.

Cushing's Syndrome/Cushing's Disease

Etiology and Pathogenesis

Cushing's syndrome develops as a consequence of prolonged exposure to relatively high concentrations of endogenous or exogenous corticosteroids. Most cases are iatrogenic in origin and associated with poorly controlled or unmonitored use of topical or systemic steroids. However, Cushing's syndrome may also arise as a result of various endogenous etiologies, such as an activating pituitary tumor (Cushing's disease) or a primary, activating, adrenal pathology (hyperadrenocorticism), as well as from the ectopic secretion of corticosteroids, ACTH, or corticotropin-releasing hormone

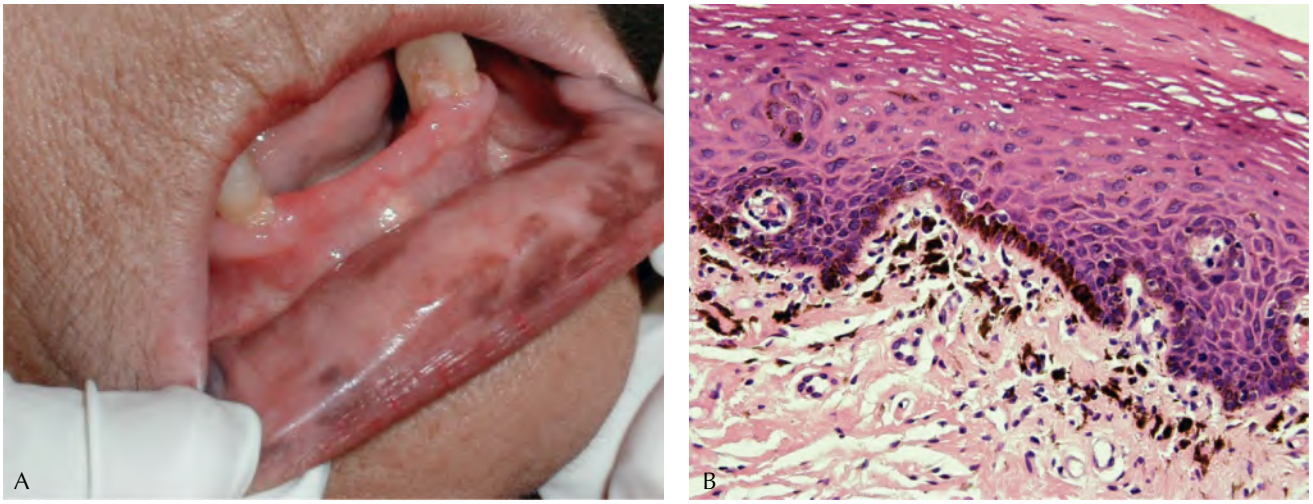

Figure 5-20 Addison's disease. (A) Patchy brown areas of pigmentations in the labial mucosa of an individual with Addison's disease. by various neoplasms, including small cell carcinoma of the lung.[48] In addition, Cushing's syndrome has been described in patients with activating, germline mutations in the ACTH receptor.[81]

Clinical Features

Overall, Cushing's syndrome is more prevalent in female patients. However, prepubertal onset is more commonly seen in boys. Apart from the wide array of systemic complications, including weight gain and the characteristic "moon facies," diffuse mucocutaneous pigmentation may be seen in a subset of patients, specifically those whose pathology is associated with increased ACTH secretion. Thus, in most cases, the affected patients have a primary pituitary neoplasm.[48] Interestingly, the pattern of oral pigmentation is essentially identical to that seen in patients with adrenal insufficiency.

Diagnosis

Three main tests are used for the diagnosis of Cushing's syndrome: low-dose dexamethasone suppression, midnight plasma cortisol, and 24-hour urinary free cortisol.[48] The pigmentation often resolves following appropriate surgical, radiation, or drug therapy for the specific source of the endocrinopathy. Pasireotide (a somatostatin analogue) is US Food and Drug Administration (FDA) approved for the treatment of Cushing's syndrome.[82]

Hyperthyroidism (Graves' Disease)

Melanosis is a common consequence of hyperthyroidism (Graves' disease), particularly in dark-skinned individuals. Studies suggest that at least 40% of black patients with thyrotoxicosis may present with mucocutaneous hyperpigmentation.[83] In contrast, melanosis is very rarely observed in Caucasian patients with the disease. The pigmentation tends to resolve following treatment of the thyroid abnormality. The mechanism by which excessive thyroid activity stimulates melanin synthesis remains unclear.

Primary Biliary Cirrhosis

Diffuse mucocutaneous hyperpigmentation may be one of the earliest manifestations of primary biliary cirrhosis.[84] Up to 47% of patients with this condition develop diffuse melanosis. This uncommon disease is of unknown etiology, although it is thought to be autoimmune in nature, as evidenced by the presence of antimitochondrial antibodies. Primary biliary cirrhosis develops mainly in middle-aged women. The disease results from damage to small intrahepatic bile ducts. The mechanism by which the associated melanosis develops is unknown.

Primary biliary cirrhosis may also be a source of generalized nonmelanocytic mucocutaneous discoloration.[84,85] Jaundice is usually an end-stage complication of primary biliary cirrhosis.[85] However, jaundice may also be associated with a variety of other etiologies, including liver cirrhosis, hepatitis, neoplasia, gallstones, congenital disorders, and infection. Jaundice is caused by excessive levels of serum bilirubin (a breakdown product of hemoglobin). Hyperbilirubinemia often induces a yellowish discoloration of the skin, eyes, and mucous membranes. Treatment of the underlying disease will lead to resolution of jaundice. A differential diagnosis should include carotenemia (excessive β-carotene levels) and lycopenemia (excessive lycopene, a compound found within tomatoes and other fruits and vegetables).[86] However, the oral mucosal tissues are not affected in either of these latter conditions.

Vitamin B_{12} (Cobalamin) Deficiency

Vitamin B_{12} deficiency may be associated with a variety of systemic manifestations, including megaloblastic anemia, neurologic signs and symptoms, and various cutaneous and oral manifestations, which may include a generalized burning sensation, erythema, and atrophy of the mucosal tissue. Diffuse mucocutaneous hyperpigmentation is a rare, and poorly recognized, complication of vitamin B_{12} deficiency.[87] This hyperpigmentation is reminiscent of Addison's disease. The mechanisms by which this melanosis develops are unknown. However, the pigmentation resolves following restoration of vitamin B_{12} levels.[88]

Peutz–Jeghers Syndrome

Peutz–Jeghers syndrome is an autosomal dominant disease that is associated with mutations in the *STK11/LKB1* tumor suppressor gene. Clinical manifestations include intestinal polyposis, cancer susceptibility, and multiple, small, pigmented macules of the lips, perioral skin, hands, and feet (Figures 5-21 and 5-22). The macules may resemble ephelides, usually measuring <0.5 cm in diameter. However, the intensity of the macular pigment is not influenced by sun exposure. Although uncommon, similar-appearing lesions may also develop on the anterior tongue and buccal and labial mucosae. The lip and perioral pigmentation is highly distinctive, although not pathognomonic for this disease (see "Laugier–Hunziker Pigmentation").[15] Histologically, these lesions show increased basilar melanin without an increase in the number of melanocytes. The medical management for Peutz–Jeghers syndrome consists of surveillance and treatment of the hamartomatous polyps.[48]

Figure 5-22 Multiple pigmented macules on the fingertips in in an 11-year-old male with Peutz–Jeghers syndrome. *Source:* Courtesy of Dr. Mario E. Ramos, private practice, Midland Park, NJ, USA.

Other genetic and acquired diseases associated with a triad of gastrointestinal disorder, cancer susceptibility, and mucocutaneous pigmented macules, among other findings, include Cowden syndrome (and the allelic Bannayan–Riley–Ruvalcaba as well as Lhermitte–Duclos syndromes) and Cronkhite–Canada syndrome.[89]

Café au Lait Pigmentation

Solitary, idiopathic café au lait ("coffee with milk") spots are occasionally observed in the general population, but multiple café au lait spots are often indicative of an underlying genetic disorder. Café au lait pigmentation may be identified in a number of different genetic diseases, including neurofibromatosis type I, McCune–Albright syndrome, and Noonan's syndrome (Table 5-6).[90] Café au lait spots typically present as tan- or brown-colored, irregularly shaped macules of variable size, which may occur anywhere on the skin. Although unusual, examples of similar-appearing oral macular pigmentation have been described in some patients.[91]

Table 5-6 Diseases commonly associated with café au lait pigmentation.

Source: Based on Shah KN. The diagnostic and clinical significance of cafe-au-lait macules. PediatrClin North Am. 2010(5);57:1131–53.

Neurofibromatosis type I is an autosomal dominant disease caused by a mutation or a deletion of the *NF1* gene localized in chromosome 17.[90] Neurofibromatosis type 1 is associated with the development of multiple neurofibromas of various histologic subtypes. In addition, the size, number, and age at onset of the cutaneous café au lait spots are of diagnostic importance for this disease. Axillary and/or inguinal freckling (Crowe's sign) and pigmented lesions of the iris (Lisch nodules) are also highly characteristic of neurofibromatosis type I.[92]

McCune–Albright syndrome and the genetically and phenotypically similar Mazabraud disease are sporadically occurring diseases that are characterized by polyostotic fibrous dysplasia, various endocrinopathies (McCune–Albright), and soft tissue myxomas (Mazabraud disease). In some patients, Addison's disease or Cushing's syndrome may be a potential consequence

of McCune–Albright syndrome. The appearance of the café au lait spots in McCune–Albright syndrome is distinct from those associated with neurofibromatosis. The borders of the pigmented macules are irregularly outlined, whereas in neurofibromatosis the borders are typically smooth.[90]

Noonan's syndrome and the allelic LEOPARD syndrome (multiple lentigines, electrocardiographic-conduction abnormalities, ocular hypertelorism, pulmonary stenosis, abnormal genitalia, retardation of growth, and sensorineural deafness) are autosomal dominant disorders that, among other findings, are also associated with pigmented mucocutaneous macules and multiple melanocytic nevi.[93] The classic-appearing café au lait spots are more characteristically seen in patients with the Noonan's phenotype. The LEOPARD phenotype is typically associated with numerous, small, freckle-like macules, often involving the facial skin.

Microscopically, when compared with adjacent uninvolved skin, genetic café au lait spots exhibit basilar melanosis without an apparent concomitant increase in the number of melanocytes. The melanocytes show giant melanosomes (macromelanosomes) that may be visible under light microscopy. However, when compared with similar-appearing lesions in otherwise normal patients, genetic café au lait spots do exhibit increased numbers of melanocytes.[90]

The pathogenesis of genetic café au lait pigmentation remains elusive. However, it has been suggested that the colocalization of neurofibromin (the neurofibromatosis type 1 gene) and amyloid precursor protein in melanosomes may be important in the development of the pigmented lesions in neurofibromatosis patients.[94]

HIV/AIDS-Associated Melanosis

Diffuse or multifocal mucocutaneous pigmentation has been frequently described in HIV-seropositive patients.[95] The pigmentation may be related to intake of various medications, including antifungal and antiretroviral drugs,[96] or as a result of adrenocortical destruction by virulent infectious organisms. However, melanosis has also been identified in some patients, including those newly diagnosed, with no history of adrenocortical disease or medication intake. In these patients, the cause of the hyperpigmentation cannot be undetermined.

Several studies suggest that melanosis may be an actual, potentially late-stage, clinical manifestation of HIV/AIDS. Goldstein and colleagues demonstrated a significant correlation between mucocutaneous pigment and CD4 cell counts/μL of 200.[97] Studies have also shown that the immune dysregulation associated with HIV/AIDS leads to increased secretion of α-MSH from the anterior pituitary gland, which may also stimulate increased melanin synthesis.

HIV/AIDS patients may present with a history of progressive hyperpigmentation of the skin, nails, and mucous membranes. The pigmentation resembles most of the other forms of diffuse melanosis. The buccal mucosa is the most frequently affected site, followed by gingiva, palate, and tongue. Like all diffuse melanoses, HIV-associated pigmentation is characterized microscopically by basilar melanin pigmentation and incontinence.

IDIOPATHIC PIGMENTATION

Laugier–Hunziker Pigmentation

Etiology and Pathogenesis

Laugier–Hunziker pigmentation (also known as Laugier–Hunziker syndrome) was initially described as an acquired, idiopathic, macular hyperpigmentation of the oral mucosal tissues, specifically involving the lips and buccal mucosae. Subsequent reports detailed involvement of other oral mucosal surfaces, as well as pigmentation of the esophageal, genital, and conjunctival mucosae and the acral surfaces. Up to 60% of affected patients may also have nail involvement, usually in the form of longitudinal melanotic streaks and without any evidence of dystrophic change.[98] The fingernails are more commonly affected than the toenails.

A relatively limited number of cases have been reported in the literature. This suggests that either this form of pigmentation is exceedingly rare, or it is poorly recognized and thus underreported. Laugier–Hunziker pigmentation is typically identified in adult patients, with relatively equal sex predilection. It appears to develop more commonly in Caucasian or light-skinned individuals; however, it remains unclear whether this represents a distinct racial predilection or simply an example of clinician bias in the interpretation of the pigmentation.

No systemic abnormalities have been identified in any of the affected individuals. As a result, some investigators have suggested changing the name of this unusual condition to mucocutaneous lentiginosis of Laugier and Hunziker, idiopathic lenticular mucocutaneous pigmentation, or acquired dermal melanocytosis. Nevertheless, a recent report of Laugier–Hunziker pigmentation occurring in a mother and three of her adult children does suggest the possibility of a genetic predisposition.

Clinical and Microscopic Features

Patients typically present with multiple discrete, irregularly shaped brown or dark brown oral macules (Figure 5-23). Individual macules are usually no more than 5 mm in diameter.[99] In rare instances, the lesions may coalesce to produce a diffuse area of involvement. Recently, it was reported that

Figure 5-23 Laugier–Hunziker pigmentation. Multiple pigmented macules were observed in this healthy female who underwent colonoscopy and laboratory studies that ruled out Peutz–Jeghers syndrome and Addison's disease. This multifocal pattern of pigmentation is reminiscent of Peutz–Jeghers syndrome.

some of these pigmented macules may wax and wane. Increased melanin pigmentation in the basal cell layer without an increase in the number of melanocytes and melanin incontinentia in the superficial lamina propria are characteristic of this syndrome.[98]

Differential Diagnosis

A differential diagnosis may include physiologic, drug-induced pigmentation, endocrinopathic disease, and Peutz–Jeghers syndrome.[99] Thus, it is critical to confirm a lack of other systemic signs or symptoms associated with the pigmentation, including gastrointestinal bleeding. If all other potential sources for the pigmentation are ruled out, the clinician may consider the diagnosis of Laugier–Hunziker pigmentation. Hence, in most cases this is a diagnosis of exclusion. Despite the close resemblance of the labial pigmentation to that observed in Peutz–Jeghers syndrome, *STK11/LKB1* gene mutations have not been identified in patients with Laugier–Hunziker pigmentation.[98]

Management

The pigmentation may be esthetically unpleasing, but is otherwise innocuous. Although treatment is generally not indicated, laser and cryotherapy have been used with some success.[100]

TREATMENT OF MUCOCUTANEOUS MELANOSIS

In general, focally pigmented lesions warrant removal, for both diagnostic and therapeutic purposes. However, apart from those cases associated with neoplasia, surgical intervention is less of an option for the treatment of multifocal or diffuse pigmentation. Drug-induced melanosis and other examples of exogenously stimulated generalized pigmentation may spontaneously subside after withdrawal of the offending substance. In other cases, the discoloration may be persistent, if not permanent. This cosmetic disfigurement may result in significant social, psychologic, and emotional stress.

Different-thickness flap, gingivectomy, cryotherapy, electrosurgery, bur abrasion, and scraping with a scalpel have all been successfully used to treat gingival pigmentation. Laser therapy has also proven to be an effective modality for use in the treatment of bothersome oral pigmentation. However, the beneficial effects may only be temporary, with at least partial recurrence of pigmentation possible in upward of 20% of treated patients. Various types of lasers have been used, including superpulsed CO_2, Q-switched Nd-YAG, and Q-switched alexandrite lasers.[58]

Perioral and facial pigmentation are more challenging to treat, since skin type may dictate the occurrence of postoperative complications, such as postinflammatory hyperpigmentation. Although laser and cryotherapy have been used to successfully treat such cases, experimental forms of phototherapy have also been employed, including intense pulsed light and fractional photothermolysis. However, first-line therapy remains the application of topical medications, such as bleaching creams. Although single agents such as azelaic acid or hydroquinone have been used more commonly, dual- or triple-combination therapy is recommended. A combination of 4% hydroquinone–0.05% retinoic acid–0.01% fluocinolone acetonide has proven to be effective in greater than 90% of patients.[101] However, the majority of patients undergoing such therapy may experience immunologic sensitivity or other treatment-related adverse events, including the development of exogenous ochronosis.[77]

Exogenous ochronosis is a form of intense cutaneous hyperpigmentation with or without atrophic striae and coarsening of the skin or the formation of numerous coalesced, black papules. This phenomenon is more commonly observed in black individuals, usually female, who have undergone long-term bleaching therapy. The intense color changes develop in the areas where the cream was applied (frequently on the face) and are related to the accumulation of a yellow-brown pigmented substance (not melanin) in the dermis.[102] This pigmentation may be permanent. Q-switched Nd:YAG laser therapy appears to be effective in reducing the dyschromia associated with exogenous ochronosis.[103]

Finally, there are several substances, including novel tyrosinase inhibitors, that have demonstrable skin-lightening effects in animal models. However, these chemicals remain largely experimental and have not yet been proven to be effective in humans.

DEPIGMENTATION

Vitiligo

Etiology and Pathogenesis

Vitiligo is a relatively common, acquired, autoimmune disease that is associated with hypomelanosis. Vitiligo affects 0.5–2.0% of the world's population, with no sex or racial predilection. Although the precise etiology remains unknown, autoimmunity, cytotoxicity, genetics, and alterations from metabolic or oxidative stress have been implicated in this condition, where the end result is the destruction of melanocytes.[104]

The pathogenesis of vitiligo is multifactorial, with both genetic and environmental factors playing a role in the development of this disease. A study has identified a single-nucleotide polymorphism in a vitiligo-susceptibility gene that is also associated with susceptibility to other autoimmune diseases, including diabetes type 1, systemic lupus erythematosus, and rheumatoid arthritis. Additional putative vitiligo-susceptibility genes have been mapped to various other chromosomal regions.[105]

Clinical Features

The classification for vitiligo includes nonsegmental vitiligo, segmental vitiligo, and unclassified/undetermined vitiligo. Multiple achromic patches with a remitting–relapsing course are seen in nonsegmental vitiligo. Segmental vitiligo shows a characteristic dermatomeric distribution of the achromic patches with a rapid onset that is usually not progressive.[106]

The onset of vitiligo may occur at any age, but tends to develop more frequently during the second and third decades of life.[107] The depigmentation is more apparent in patients who have a darker skin tone, yet the disease actually occurs in all races. Vitiligo may also arise in patients undergoing immunotherapy for the treatment of malignant melanoma. Studies suggest that this phenomenon may be associated with a better prognosis for this group of patients.[55]

Vitiligo rarely affects the intraoral mucosal tissues. However, hypomelanosis of the inner and outer surfaces of the lips and perioral skin may be seen in up to 20% of patients (Figure 5-24).[108]

Figure 5-24 A 44-year-old Hispanic female presenting segmental vitiligo involving the forehead, face, and lips.

Pathology

Microscopically, there is a destruction of melanocytes by antigen-specific T cells and complete loss of melanin pigmentation in the basal cell layer.[104] The use of histochemical stains such as Fontana–Masson will confirm the absence of melanin.

Management

In most cases, the objective of therapeutic intervention is to stimulate repigmentation. Topical corticosteroids, topical calcineurin inhibitors, UVB narrow band (NB), and psoralen and ultraviolet A exposure (PUVA) have proven to be effective nonsurgical therapies.[106] In rare cases, small foci of normal pigmented skin may be contained within otherwise diffuse areas of hypomelanosis. Thus, to create a unified skin color, cutaneous bleaching may be considered.

Labial vitiligo is more resistant to treatment because of the lack of hair follicles at the affected site. Hair follicles typically have a reservoir of melanocytes that can be stimulated to produce pigment. Thus, surgical intervention may be the only option to achieve an esthetic result. Autologous epithelial grafts have also been reported to yield an acceptable cosmetic outcome. Split-thickness skin grafts have been reported as having the highest repigmentation success rate. Punch grafting and micropigmentation (whereby an exogenous brown pigment is injected into the lip, much like a tattoo) have also been used. In rare instances, surgical intervention may stimulate spontaneous repigmentation of vitiliginous lesions elsewhere on the body.[109,110]

HEMOGLOBIN AND IRON-ASSOCIATED PIGMENTATION

Ecchymosis

Traumatic ecchymosis is common on the lips and face, yet uncommon in the oral mucosa, except in cases related to blunt-force trauma or oral intubation. Immediately following the traumatic event, erythrocyte extravasation into the connective tissue will appear as a bright red macule or as a swelling if a hematoma has formed. The lesion will assume a brown discoloration within a few days, after the hemoglobin has degraded to hemosiderin. The differential diagnosis must include other focally pigmented lesions. If the patient recalls an episode of trauma, however, the lesion should be observed for two weeks, by which time it should have resolved.

When multiple brown macules or swellings are observed and ecchymosis is included in the differential diagnosis, a hemorrhagic diathesis or coagulation disorder should be considered.[111] Patients taking anticoagulants may present with oral ecchymosis, particularly on the buccal mucosa or tongue, either of which can be traumatized while chewing. Ecchymoses of the oral mucosa may also be encountered in patients with liver cirrhosis, leukemia, and additionally in patients with end-stage renal disease who are undergoing dialysis treatment. Laboratory tests, including bleeding time, prothrombin time, partial thromboplastin time, and international normalization ratio (INR), should be obtained in instances of spontaneous ecchymoses in order to explore defects in the coagulation pathways.

Purpura/Petechiae

Capillary hemorrhages will appear red initially and turn brown in a few days once the extravasated red cells have lysed and have been degraded to hemosiderin. The distinction between purpura and petechiae is essentially semantic and based solely on the size of the focal hemorrhages. Petechiae are typically characterized as being pinpoint or slightly larger than pinpoint, and purpura as multiple, small 2–4 mm collections of extravasated blood.[111] The same precipitating events can elicit either clinical presentation.

Oral purpura/petechiae may develop as a consequence of trauma, or viral or systemic disease (Table 5-7). Petechiae secondary to platelet deficiencies or aggregation disorders are usually not limited to the oral mucosa and may occur concurrently on the skin. Viral disease is more commonly associated with oral rather than cutaneous petechiae. In most cases, the petechiae are identified on the soft palate, although any mucosal site may be affected. When trauma is suspected, the patient should be instructed to cease whatever activity may be contributing to the presence of the lesions, which should then resolve within two weeks. Failure to do so should be viewed with caution as a hemorrhagic diathesis, a persistent infectious disease, or other systemic disease may be present and thus appropriate laboratory investigations must be undertaken.

Table 5-7 Causes of oral purpura/petechiae.

Amyloidosis
Aplastic anemia
Bulimia
Chronic renal failure
Fellatio
Forceful coughing
Hemophilia
Henoch–Schönlein purpura
HIV/AIDS
Infectious mononucleosis
Leukemia
Liver cirrhosis
Nonspecific trauma
Oral intubation
Oral submucous fibrosis
Overexertion
Papular–purpuric "gloves and socks" syndrome
Streptococcal infection
Systemic lupus erythematosus
Thrombocytopenia
Von Willebrand's disease

Hemochromatosis

Hemochromatosis is a chronic, progressive disease characterized by excessive iron deposition (usually in the form of hemosiderin) in the liver and other organs and tissues. Idiopathic, neonatal, blood transfusion, and heritable forms of this disease are recognized. Complications of hemochromatosis may include liver cirrhosis, diabetes, anemia, heart failure, hypertension, and bronzing of the skin. An increased incidence of cancer in patients with hemochromatosis has been reported.[112]

Cutaneous pigmentation is seen in over 90% of affected patients, regardless of the etiology of the disease.[113] The primary oral manifestation of hemochromatosis is a blue-gray to brown pigmentation, mainly affecting the palate and gingiva.[114]

Early in the course of disease, the pigmentation may be the result of basilar melanosis rather than an iron-associated pigment.[113] Iron deposition within the adrenal cortex may lead to hypoadrenocorticism and ACTH hypersecretion, with the associated Addisonian-type changes. In the later stages of hemochromatosis, the pigmentation is usually a result of hemosiderosis and melanosis.

A lower labial gland biopsy is a simple and effective method for the diagnosis of hemochromatosis.[115] Increased melanin pigment may be seen in the basal cell layer, whereas golden or brown-colored hemosiderin can be seen diffusely scattered throughout the submucosal and salivary gland tissues. A Prussian blue stain can confirm the presence of iron. Since hemochromatosis can cause a number of serious complications, medical referral is warranted.

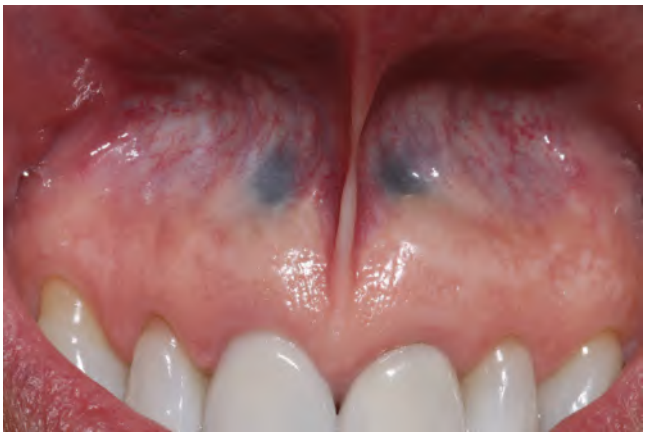

Figure 5-25 Amalgam tattoo of the maxillary alveolar mucosa. The pigment was associated with retrograde amalgam restorations.

EXOGENOUS PIGMENTATION

Amalgam Tattoos

Etiology and Pathogenesis

The most common pigmented lesion in the oral mucosa is the amalgam tattoo.[116] This is an iatrogenic condition resulting from the inadvertent deposition of amalgam restorative material into the submucosal tissue.

Clinical Features

Amalgam tattoos affect approximately 1–3% of the general population.[117] The lesions are typically small, asymptomatic, macular, and bluish gray or even black in appearance. They may be found on any mucosal surface. However, the gingiva, alveolar mucosa, buccal mucosa, and floor of the mouth represent the most common sites.[116] The lesions are typically discovered in the vicinity of teeth with large amalgam restorations or crowned teeth that probably once had amalgams, around the apical region of endodontically treated teeth with retrograde restorations or obturated with silver points, and in areas in and around healed extraction sites (Figure 5-25). Amalgam tattoo of the head and neck skin may occur in dentists and represents an occupational hazard resulting from failure to use facial protective barriers.

Pathology

Microscopically, amalgam tattoos show a fine brown granular stippling of collagen fibers, with a particular affinity for vessel walls and nerve fibers (Figure 5-26), with little or no inflammation. In some cases, large aggregates of black material may also be observed and this could result in a foreign body–type giant cell granulomatous inflammation. However, a mild to moderate lymphocytic inflammatory infiltrate is more commonly seen.[116]

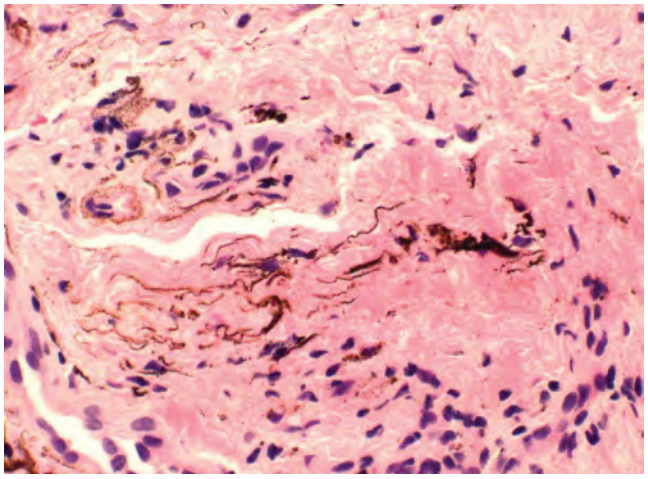

Figure 5-26 Amalgam tattoo. Spherules of restorative dental material (amalgam) are seen decorating collagen fibers. A characteristic perivascular distribution of the particles is observed (hematoxylin and eosin stain; ×400 original magnification).

Differential Diagnosis

A typical differential diagnosis includes melanotic macule, nevus, and melanoma.

Management

If large enough, amalgam particles can be identified on dental radiographs. In some patients, surgical removal may be warranted due to esthetic considerations. A two-stage surgical approach (subepithelial connective tissue graft followed by laser surgery) developed to eliminate amalgam tattoo has yielded excellent results.[118] However, since amalgam tattoos are innocuous, their removal is not always necessary, particularly when they can be documented radiographically. In the absence of radiographic evidence of amalgam, or in the event that the lesion appears suddenly or is not in proximity to a restored tooth, a biopsy is warranted.

Pigmentation associated with other dental restorative materials has also been described. Metal components from almost all forms of cast alloy material can be detected in adjacent tissues. Titanium has been associated with pigmentation of the skin, specifically in areas around orthopedic implants.[119] Thus, it is conceivable that dental implants may also be a potential source of exogenous oral pigmentation.

Graphite Tattoos

Graphite tattoos are an unusual source of focal exogenous pigmentation. They are most commonly seen on the palate and gingiva and represent traumatic implantation of graphite particles from a pencil (Figure 5-27). The lesions may be indistinguishable from amalgam tattoos, often presenting as a solitary gray or black macule. Since the traumatic event often occurs in childhood, many patients may not report a history of injury. Thus, a biopsy is often warranted. Microscopically, graphite particles resemble those of amalgam. When the graphite tattoo involves areas of cosmetic concern, removal of the lesion and a subsequent autogenous connective tissue graft provide a highly esthetic outcome.[120]

Ornamental Tattoos

Mucosal tattoos in the form of lettering or intricate artwork are becoming an increasingly common phenomenon (Figure 5-28). Amateur tattoo inks are permanent and consist of simple carbon particles originating from a variety of sources, including burnt wood, plastic, or paper, and from a variety of inks, such as India ink, pen ink, and plant-derived matter. Q-switched laser therapy has been used successfully to remove tattoos of the oral mucosa.[121]

Figure 5-27 Graphite tattoo. A 4-year-old male with a round bluish macule on the hard palate, posterior to the incisive papilla. The child fell down with a pencil in his mouth and punctured his palate.

Figure 5-28 Intentional tattoo. Words written in the lower labial mucosa.

Figure 5-29 Ornamental tattoo. A 44-year-old Senegalese woman who performed her own gingival tattoo with eight needles bunched together, using the flame and soot from burning peanuts. *Source:* Courtesy of Dr. Darren Cox, University of the Pacific, San Francisco, CA, USA.

In certain tribal cultures, ornamental mucocutaneous tattooing is considered a rite of passage and esthetically pleasing. In these cases, the pigment is plant derived. Female members of certain tribes are more likely to exhibit this form of exogenous pigmentation, usually in an effort to make themselves more attractive or desirable (Figure 5-29).

An unusual South African female tribal custom includes brushing the teeth and gums with a chewed root of the tree *Euclea natalensis*, in the belief that it promotes oral health.[122] This plant root contains naphthoquinones and other organic substances that have putative antibacterial properties. Naphthoquinones are pigmented, and the mouths of root users are typically bright orange.[123] Unlike ornamental tattoos, this form of pigmentation is usually transient and reversible.

Medicinal Metal-Induced Pigmentation

Historically, a variety of metallic compounds have been used medicinally for the treatment of various systemic diseases. Fortunately, with the advent of methotrexate for the treatment of rheumatoid arthritis, gold therapy is less in demand.[124] Colloidal silver is another metal-based substance that has been historically touted for its beneficial health effects. Although its use in Western medicine has been significantly curtailed, it has become widely available among patients using complementary and alternative medicine therapies.[125] Gold and colloidal silver have both been associated with diffuse cutaneous pigmentation. Silver may cause a generalized blue-gray discoloration (argyria), whereas gold-induced pigment may appear blue-gray or purple (chrysiasis).[124,125] In both cases, the pigmentation may be persistent, if not permanent, even following discontinuation of the substance. Rare examples of diffuse oral argyria have been reported. Chrysiasis does not involve the oral mucosal tissues, since it is thought that exposure to ultraviolet light or other high-intensity light sources precipitates the pigmentation. However, oral lichenoid eruptions have been associated with systemic gold therapy.[60]

In contrast to the systemic therapies, metal salts remain a component of some topical medications and other substances that are used in clinical practice. Examples include silver nitrate and zinc oxide. Silver nitrate cautery has been used to treat recurrent aphthous stomatitis, and zinc oxide is a common component of sunblock creams. Both substances have been associated with focal mucocutaneous pigmentation. Zinc oxide–containing sunblock, which is used to treat severely chaffed lips, may result in the development of hyperpigmentation. Histologically, the findings are similar to an amalgam tattoo. However, scanning electron microscopy and radiographic microanalysis unveil the presence of zinc in elastic fibers.[126] Medicinal silver-associated pigment appears as brown or black particulate matter dispersed throughout the connective tissue. A clinicopathologic correlation is necessary since, clinically and microscopically, these forms of pigmentation may be difficult to differentiate from amalgam tattoos.

Generalized black pigmentation of the tongue has been attributed to the chewing of bismuth subsalicylate tablets, a commonly used antacid.[127] This phenomenon is unlike black hairy tongue, which is associated with elongation of the filiform papillae, hyperkeratosis, and superficial colonization of the tongue by bacteria. Black tongue induced by bismuth subsalicylate is caused by deposition of actual pigment (bismuth sulfide), without any other lingual changes. Discontinuation of the antacid and cleansing of the tongue are curative. It should be noted that typical black hairy tongue may also be attributed to the use of bismuth subsalicylate.

Heavy Metal Pigmentation

Diffuse oral pigmentation may be associated with ingestion of heavy metals. Nowadays, this phenomenon is rarely encountered. Yet, it remains an occupational and health hazard for some individuals who work in certain industrial plants and for those who live around these types of facilities. Other relatively common environmental sources include paints, old plumbing, and seafood.

Lead, mercury, bismuth, and arsenic have all been shown to be deposited in oral tissue if ingested in sufficient quantities or over an extended period of time.[72] These ingested metal salts tend to extravasate from vessels in areas of chronic inflammation. Thus, in the oral cavity, the pigmentation is usually found along the free marginal gingiva, where it often dramatically outlines the gingival cuff. This metallic line usually has a gray to black appearance. In some patients, the oral pigmentation may be the first sign of heavy metal toxicity. Additional systemic signs and symptoms of heavy metal poisoning may include behavioral changes, neurologic disorders, intestinal pain, and sialorrhea. Diffuse mucocutaneous melanosis may also be observed in some affected individuals.[128]

Drug-Induced Pigmentation

Minocycline (a tetracycline derivative frequently used in the treatment of acne) is a relatively common cause of drug-induced non-melanin-associated oral pigmentation. Like tetracycline, minocycline can cause pigmentation of developing teeth. However, most patients are prescribed minocycline in early adulthood. When taken chronically, minocycline metabolites may become incorporated into the normal bone. Therefore, whereas the teeth may be normal in appearance, the surrounding bone may appear green, blue, or even black. In addition, the roots show a green color, while developing roots tend to be black. As a result, the palatal and alveolar mucosae may appear similarly and diffusely discolored.[129]

Minocycline can also induce actual pigmentation of the oral soft tissues, as well as the skin and nails. Minocycline-induced soft tissue pigmentation may appear as gray, brown, or black. The pigmentation is either patchy or diffuse. Although a biopsy may reveal basilar melanosis, more commonly aggregates of fine brown or golden particles are identified within the lamina propria. The particles are often identified in the cytoplasm of macrophages. Superficially, the pigment in the lamina propria may

resemble melanin and will stain with a melanin-specific (Fontana–Masson) histochemical stain. However, an iron stain (Prussian blue) will also highlight many of the same particles.[129] Thus, it is likely that the particulate substance represents a precipitated drug metabolite rather than true melanin.

The mucosal discoloration produced by minocycline often subsides within months after discontinuation of the medication. Nowadays, acceptable esthetic outcomes are obtained even in severe cases of cutaneous pigmentation associated with minocycline intake when alexandrite 755 nm laser therapy is used.[130] However, the bone pigment may persist for longer periods of time, if not indefinitely.

Methacycline, another tetracycline derivative that is no longer widely used in clinical practice, can also produce a similar form of pigmentation.[131]

Hairy Tongue

Hairy tongue is a relatively common condition of unknown etiology.[132] The change in oral flora associated with chronic antibiotic therapy may be causative in some patients. The discoloration involves the dorsal tongue, particularly the middle and posterior one-third. Rarely are children affected. The filiform papillae are elongated, sometimes markedly, and have the appearance of fine hairs. The hyperplastic papillae then become pigmented by colonizing chromogenic bacteria, which can impart a variety of colors, including white, green, brown, or black (Figure 5-30). Various foods, drinks, and confectionery can contribute to the diffuse discoloration. The smoking of both tobacco and crack cocaine has been associated with black hairy tongue.[133] Rare examples of black hairy tongue have been linked to the use of psychotropic medications, tetracycline, linezolid, olanzapine, bismuth, and erlotinib.[134,135]

Black hairy tongue is so characteristic in its presentation that biopsy is not required, and a clinical diagnosis is usually appropriate. Microscopically, the filiform papillae can be seen as extremely elongated and hyperplastic with hyperkeratosis. Superficial microbial colonization of the papillae is a prominent feature. The treatment is mechanical and consists in using a tongue scraper, and limiting the ingestion of color-forming foods and drinks until the discoloration resolves. Since the cause is often unknown, the condition may recur.

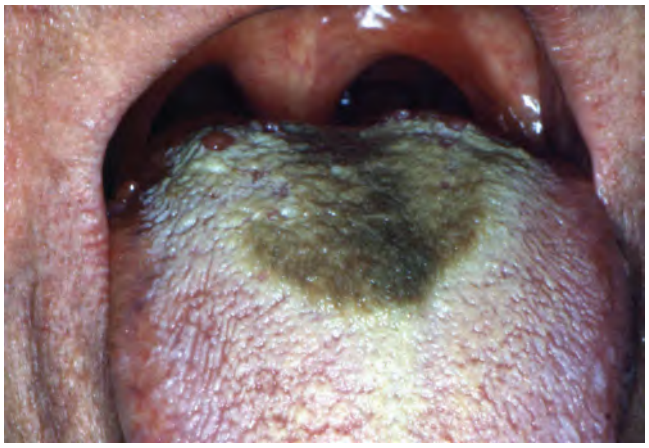

Figure 5-30 Hairy tongue. Elongated lingual filiform papillae displaying a gamut of colors ranging from white to brown and black discoloration of the dorsum of the tongue.

CONCLUSION

Oral pigmentation may be focal, multifocal, or diffuse. The lesions may be blue, red, purple, brown, gray, or black. They may be macular or tumefactive. Importantly, some are localized, harmless accumulations of melanin, hemosiderin, or exogenous metal, while others are harbingers of systemic or genetic disease and may be associated with life-threatening medical conditions that require immediate intervention. The differential diagnosis for any given pigmented lesion can be extensive and can include examples of endogenous and exogenous pigmentation. Although biopsy is a helpful and necessary aid in the diagnosis of focally pigmented lesions, the more diffuse lesions require a thorough history and laboratory studies in order to arrive at a definitive diagnosis.

Benign Lesions of the Oral Cavity and the Jaws

A. Ross Kerr, DDS, MSD
Denise A. Trochesset, DDS

This chapter provides an overview of the etiology and pathogenesis, epidemiology, clinical and histopathologic manifestations, differential diagnosis, applicable laboratory findings, and management of nonmalignant growths and tumors of the oral cavity and the jaws. Prevalence data for these entities is variable and based on population screening studies[1,2,3] or large case series, and many of the entities described occur at a sufficiently low prevalence to be reported as rare. Most entities are not true neoplasms, and therefore a variety of miscellaneous etiologies are discussed. If left untreated, some of the entities considered in this chapter can lead to extensive tissue destruction and deformity, whereas others may have a lesser impact, albeit they negatively affect oral function. Regardless, one of the major clinical considerations in the management of these

Burket's Oral Medicine, Thirteenth Edition. Edited by Michael Glick, Martin S. Greenberg, Peter B. Lockhart, and Stephen J. Challacombe.

growths and tumors is to identify their benign nature and to distinguish them from potentially life-threatening malignant neoplasms. Identification can only be established with certainty by microscopic examination of excised tissue; therefore, biopsy is often an essential step in their diagnosis and management.

VARIANTS OF NORMAL

Structural variations of the oral cavity and the jaws are sometimes mistakenly identified as pathologic, but they are usually easily recognized as being within the range of normal findings, and biopsy is rarely indicated. One cannot appreciate the abnormal before understanding the range of normal. Examples of such structural variants are tori, enlarged papillae associated with the opening of Stensen's duct, Fordyce spots, and sublingual varicosities in older individuals.

Tori/Exostoses

Etiology and Pathogenesis

Tori and exostoses are considered to be normal structural variants. Their etiology is multifactorial and poorly defined, although genetics is a dominant factor.[4] There is no strong evidence to either support or refute bruxism or other parafunctional habits as causes. The growth of tori and exostoses is highly variable and their negligible growth after an initial slow but steady period of development suggests that they are unlikely to be inflammatory hyperplasias or neoplasms.

Epidemiology

The prevalence of tori is highly variable, ranging from <5% to almost 30% in different studies and populations. Smaller studies using dental casts to determine the presence of any torus or exostosis demonstrate significantly higher prevalence, >50%. Their onset is at any age, but most commonly during the third decade, and with no consistent sex predilection.

Clinical and Histologic Manifestations

Exostoses manifest as localized nodular enlargements of the cortical bone of the midline of the palate (torus palatinus),[5] the lingual aspect of the mandible (torus mandibularis), and the buccal aspects of either jaws (Figure 6-1). Other than the torus palatinus, exostoses have a bilateral presentation. They are typically small, although rarely they may become sufficiently large to interfere with oral function. Histologically, tori consist of layers of dense cortical bone

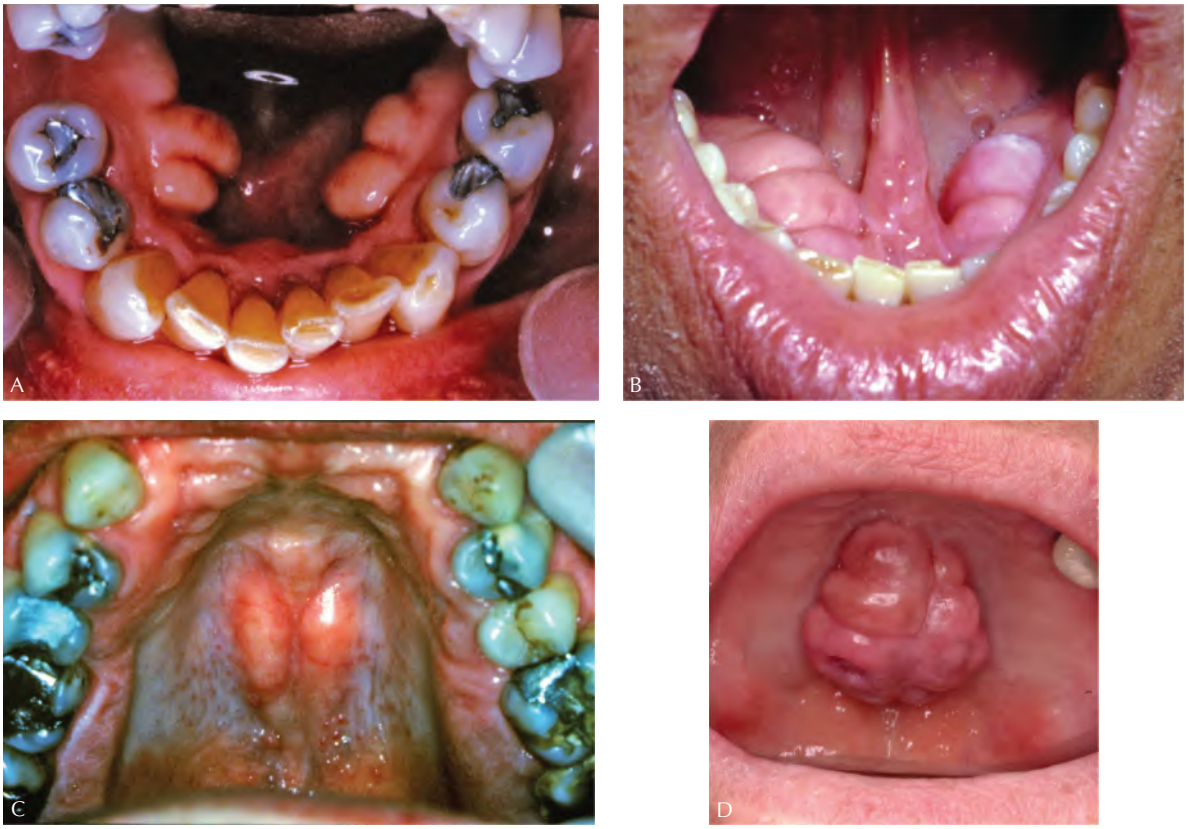

Figure 6-1 (A) Mandibular tori (tori mandibularis). (B) Mandibular tori. Note traumatic keratosis on the left side due to the large size of the tori. (C) Maxillary torus (torus palatinus). (D) Maxillary torus. Note the large size with a "pedunculated base."

covered by periosteum and a thin overlying layer of epithelium with minimal rete peg development.

Differential Diagnosis

Similar nodular growths or exostoses arising on the buccal aspect of the maxillary and mandibular alveolae must be differentiated from bony enlargement secondary to bone diseases such as fibrous dysplasia or Paget's disease.

Management

No management is required unless tori pose a functional problem such as a mechanical problem in the construction of dentures, or if they become frequently traumatized as a result of their prominent position and the resulting traumatic ulcers are slow to heal. In such cases, surgical removal is indicated.

Unencapsulated Lymphoid Aggregates

Etiology and Pathogenesis

These are normal structures, distinct from the palatine and lingual tonsils, and comprise part of Waldeyer's ring, They may increase in size as a result of benign (reactive) processes [6] or due to lymphoid neoplasms (i.e., lymphomas).

Clinical Manifestations

They may be located on the posterolateral aspects of the tongue (Figure 6-2), anterior tonsillar pillar, posterior pharyngeal wall, soft palate, and dorsal tongue. Histologic criteria based on architectural, cytologic, and immunologic features of the lymphoid aggregate have been described.

Differential Diagnosis

These may masquerade clinically as a malignancy.

Management

No management is required unless these aggregates demonstrate unilateral and progressive enlargement, in which case a biopsy is indicated to rule out malignancy.

Fordyce Spots

Etiology and Pathogenesis

These are ectopic sebaceous glands and it is unclear why some individuals develop them. The link between hyperlipidemia and Fordyce spots has not been substantiated.

Epidemiology

Fordyce spots are common and have been reported to occur in up to 80% of patients.[7]

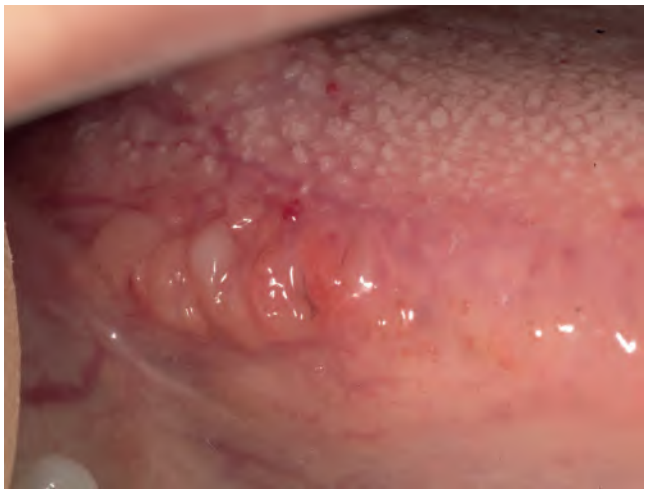

Figure 6-2 Right posterolateral tongue revealing a prominent foliate papilla region containing unencapsulated lymphoid aggregates. A similar presentation was seen on the left side.

Clinical Manifestations

The most common locations for Fordyce spots are the buccal mucosae and lip vermillion.

Management

Typically no treatment is required. There are surgical options for patients with a high concentration of labial Fordyce spots deemed esthetically obtrusive.

BENIGN SOFT TISSUE LESIONS

INFLAMMATORY/REACTIVE EXOPHYTIC SOFT TISSUE LESIONS

The term *inflammatory/reactive soft tissue tumors* is used to describe a large range of commonly occurring exophytic lesions of the oral mucosa that histologically represent inflamed fibrous and granulation tissue. The majority of these occur peripherally on the oral mucosal surfaces that may be subject to masticatory trauma (i.e., as the result of chronic trauma from ill-fitting dentures, biting, or contact with fractured teeth), related to the chronic inflammatory stimuli (i.e., overhanging restorations, calculus), or in some lesions the levels of circulating hormones or medications play a role. The number and size of these reactive hyperplastic lesions vary depending on the degree to which one or more of the components of the inflammatory reaction and healing response are exaggerated. Some are predominantly epithelial overgrowths with only scanty connective tissue stroma; others are fibromatous, with a thin epithelial covering, and may exhibit either angiomatous, desmoplastic (collagenous), or fibroblastic features. In many lesions, examples of each of these histologic patterns is revealed. Like scar tissue, some

inflammatory hyperplasias appear to mature and become less vascular (paler and less friable) and more collagenous (firmer and smaller) with time. Others appear to have a high proliferative ability for exophytic growth until they are excised. This variability of histologic appearance is reflected in the wide range of clinical characteristics exhibited by inflammatory hyperplasias.[8] If the chronic irritant is eliminated when the lesion is excised, the majority of inflammatory hyperplasias will not recur, thus confirming the benign nature of these lesions.

Irritation Fibroma

Etiology and Pathogenesis

Irritation fibromas develop following trauma, such as a cheek or lip bite.

Epidemiology

They are the most common exophytic soft tissue lesion, with a prevalence of approximately 1%, and they comprise 10–15% of exophytic soft tissue lesions submitted for histopathologic examination.

Clinical Manifestations

Irritation fibromas are usually asymptomatic and may occur as either pedunculated or sessile (broad-based) pink nodules on any surface of the oral mucosa, but most commonly involving the buccal or labial mucosae (Figure 6-3). The majority are rarely >1 cm in diameter.

Differential Diagnosis

These include giant cell fibroma, neurofibroma, schwannoma, granular cell tumor, leiomyoma, rhabdomyoma, mucocele, or malignant minor salivary gland neoplasms.

Figure 6-3 Irritation fibroma (traumatic fibroma). Patient reported a daily habit of biting this lesion for several months.

Management

An excisional biopsy is indicated except when the procedure would produce marked deformity; in such a case, incisional biopsy to establish the diagnosis is mandatory. The irritant, if present, should also be eliminated when the lesion is excised to reduce the risk for recurrence.

Other Solitary Fibrous Lesions

Pulp polyps (aka chronic hyperplastic pulpitis) are analogous to a fibroma. They occur when the pulpal connective tissue proliferates through a large carious pulpal exposure and fills the cavity in the tooth with a mushroom-shaped polyp that is connected by a stalk to the pulp chamber (Figure 6-4). Masticatory pressure may lead to keratinization of the epithelium covering these lesions. Pulp polyps contain few sensory nerve fibers and are remarkably insensitive. The crowns of teeth affected by pulp polyps are usually so badly destroyed by caries that endodontic treatment is not feasible.

Giant cell fibromas comprise a small subset (<5%) of solitary fibrous lesions. Their etiology is unknown, and these exophytic lesions are typically smaller than the irritation fibroma.[9] They most often involve the gingivae, exhibit a nodular surface, and are histologically distinguished from other fibromas by the presence of stellate-shaped and multinucleated cells in the connective tissue.

Although they are nonreactive, it is worth mentioning that fibromas are part of the manifestations in two rare syndromes: Cowden syndrome and tuberous sclerosis complex. Cowden syndrome (multiple hamartoma and neoplasia syndrome) is an autosomal dominant disorder affecting multiple organ systems[10] and caused by mutations in the phosphatase and tensin homolog gene (PTEN). Oral and perioral findings include multiple papules on the lips and gingivae, papillomatosis (benign fibromatosis) of the buccal, palatal, faucial, and oropharyngeal mucosae often producing a "cobblestone" effect, and the tongue may also present as pebbly or fissured. Multiple papillomatous nodules (histologically inverted follicular keratoses or trichilemmomas) are often present on the perioral, periorbital, and perinasal skin, the pinnae of the ears, and the neck. These nodules are often accompanied by lipomas, hemangiomas, neuromas, vitiligo, café au lait spots, and acromelanosis elsewhere on the skin. A variety of neoplastic changes occur in the organs exhibiting hamartomatous lesions, with an increased rate of breast and thyroid carcinoma and gastrointestinal malignancy. Squamous cell carcinoma of the tongue and basal cell tumors of the perioral skin have also been reported.

Tuberous sclerosis complex is an inherited disorder[11] caused by mutations in the tuberous sclerosis complex (*TSC1* or *TSC2*) genes that is characterized by seizures and intellectual disability, associated with hamartomatous glial proliferations and neuronal deformity in the central nervous system. Fine wart-like lesions (adenoma sebaceum) occur in a butterfly distribution over the cheeks and forehead (Figure 6-5A),

Figure 6-4 (A) Young male with tuberous sclerosis. There are extensive wart-like lesions (adenoma sebaceum) in a butterfly distribution over the face. (B) Same patient as in (A) showing intraoral fibromas. Generalized hypoplastic pitted enamel changes are absent.

and histologically similar lesions (vascular fibromas) have been described intraorally (Figure 6-5B). Characteristic hypoplastic enamel defects (pitted enamel hypoplasia) occur in 40–100% of those affected. Rhabdomyoma of the heart and other hamartomas of the kidney, liver, adrenal glands, pancreas, and jaw have been described.

Fibrous Inflammatory Hyperplasias/Epulis Fissuratum

Etiology and Pathogenesis

These are reactive inflammatory lesions associated with the periphery of ill-fitting dentures.[12] They have no malignant potential.

Epidemiology

The prevalence is <0.5% in the general population and comprises <2% of exophytic soft tissue lesions submitted for histopathologic examination.

Clinical and Histologic Manifestations

The growth is often split by the edge of the denture, resulting in a fissure, one part of the lesion lying under the denture and the other part lying between the lip or cheek and the outer denture surface (Figure 5-6). Histologically they resemble the irritation fibroma.

Differential Diagnosis

The rolled border, albeit nonindurated, can resemble some squamous cell carcinomas.

Management

Many such hyperplastic growths will become less edematous and inflamed following the removal of the associated chronic irritant, but they rarely resolve entirely. In the preparation of the mouth to receive dentures, these lesions are excised (i.e., by conventional scalpel or laser excision) to prevent further irritation and to ensure a soft tissue seal for the denture periphery. Recurrence following excision is almost always a result of a failure to eliminate the source of irritation. The occasional report of squamous cell carcinoma arising in an area of chronic denture irritation, however, underlines the importance of microscopic examination of the excised tissue.

Inflammatory Papillary Hyperplasia

Etiology and Pathogenesis

The exact pathogenesis is unclear, but this condition is usually associated with chronic denture irritation and denture stomatitis due to chronic candidal infection.[12]

Epidemiology

Inflammatory papillary hyperplasia is a common lesion in approximately 3–4% of denture wearers. Old and ill-fitting

Figure 6-5 Fibrous hyperplasia (epulis fissuratum) secondary to a poorly fitting mandibular complete denture.

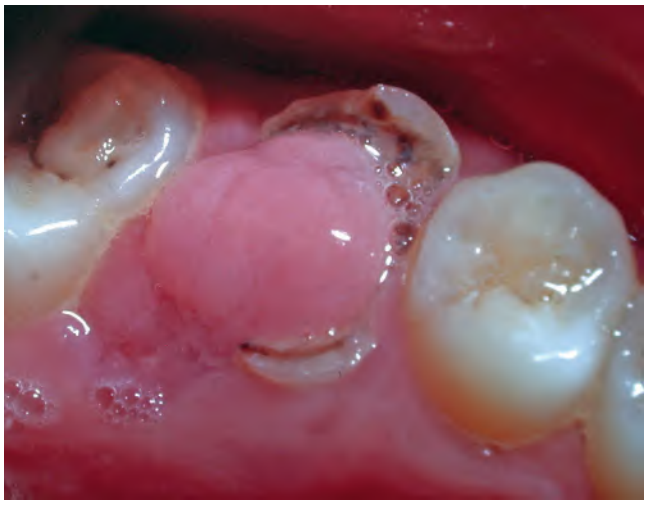

Figure 6-6 Pulp polyp (hyperplastic pulpitis) within a carious maxillary premolar.

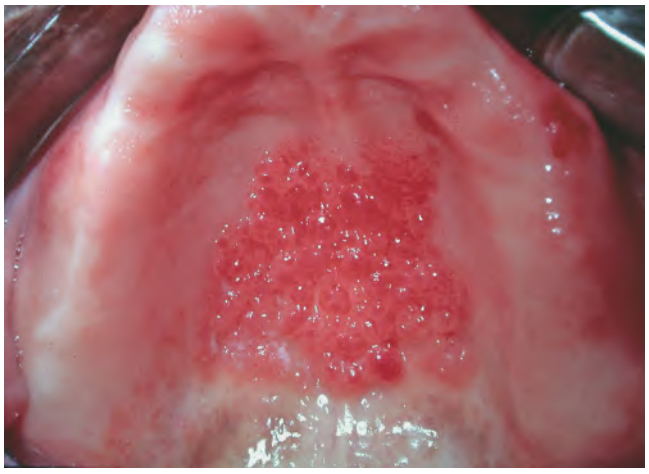

Figure 6-7 Papillary hyperplasia under a poorly fitting maxillary complete denture.

complete maxillary dentures appear to be the strongest stimuli, but the lesion may also be seen under partial maxillary dentures.

Clinical Manifestations

This condition develops on the central hard palate, with a characteristic red to scarlet lesion demonstrating swollen and tightly packed projections resembling the surface of an overripe berry (Figure 6-7). Such lesions are friable, and often bleed with minimal trauma.

Differential Diagnosis

Squamous cell carcinoma.

Management

Mild cases may be treated successfully by topical or systemic antifungals alone;[6] otherwise, papillary hyperplasia may be surgically excised or removed by electrocautery, cryosurgery, or laser surgery. The old denture or a palatal splint can be used as a postoperative surgical dressing, followed by fabrication of a new denture.

Pyogenic Granuloma and Pregnancy Tumor

Etiology and Pathogenesis

The etiology of pyogenic granulomas is thought to be in response to chronic irritation.[13] Their propensity for involving the gingival margin supports this etiology and suggests that calculus, food materials, and overhanging dental restoration margins are important irritants that should be eliminated when the lesion is excised. Hormones play a role in the etiology of the lesion in the setting of pregnancy (where the lesion is named a pregnancy tumor), although local irritation is also an important etiologic factor.

Epidemiology

Fewer than 5% of exophytic soft tissue lesions submitted for histopathologic examinations are pyogenic granulomas.

They have a female predilection (>2:1 ratio). Pregnancy tumors occur toward the end of pregnancy (when levels of circulating estrogens are highest), and they tend to shrink after delivery (when there is a precipitous drop in circulating estrogens).

Clinical and Histologic Manifestations

Pyogenic granulomas typically present as solitary hemorrhagic, often pedunculated, nodules of variable size that occur most frequently on the gingiva (Figure 6-8), although they may occur on any mucosal surface. Their friable, hemorrhagic, and frequently ulcerated appearance correlates with their histologic structure, demonstrating proliferating endothelial tissue, much of which is canalized into a rich vascular network with minimal collagenous support. Neutrophils, as well as chronic inflammatory cells, are consistently present throughout the edematous stroma, and form into microabscesses. These histologic features resemble hemangiomas. Despite the common name for the lesion, a frank discharge of pus is not present, and when such a discharge does occur it is likely a sinus tract emanating from an underlying periodontal or periapical abscess, the opening of which is often marked by a nodule of granulation tissue (parulis).

Differential Diagnosis

When involving the gingiva, the differential includes other reactive gingival lesions, including peripheral ossifying fibroma and peripheral giant cell granuloma. Hemangiomas may appear similar clinically. Malignant neoplasms may also be included in the differential (e.g., squamous cell carcinoma, or other rarer entities).

Management

Surgical excision and successful removal of the associated irritant are associated with a low rate of recurrence. Scrupulous oral hygiene can prevent pregnancy tumors.

Peripheral Ossifying or Cementifying Fibroma

Etiology and Pathogenesis

This is a reactive lesion of unclear etiology, most likely related to local trauma/irritation.

Epidemiology

These lesions occur in teenagers and young adults and are more common in women.

Clinical/Histologic Manifestations

They occur exclusively on the gingiva, typically located in the interdental papilla region (Figure 6-9), and vary in presentation from pale pink to cherry red. This reactive proliferation is named because of the histologic evidence of calcifications that are seen in the context of a hypercellular fibroblastic stroma.

Differential Diagnosis

The differential includes other reactive gingival lesions, including pyogenic granuloma and peripheral giant cell granuloma. Malignant neoplasms may also be included in the differential (e.g., squamous cell carcinoma, or other rarer entities).

Management

Treatment should include the elimination of subgingival irritants and periodontal pockets, as well as excision of the gingival growth.

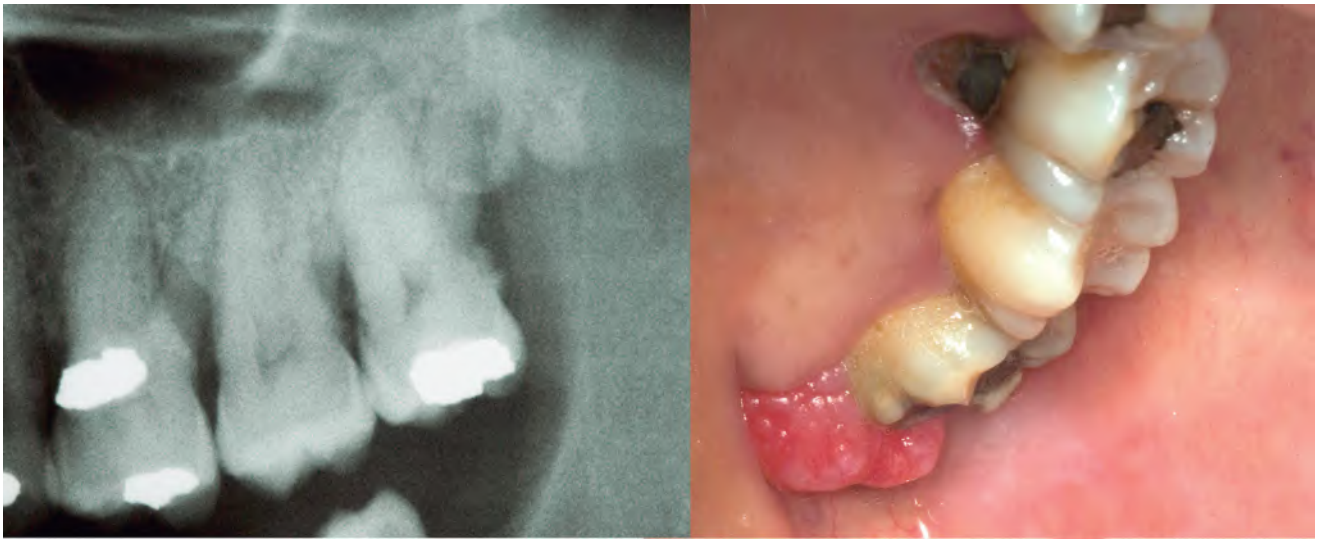

Figure 6-8 Pyogenic granuloma associated with a periodontal defect on the distal aspect of the maxillary left third molar. There is radiographic evidence of subgingival calculus, a likely etiologic factor.

Figure 6-9 Peripheral ossifying fibroma in a teenage male associated with the maxillary buccal gingiva. The lesion was pedunculated.

Peripheral Giant Cell Granuloma

Etiology and Pathogenesis

This is a reactive lesion of unclear etiology, most likely related to local trauma/irritation. It is the soft tissue counterpart to the central giant cell granuloma.

Epidemiology

Peripheral giant cell granulomas are five times as common as the central lesions.

Clinical and Histologic Manifestations

Giant cell granulomas are solitary and occur either as a peripheral exophytic lesion found exclusively on the gingiva or as a centrally located lesion within the jaw, skull, or other facial bones (described in the section that includes bone lesions).

Differential Diagnosis

The differential includes other reactive gingival lesions, including pyogenic granuloma and peripheral ossifying or cementifying fibroma. Malignant neoplasms may also be included in the differential (e.g., squamous cell carcinoma, or other rarer entities).

Management

Peripheral giant cell granuloma is treated identically to the other reactive gingival lesions, by surgical excision and the elimination of local factors contributing to gingival/periodontal disease.

Nodular Fasciitis

Etiology and Pathogenesis

This is a reactive proliferation of myofibroblasts and although the etiology is unknown, trauma is a likely factor. Growth rates are variable but can be rapid.

Epidemiology

Oral nodular fasciitis is rare and occurs at all ages, with the majority during the fourth and fifth decades, with no sex predilection.

Clinical and Histopathologic Manifestations

The most common oral site is the buccal mucosa and most have an exophytic presentation. Nodular fasciitis has distinctive microscopic features revealing the myofibroblast as the predominant cell type. The microscopic features can resemble a sarcoma, and may present a diagnostic challenge for the pathologist.

Differential Diagnosis

Benign or malignant soft tissue growths.

Management

Conservative surgical excision and submission for histology.

Proliferative Myositis and Focal Myositis

Etiology and Pathogenesis

These entities are reactive fibroblastic lesions that infiltrate around individual muscle fibers.

Epidemiology

They are exceedingly rare.

Clinical Manifestations

Lesions most frequently involve the tongue and other neck and jaw muscles. Despite the nomenclature, these lesions do not show histologic signs of inflammation.

Differential Diagnosis

Lesions of skeletal muscle that have similar clinical features and are differentiated by histopathologic findings.

Management

Conservative surgical excision and submission for histopathology.

Reactive Gingival Enlargement

Gingival enlargement or overgrowth is usually caused by local inflammatory conditions such as poor oral hygiene, food impaction, or mouth breathing.[14] Systemic conditions such as hormonal changes or drug therapy may also cause or contribute to the severity of gingival enlargement. Histologically, there are a number of explanations for gingival enlargement: hypertrophy (an increase in cell size), hyperplasia (an actual increase in cell number), edema, vascular engorgement, the presence of an inflammatory cell infiltrate, or an increase in dense fibrous connective tissue. One or more of these explanations may predominate depending on the underlying cause.

Inflammatory Gingival Enlargement

Etiology and Pathogenesis

Inflammatory gingival enlargement occurs in sites where there has been chronic suboptimal oral hygiene with heavy biofilm accumulation, supragingival calculus formation, impaction of food, or the presence of aggravating factors such as orthodontic appliances, mouth breathing, hormonal changes, or other systemic diseases. Gingival enlargement primarily affecting the maxillary anterior region may be observed in mouth breathers, and hormonal changes (such as during pregnancy or puberty) may exaggerate the local immune response to local factors and contribute to gingival enlargement.

Epidemiology

Gingivitis is highly prevalent (>90%), particularly in a pediatric and adolescent population, but conservative estimates of severe gingivitis associated with gingival enlargement are <5%.

Clinical and Histologic Manifestations

The clinical diagnosis of inflammatory gingival enlargement is straightforward, with tissues exhibiting a glossy edematous bright red or purplish color, pitting edema, and a tendency to hemorrhage on slight provocation (Figure 6-10). A malodor may result from the decomposition of food debris and accumulation of bacteria. Pseudopockets formed by gingival enlargement make the maintenance of good oral hygiene difficult, perpetuating a cycle of inflammation. Longstanding inflammatory gingival enlargement may demonstrate relatively firm, resilient, and pink gingivae that do not bleed readily. This is due to a greater fibrous component with an abundance of fibroblasts and collagen fibers. Chronic inflammatory gingival enlargement is a risk factor for periodontal disease. Histologically, the exudative and proliferative features of chronic inflammation are seen: a preponderance of inflammatory cells, vascular engorgement, new capillary formation, and associated degenerative changes.

Figure 6-10 Inflammatory gingival enlargement secondary to local factors.

Differential Diagnosis

Drug-induced gingival enlargement, other systemic diseases (including acute myelogenous leukemia, von Recklinghausen's neurofibromatosis [neurofibromatosis 1], Wegener's granulomatosis, sarcoidosis, Crohn's disease, primary amyloidosis, Kaposi's sarcoma, acromegaly, and lymphoma), and hereditary gingivofibromatosis.

Management

Treatment of inflammatory gingival enlargement begins with the establishment of excellent oral hygiene, together with the elimination of all local and/or systemic predisposing factors if possible. This includes a professional debridement (supragingival scaling or subgingival root planing) and prophylaxis, and correction of faulty restorations, carious lesions, or food impaction sites. Close follow-up after initial therapy is required to assess improvements in home care and tissue response that will dictate subsequent treatment options.

For refractory cases, adjunctive topical or systemic antimicrobials or surgical options may be indicated. The successful treatment of gingival enlargement in mouth breathers depends primarily on the elimination of the habit. Patients should be referred to an otolaryngologist to determine if there is any obstruction of the upper air passages and/or to an orthodontist to assess the potential for treatment to permit the normal closure of the lips during sleep. A tissue biopsy should be considered whenever the cause is unclear, when there is a poor response to local therapy, or to rule out rare systemic diseases that may present with gingival enlargement (e.g., acute myelogenous leukemia).

Drug-Induced Gingival Enlargement

Etiology and Pathogenesis

Drug-induced gingival enlargement is most commonly associated with the administration of anticonvulsants (principally phenytoin), cyclosporine, and calcium channel blocking agents (principally nifedipine).[15] Contributing local factors aside, the extent of inflammation and fibrosis is largely influenced by the drug type, dosing, and duration. Phenytoin-induced gingival enlargement exhibits the most fibrosis, and in contrast cyclosporine induces the least fibrosis, but in both the gingivae are enlarged and highly inflamed. The blend of fibrosis versus inflammation falls between these two extremes for calcium channel blocker–induced enlargement. These drugs likely exert their influence by the dysregulation of cytokines and growth factors, and also differentially affect the response of innate and adaptive immune systems.

Epidemiology

Phenytoin-induced gingival enlargement (Figure 6-11) is the most prevalent, affecting approximately 50% of patients who use the drug for longer than three months. Although rare, gingival enlargement has also been reported in patients taking

Figure 6-11 Gingival enlargement secondary to longstanding phenytoin use.

Figure 6-12 Gingival enlargement secondary to longstanding cyclosporine use.

other anticonvulsants, namely valproic acid, phenobarbital, and vigabatrin. The immunosuppressant agent cyclosporine causes gingival enlargement in 25–30% of adults and, notably, in more than 70% of children (Figure 6-12). Nifedipine and dilitiazem are responsible for most cases of calcium channel blocker–induced gingival enlargement, with a prevalence of 5–20%. There are also reports of gingival enlargement following use of verapamil, felodipine, and amlodipine.

Clinical Manifestations

There is a characteristic clinical appearance of drug-induced gingival enlargement. After approximately one month of use of the drug, interdental papillae enlargement begins, usually in the anterior regions, and enlargement may become more extensive, leading to gingival disfigurement and associated esthetic and functional complications.

Differential Diagnosis

Inflammatory gingival enlargement, other systemic diseases (including acute myelogenous leukemia, von Recklinghausen's neurofibromatosis [neurofibromatosis 1], Wegener's granulomatosis, sarcoidosis, Crohn's disease, primary amyloidosis, Kaposi's sarcoma, acromegaly, and lymphoma), and hereditary gingivofibromatosis.

Management

Prevention through optimal oral hygiene is essential to minimize the severity of enlargement. For patients treated for epilepsy, medications must be reviewed before orthodontic treatment begins. There are several treatment options for drug-induced gingival enlargement. The most predictable treatment is either the withdrawal or change of medication and there are a variety of new-generation anticonvulsants, immunosuppressants, and antihypertensives available. Tacrolimus has been shown to be an effective replacement for cyclosporine and does not seem to cause gingival enlargement.

Nonsurgical treatments such as professional gingival debridement and topical or systemic antimicrobials may ameliorate gingival enlargement. Surgical management is reserved for severe cases, although recurrence is common. Conventional gingivectomy is commonly performed, although periodontal flap surgery may be indicated if there are mucogingival considerations, or in pediatric patients in whom tooth eruption might be affected. Laser ablation gingivectomy may offer an advantage over conventional surgery since procedures are faster and there is improved hemostasis and more rapid healing.

Other Causes of Gingival Enlargement

Although not strictly reactive, gingival enlargement may rarely be the result of genetic predisposition. Hereditary gingivofibromatosis (Figure 6-13), is linked to both autosomal dominant and recessive patterns of inheritance, and genetic heterogeneity and variable expressivity contribute to the difficulty encountered in assigning this diagnosis to a specific syndrome.[16] Putative inherited mutations are in the *SOS1 or CAMK4* genes. In contrast, there are a number of syndromes in which gingival enlargement is one of the manifestations. Enlargement may be present at birth or may become apparent only with the eruption of the deciduous or permanent dentitions. Tooth migration, prolonged retention of the primary dentition, and diastemata are common, and enlargement may completely cover the crowns of the teeth, resulting in compromised oral function.

Patients with acute myelogenous leukemia (principally acute monocytic [M4] or acute myelomonocytic [M5] leukemia) may present with gingival leukemic infiltrates (Figure 6-14). Others include von Recklinghausen's neurofibromatosis (neurofibromatosis 1), Wegener's granulomatosis, sarcoidosis, Crohn's disease, primary amyloidosis, Kaposi's sarcoma, acromegaly, and lymphoma.

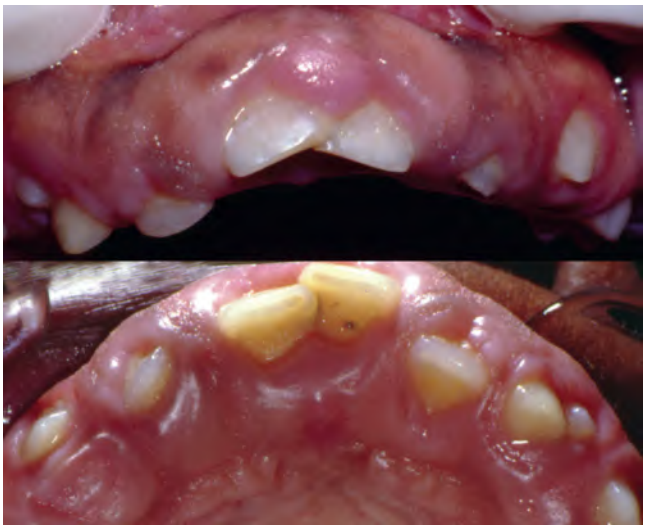

Figure 6-13 Hereditary gingival fibromatosis. Note the severity, with almost complete coverage of teeth in some locations.

Figure 6-14 Gingival enlargement associated with acute myelogenous leukemia.

BENIGN SOFT TISSUE TUMORS

Oral mucosal benign tumors comprise lesions that are formed from epithelium, fibrous connective tissue, adipose tissue, nerve, and muscle. Benign proliferations of blood vessels and lymphatic vessels resemble neoplasms, but do not have unlimited growth potential and therefore are more appropriately considered hamartomatous proliferations.

Epithelial Tumors

Human Papillomavirus-Induced Growths

Etiology and Pathogenesis

These growths are not true neoplasms, but rather virally induced tissue proliferations.[17] There are almost 200 human papillomavirus (HPV) genotypes, of which at least 30 have been detected in oral lesions. Much attention has been focused on the relationship between oncogenic genotypes (predominantly HPV 16) and oropharyngeal carcinogenesis (see Chapter 7, "Head and Neck Cancer"). Benign HPV-induced lesions are not routinely genotyped, and in case series where such lesions were genotyped, HPV positivity was variable (ranging from 13 to 100%), suggesting methodologic inconsistencies. In those lesions that are HPV positive, nononcogenic genotypes predominate. The virus infects the basal cell layer of the epithelium following mucosal trauma, there is integration of the viral genome, and proliferation of the epithelium leading to the development of a clinically visible lesion or lesions. The virus is most often transmitted by direct contact with another infected person, although such a history may not be evident, suggesting transmission by autoinoculation or casual contact. Lesions associated with sexual contact (referred to as condyloma acuminatum) or vertical transmission are also covered in Chapter 21, "Infectious Diseases."

Epidemiology

HPV-induced growths are estimated to have a prevalence of <0.4% and comprise <5% of all oral biopsy specimens submitted for histology. Current effective vaccines for HPV may be expected to result in a decrease in prevalence of HPV-induced lesions. Patients living with HIV infection are at higher risk for developing HPV-induced growths than immunocompetent patients. Viral papillomas (also called squamous papilloma), largely associated with HPV 6 and 11, are the most commonly appearing of the HPV-induced growths (Figure 6-15) and they usually occur in the third to fifth decades. Verruca vulgaris is predominantly cutaneous (associated with HPV 2 and 57), and condyloma accuminatum, similar to genital warts, is associated with HPV 6 and 11. Heck's disease is endemic in some Eskimo and Native American communities and associated with HPV 13 and 32.

Clinical and Histologic Manifestations

Viral papillomas most commonly present as an isolated small growth (<1 cm diameter) on the palate, ranging in color from white to pink, their surface is papillary/verrucous, and they are pedunculated more often than sessile. Condyloma accuminata are typically larger in size than viral papillomas, are often flat-topped, and may present as a single main growth associated with smaller satellite lesions. The common wart, verruca vulgaris, is generally found on the skin (sometimes in association with similar skin lesions, often on the fingers). When involving the oral cavity, these warts are similar in appearance to viral papillomas and they tend to involve the lips, gingivae, and hard palate.

Focal epithelial hyperplasia (Heck's disease) is characterized by numerous soft, well-circumscribed, comparatively flat, and sessile papules distributed throughout the oral

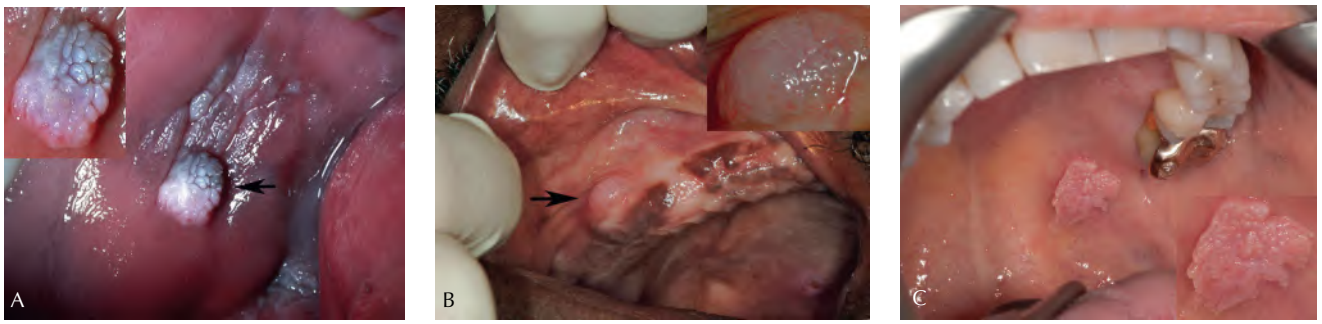

Figure 6-15 (A) Viral papilloma involving the right buccal mucosa. Note the papillary and highly keratinized surface, presumably related to the location (see inset). (B) Viral papilloma with a pebbled surface (inset) involving the right maxillary alveolar ridge. (C) Viral papilloma with a papillary surface (inset) involving the soft palate.

mucosa. Histologically, FEH is characterized by non-dyskeratotic nodular acanthosis, which forms the basis of the papules, and a subepithelial lymphocytic infiltration. Intraoral papillomatosis, often florid, has been found in a small subset of HIV-infected patients (Figure 6-16), particularly since the advent of active antiretroviral therapy, and may be associated with numerous HPV genotypes. Florid papillomatosis may also occur in patients with conditions such as ichthyosis hystrix (a congenitally acquired deforming skin papillomatosis) and Down syndrome.

Differential Diagnosis

Verruciform xanthoma, giant cell fibroma, or a verrucous leukoplakia or papillary squamous cell carcinoma can mimic solitary benign HPV-induced growths. White sponge nevus, or proliferative verrucous leukoplakia, may mimic florid benign HPV-induced growths.

Management

Oral viral papillomas and warts are clinically similar, and local excision is desirable. Care should be exercised when removing HPV-induced oral growths with electrocautery or laser, as there exists the possibility of aerosolizing viral particles. Due to the widespread manifestations, florid disease is challenging to manage surgically, and there is no current evidence-based medical management.

Keratoacanthoma

Etiology and Pathogenesis

The rapid growth of a keratoacanthoma may be quite frightening, to the point where it is often mistakenly diagnosed as squamous or basal cell carcinoma.

Epidemiology

They are exceedingly rare.

Clinical and Histologic Manifestations

The usual location is on the upper lip, where they are dome-like, sharply demarcated, appear fixed to the surrounding tissue, and are usually capped by thick keratin.[18] The proliferating epithelium consists of masses of well-differentiated squamous cells that often produce keratin pearls, yet show little cellular atypia.

Differential Diagnosis

Squamous cell or basal cell carcinoma.

Management

Occasionally, the lesion matures, exfoliates, and heals spontaneously. In most cases, however, treatment of this lesion is conservative excision, although some believe that it is not clearly separable from squamous cell carcinoma and advocate wide excision to prevent recurrence.

Other Benign Epithelial Growths

Molluscum contagiosum is a dermatologic infection caused by a poxvirus that is acquired by direct skin contact. Both intraoral and labial lesions of molluscum contagiosum occur, predominantly in HIV-infected patients, and these are characterized by clusters of tiny firm papules. Histologically, these papules are composed of clumps of proliferating epithelial cells with prominent eosinophilic molluscum inclusion bodies that are commonly associated with poxvirus infections.

Vascular Anomalies

These entities have been classified using standardized terminology developed by the International Society for the Study of Vascular Anomalies and may be subdivided into vascular tumors and vascular malformations.[19]

Hemangiomas

Etiology and Pathogenesis

Hemangiomas of the head and neck are vascular tumors and true endothelial cell neoplasms. They appear a few weeks after birth and grow rapidly, and in most cases undergo involution over time, with residual telangiectatic, fatty, or scar tissue apparent in approximately 50% of patients.

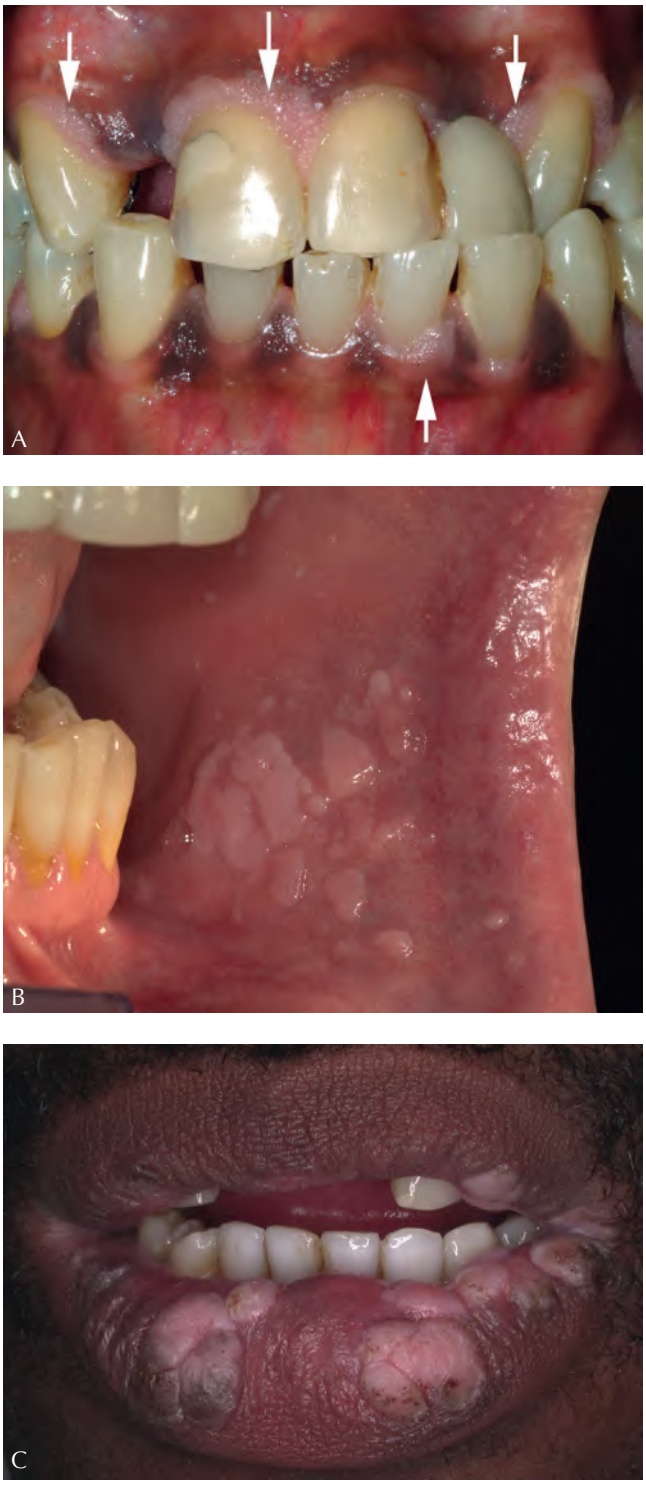

Figure 6-16 (A) HIV-associated florid papillomatosis involving free marginal gingivae. (B) HIV-associated florid papillomatosis involving buccal mucosa. Note coalescing papules, which are flat. (C) HIV-associated florid papillomatosis involving the lips.

Epidemiology

Hemangiomas are present in approximately 4–5% of infants. The majority (approximately 70%) involve the head and neck.

Clinical and Histologic Manifestations

They have been described in almost all head and neck locations in a variety of presentations: superficial and deep, small and large, most commonly as solitary lesions but also as multiple lesions. Small lesions may be clinically and histologically indistinguishable from pyogenic granulomas and superficial venous varicosities.

Differential Diagnosis

Oral hemangiomas may be similar in appearance to vascular malformations, or pyogenic granulomas.

Management

Given the propensity for involution, surgery should only be considered for those that do not involute, are esthetically obtrusive, or bleed easily.

Capillary, Venous, and Arterial/Arteriovenous Vascular Malformations

Etiology and Pathogenesis

These malformations are classified depending on the vessel type involved or flow types: arterial and arteriovenous (high flow), capillary (Figure 6-17), or venous (low flow). They are structural aberrations in components of the vascular apparatus and may be clinically apparent at birth, grow slowly proportional to the growth of the child (characterized by hypertrophy), and never involute. Centrally located malformations must be distinguished from the many osteolytic tumors and cyst-like lesions that affect the jaws (see later). Arterial and arteriovenous malformations may first develop following hormonal changes (such as puberty), infections,

Figure 6-17 Vascular malformation involving the tongue, which developed two months before in a 25-year-old female.

or trauma. Venous malformations can sometimes appear first in early adulthood.

Epidemiology

It is challenging to estimate the prevalence of vascular malformations because of the older classification systems for vascular anomalies implemented in large screening studies. However, the prevalence of oral vascular malformations is approximately 0.2–0.5%.

Clinical Manifestations

Arterial or arteriovenous malformations may be firm, pulsatile, and warm. Venous malformations are soft and easily compressible. Diascopy is the technique of applying pressure to a suspected vascular lesion to visualize the evacuation of coloration (Figure 6-18) and may facilitate the differentiation of a small vascular lesion from ot her nonblanchable red or pigmented lesions.

Differential Diagnosis

The diagnosis of malignant neoplasms must always be entertained if lesions demonstrate progressive enlargement.

Figure 6-18 Diascopy of a small capillary malformation on the lateral border of the tongue. Note blanching of the lesion.

Management

Care should be taken in performing biopsies or excising all vascular lesions, as they have a tendency for uncontrolled hemorrhage and the extent of the lesion is unknown, since only a small portion may be evident in the mouth. Therefore, identification of the precise anatomic location and depth of tissue extent is warranted before treatment, particularly for the high-flow lesions. A number of imaging modalities may be indicated, including ultrasound, contrast-enhanced magnetic resonance imaging or computed tomography (CT), and dynamic MR angiography. Treatment modalities (alone or in combination) for peripheral vascular malformations depend on the type of malformation and include sirolimus, sclerotherapy, embolization, or surgical excision/resection using electrocoagulation.

Other Angiomatous Syndromes

A number of syndromes are associated with vascular malformations, including Osler–Weber–Rendu syndrome (hereditary hemorrhagic telangiectasia; Figure 6-19), blue rubber bleb nevus syndrome, Bannayan–Zonana syndrome, Sturge–Weber syndrome (Figure 6-20),[20] Klippel–Trénaunay syndrome, Servelle–Martorell syndrome, von Hippel–Lindau syndrome, and Maffucci syndrome.

Lymphatic Malformations

Etiology and Pathogenesis

Macrocystic, microcystic, or mixed cystic lymphatic malformations may be localized or regional, and they are characterized by an abnormal proliferation of lymphatic vessels. The most common extraoral and intraoral sites are the neck (predominantly in the posterior triangle) and tongue, respectively. The vast majority (80–90%) of lymphangiomas arise

Figure 6-19 Osler–Wendu–Rendu syndrome (hereditary hemorrhagic telangiectasia). Note discrete multiple red papules associated with dilated vessels. Patient has similar papules distributed on his labial mucosae and finger tips.

Figure 6-20 Sturge–Weber syndrome. Hypervascular changes are unilateral, which is consistent with a trigeminal nerve distribution, in this case following the second (maxillary) branch of the left trigeminal nerve.

within the first two years of life and are an important cause of congenital macroglossia.

Epidemiology

Lymphatic malformations are rare.

Clinical and Histologic Manifestations

Clinically, lymphangiomas are a slow-growing and painless soft tissue mass. Frequently they are without a clear anatomic outline, dissecting tissue planes, and can be more extensive than anticipated. Intraosseous lymphangiomas have been reported. Occasionally, they may undergo a rapid increase in size secondary to inflammation from an infection or hemorrhage from trauma. Large lymphangiomas may become life-threatening if they compromise the airway or vital blood vessels, and those spreading into and distending the neck are macrocystic and are referred to as cystic hygromas. Abnormalities of the tongue mucosa overlying a lymphatic malformation may give the appearance of a localized glossitis and may draw attention to the presence of a lesion buried deep in the tongue. The typical oral lymphatic malformation has a racemose or pebbly surface.

Differential Diagnosis

Includes other vascular malformations, amyloidosis, neurofibromatosis, and other causes of macroglossia.

Management

The treatment of lymphatic malformations is dictated by their type, anatomic site, and extent of infiltration into surrounding structures. Sclerotherapy (with chemotherapeutic agents such as picabinil [OK-432], bleomycin, or doxycycline) is advocated over surgical excision in most cases. Recurrence of oral lymphangiomas has been reported, presumably because the lesion is interwoven between muscle fibers, preventing complete removal.

Other Vascular Growths

An unusual abnormality, glomus tumor (glomangioma), develops as a small, painful, unencapsulated nodule. It represents a proliferation of the modified smooth muscle pericytic cells found in the characteristic type of peripheral arteriovenous anastomosis known as the glomus. In addition to having a distinctive histology, these lesions also may secrete various catecholamines. The glomus tumor is rare in the mouth and occurs more often around the carotid body, in the jugulotympanic region, and in the vagus nerve. Glomus tumors arising in the carotid bodies may produce neck masses and are referred to as chemodectomas or paragangliomas.

Neurogenic Tumors[21]

Traumatic Neuroma

Etiology and Pathogenesis

A traumatic neuroma is a reactive lesion caused by injury to a peripheral nerve. When a nerve and its sheath are damaged, the proximal end of the damaged nerve proliferates into a mass of nerve and Schwann cells mixed with dense fibrous scar tissue.[22] In the oral cavity, injury to a nerve may occur from injection of local anesthesia, surgery, or other sources of trauma.

Epidemiology

Traumatic neuromas are rare and tend to occur in adults.

Clinical Manifestations

Traumatic neuromas in the oral cavity may occur in any location where a nerve is damaged, and the mental foramen area, tongue, and lower lip are the most common sites. Traumatic neuromas may lead to either reduced sensation or, in approximately 20% of cases, elicit discomfort.[22] The discomfort may

range from pain on palpation or pressure from an overlying denture (in the case of a neuroma involving the mental foramen area) to severe and constant pain.

Differential Diagnosis

Any smooth-surfaced submucosal exophytic lesion may be included in a differential diagnosis, including the palisaded encapsulated neuroma, neurofibroma, schwannoma, irritation fibroma, tumors of muscles, and minor salivary gland neoplasms.

Management

Traumatic neuromas are treated by surgical excision and recurrence is rare.

Palisaded Encapsulated Neuroma

Etiology and Pathogenesis

This is considered a reactive neoplasm, likely in response to trauma.

Epidemiology

This lesion is rare and most often occurs in older adults.

Clinical and Histologic Manifestations

The lesions are solitary, a feature that distinguishes them from the neuromas in MEN syndrome (see later). They are typically painless and the most common location is the hard palate.[23] Histologically, there is a well-circumscribed, partially encapsulated nodule composed of spindle-shaped cells exhibiting areas of nuclear palisading, often admixed with axons. They contain Schwann cells, perineural cells, and axons, and can be distinguished from neurofibromas and schwannomas both by their light microscopic appearance and by immunohistochemical stain that is positive for EMA and S-100.

Differential Diagnosis

Any smooth-surfaced submucosal exophytic lesion may be included in a differential diagnosis, including the palisaded encapsulated neuroma, neurofibroma, neurilemmoma, irritation fibroma, tumors of muscle tissue, and minor salivary gland neoplasms.

Management

Palisaded encapsulated neuromas are treated by surgical excision and recurrence is rare.

Oral Mucosal Neuromas and Multiple Endocrine Neoplasia Syndrome 2B (MEN 2B)

MEN 2B is caused by inherited mutations in the Met918Thr *RET* gene and characterized by tumors or hyperplasias of neuroendocrine tissues.[24] Patients with MEN 2B present with a characteristic phenotype that includes medullary thyroid carcinoma, pheochromocytoma, prominent corneal nerve fibers, a "Marfanoid" body habitus, enlarged lips, and neuromas on the eyelids and oral mucosal tissues. Identification of mucosal neuromas may precede other components of the syndrome. Management includes prophylactic total thyroidectomy, ideally before the age of 1 year.

Neurofibroma and Schwannoma (aka Neurilemmoma)

Etiology and Pathogenesis

These are benign tumors derived from the tissue that envelops nerves and includes Schwann cells and fibroblasts.[25] Although distinct tumors microscopically, they are quite similar in their clinical presentation and behavior.

Epidemiology

These benign tumors are rare and may occur at any age, without any sex predilection.

Clinical and Histologic Manifestations

They are typically asymptomatic and the tongue is the most common intraoral location (Figure 6-21). Microscopic examination of a neurofibroma reveals a fairly well-delineated but diffuse proliferation of spindle-shaped Schwann cells. A schwannoma is encapsulated and exhibits varying amounts of two different microscopic patterns. One pattern consists of cells in a palisaded arrangement around eosinophilic areas, and the other consists of less cellular spindle-shaped cells in a loose myxoid-appearing stroma. Differences in immunohistochemical staining have been demonstrated and may be helpful in establishing the definitive diagnosis.

Differential Diagnosis

Any smooth-surfaced submucosal exophytic lesion may be included in a differential diagnosis, including the palisaded encapsulated neuroma, irritation fibroma, tumors of muscle tissue, and minor salivary gland neoplasms.

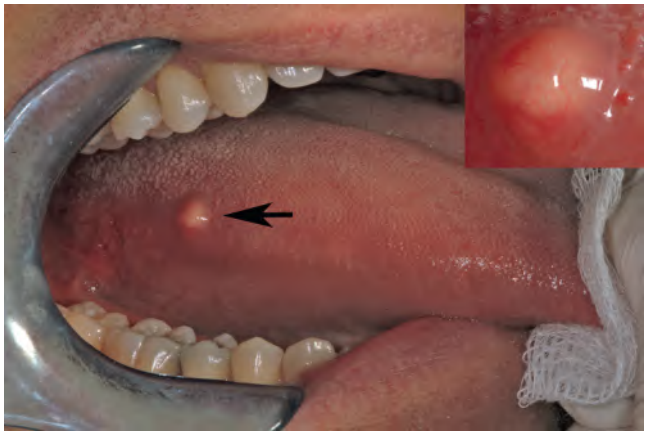

Figure 6-21 Neurogenic tumor involving the right lateral tongue.

Management

The treatment for a neurofibroma or schwannoma is surgical excision. They generally do not recur.

Multiple neurofibromas occur in a genetically inherited disorder known as neurofibromatosis 1 (NF1) or von Recklinghausen's disease. This disease is transmitted as an autosomal dominant trait, and a germline mutation in the *NF1* gene has been identified. Oral neurofibromas are a common feature of the disease. The presence of numerous neurofibromas or a plexiform-type neurofibroma is pathognomonic of NF1. Patients with NF1 are at increased risk of the development of a number of malignant tumors, especially malignant peripheral nerve sheath tumor, leukemia, and rhabdomyosarcoma.

Granular Cell Tumor

Etiology and Pathogenesis

The pathogenesis of this tumor has not been established, but most evidence suggests that it is reactive and arises from Schwann cells or their primitive mesenchymal precursors.

Epidemiology

These are rare, and the majority of cases occur in adults, with a female predilection.

Clinical and Histologic Manifestations

The granular cell tumor most often occurs on the dorsal tongue (Figure 6-22A), followed by the buccal and labial mucosae. Other intraoral sites include the palate (Figure 6-22B), gingiva, and floor of the mouth. The tumor appears as a painless, often yellowish, nonulcerated nodule. The granular cell tumor is a benign tumor composed of large oval-shaped cells with a granular cytoplasm.[26] The granular cells are found in the connective tissue and the overlying surface epithelium exhibits pseudoepitheliomatous hyperplasia. Immunocytochemical staining reveals reactivity to S-100 protein, vimentin, CD-68, calretinin, NKI/C3, Inhibin-α, p75, and PGP9.5.

Differential Diagnosis

Any smooth-surfaced submucosal exophytic lesion may be included in a differential diagnosis, including the palisaded encapsulated neuroma, neurofibroma, schwannoma, irritation fibroma, verruciform xanthoma, tumors of muscle tissue, and minor salivary gland neoplasms.

Management

This tumor is treated by conservative surgical excision and does not recur.

The congenital epulis of the newborn is a very rare benign neoplasm composed of cells that closely resemble those seen in the granular cell tumor that occurs in adults. It is present at birth and usually presents as a smooth-surfaced, sessile, or pedunculated mass on the anterior maxillary alveolar ridge. It almost always occurs in girls. The ultrastructural and immunohistochemical features are distinct from the granular cell tumor, confirming that this lesion is a separate entity. The congenital epulis is treated by surgical excision and does not recur, and occasionally it will regress without treatment.

Melanotic Neuroectodermal Tumor of Infancy

Etiology and Pathogenesis

Melanotic neuroectodermal tumor of infancy is a benign neoplasm originating from neural crest cells that almost always occurs during the first year of life.

Epidemiology

This entity is exceedingly rare.

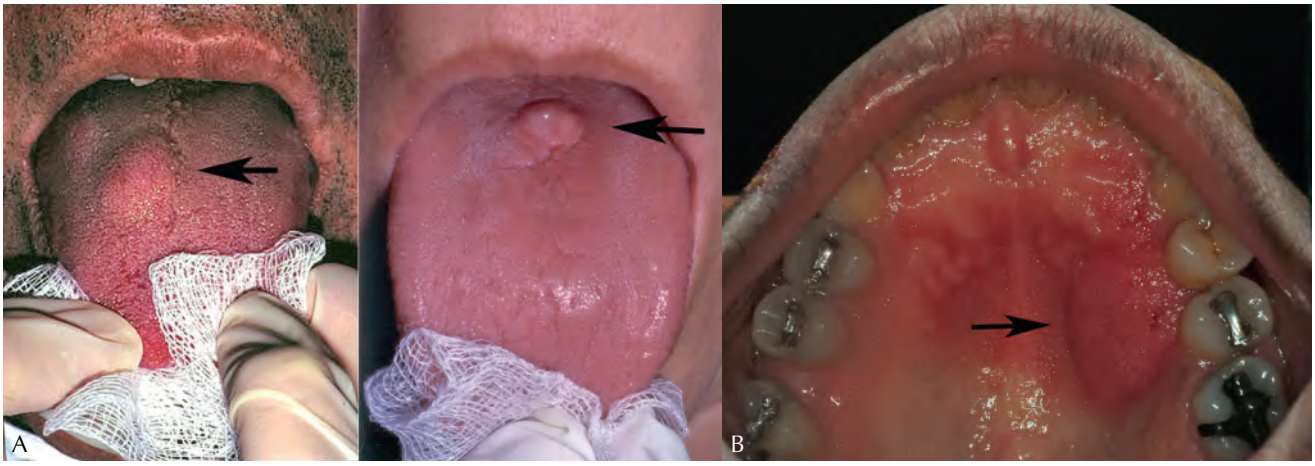

Figure 6-22 (A) Granular cell tumors of the tongue, the most common site for this benign lesion. (B) Granular cell tumor involving the palate, an unusual site.

Clinical and Histologic Manifestations

The tumor most commonly occurs in the maxilla, followed by the skull, mandible, and brain. The tumor presents as a rapidly enlarging mass that destroys bone and may exhibit blue-black pigmentation. Histologically, the tumor is composed of collections of cells that resemble melanocytes, admixed with smaller round cells and variable amounts of melanin.

Differential Diagnosis

Given the rapid growth, malignant neoplasms must be considered, including sarcomas, and lymphomas.

Laboratory Findings

High levels of urinary vanillylmandelic acid are often found in patients with this tumor.

Management

Conservative surgical removal is usually adequate, but this tumor has a high recurrence rate and malignant transformation has been reported rarely.

Lipoma

Etiology and Pathogenesis

The lipoma is a benign mesenchymal tumor of mature adipocytes.

Epidemiology

Lipomas involving the oral cavity are rare (<3% of all lipomas). They occur in individuals over 40 years of age, and without any sex predilection.

Clinical and Histologic Manifestations

The majority of oral lipomas are found on the buccal mucosa and tongue. When occurring in the superficial soft tissue, the lipoma appears as a yellow/orange mass with a thin epithelial surface, demonstrating a delicate pattern of blood vessels (Figure 6-23). There are several microscopic variants of the lipoma. The classic description is of a well-delineated tumor composed of lobules of mature fat cells that are uniform in size and shape.[27] The most common variants are fibrolipomas (i.e., those with a significant fibrous connective tissue component), followed by spindle cell lipomas (i.e., those with an admixture of uniform spindle cells), rarely sialolipomas, angiolipomas, myxoid lipomas, and an intramuscular lipoma.

Differential Diagnosis

The yellow/orange color is pathognomic. Other yellowish entities include abscess, sialolith, lymphoepithelial cyst, or granular cell tumor.

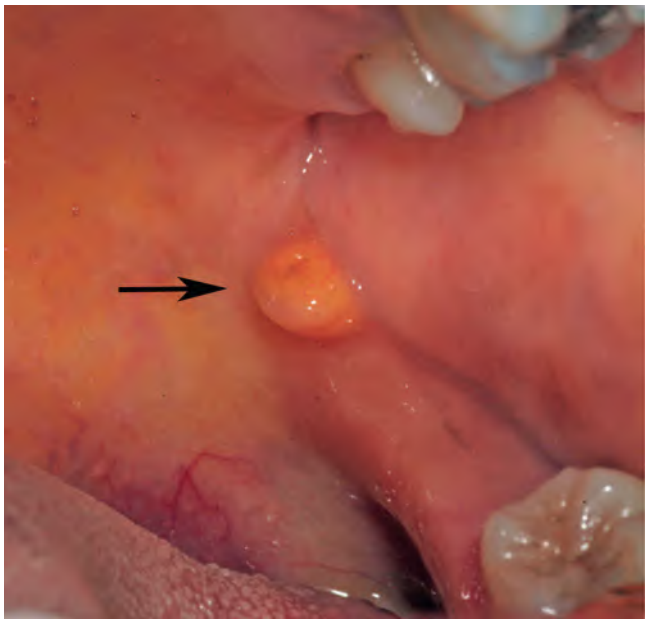

Figure 6-23 Lipoma involving the buccal mucosa. Note the yellow color.

Management

The lipoma is treated by conservative surgical excision and generally does not recur. Intramuscular lipomas have a somewhat higher recurrence rate because they are more difficult to remove completely.

Tumors of Muscle

Etiology and Pathogenesis

These are benign neoplasms of striated (rhabdomyoma) and smooth (leiomyoma) muscle.

Epidemiology

Tumors of muscle are exceedingly rare in the oral cavity.

Clinical Manifestations

Oral rhabdomyomas have been reported to occur almost exclusively on the tongue. The vascular leiomyoma (angioleiomyoma) is the least rare of the leiomyoma variants and solitary lesions have been reported to involve multiple oral sites.[28]

Differential Diagnosis

Any smooth-surfaced submucosal exophytic lesion may be included in a differential diagnosis, including the palisaded encapsulated neuroma, neurofibroma, schwannoma, irritation fibroma, granular cell tumor, and minor salivary gland neoplasms.

Management

Treatment is local surgical excision, and recurrence is rare.

BENIGN HARD TISSUE LESIONS

BENIGN FIBRO-OSSEOUS LESIONS

The term "benign fibro-osseous lesion" (BFOL) is a generic histologic designation for a diverse group of bone lesions that are named for the similarity of their histopathologic morphology (see classification in Box 6-1). They are composed of cellular fibrous connective tissue admixed with either osteoid matrix, woven new bone and bone trabeculae, or rounded small to large calcified masses that have traditionally been described as cementoid material. BFOLs of the jaws include fibrous dysplasia, ossifying fibroma, and the cemento-osseous dysplasias. Since the histopathology is so similar in these lesions, imaging with radiographic correlation is critical for the diagnosis.

Fibrous Dysplasia

Fibrous dysplasia is a condition that is characterized by the replacement of normal bone with fibro-osseous tissue. The well-vascularized and cellular fibrous tissue contains trabeculae or spherules (small spheres) of poorly calcified nonlamellar bone that are formed by osseous metaplasia.

Etiology and Pathogenesis

The pathogenesis is related to *GNAS* (guanine nucleotide binding protein, alpha stimulating) gene mutation. The most widely accepted theory is that fibrous dysplasia results from an abnormality in the development of bone-forming mesenchyme.

Epidemiology

Fibrous dysplasia presents in childhood, typically with a slowly progressive enlargement of bone that generally slows or ceases with puberty.

Box 6-1 Benign Fibro-osseous Lesions

Fibrous Dysplasia

- Monostotic
- Polyostotic

Ossifying Fibroma
  Juvenile (active or aggressive)

Cemento-osseous Dysplasia

- Periapical
- Focal
- Florid

Clinical and Histologic Manifestations

Radiographically, fibrous dysplasia classically presents with a "ground glass" appearance and may have varying degrees of radiopacity and lucency depending on the amount of calcified material present. The abnormal bone merges with the adjacent normal bone, which leads to a lack of circumscription or delineation of these lesions. Plain film imaging and CT are useful in the diagnosis of fibrous dysplasia.

Biopsy of involved bone reveals a tissue that is often described clinically as "gritty" or "sandy." Several forms of fibrous dysplasia have been described. The monostotic form, characterized by the involvement of a single bone, is the most common form. Polyostotic forms are characterized by the involvement of more than one bone and include different types: (1) craniofacial fibrous dysplasia, in which the maxilla and adjacent bones are involved; (2) Jaffe's type (or Jaffe–Lichtenstein type), in which there is multiple bone involvement along with an irregular macular melanin pigmentation of the skin (café au lait spots); and (3) rare cases in children (McCune–Albright syndrome or Albright syndrome), in which there is severe, progressive bone involvement with café au lait skin pigmentation and endocrine abnormalities such as precocious puberty.

Laboratory Findings

An elevation in serum alkaline phosphatase may be seen in patients with extensive polyostotic disease.

Management

In most cases, once diagnosis has been confirmed, management with close monitoring or with superficial recontouring of the lesion is sufficient. Curettage is sometimes used for large radiolucent lesions. Radiotherapy is contraindicated in the treatment of fibrous dysplasia. Early treatment using radiotherapy may have played a role in the rare cases of malignant transformation to fibrosarcoma or osteogenic sarcoma. Attempts at treating advanced cases of the polyostotic form with calcitonin have not been successful, but more recently use of bisphosphonates has had some use in limiting bone loss.

The *clinical problems* associated with fibrous dysplasia of bone are related to the site and extent of involvement. In the long bones, deformity and fractures are common complications that often lead to the initial diagnosis. In the jaws and other parts of the craniofacial skeleton, involvement of adjacent structures such as the cranial sinuses, cranial nerves, and ocular contents can lead to serious complications in addition to cosmetic and functional problems. Intracranial lesions arising from the cranial bones may produce seizures and electroencephalographic changes. Extension into and occlusion of the maxillary and ethmoid

sinuses and mastoid air spaces are common. Proptosis, diplopia, and interference with jaw function also often prompt surgical intervention.

Systematic review of craniofacial fibro-osseous disease demonstrates an increased risk of developing a malignant transformation in patients with fibrous dysplasia. The most common malignant transformation is to osteogenic sarcoma and the average time from initial diagnosis of BFOL to malignancy was 18.2 years; therefore, long-term follow-up is indicated.

Ossifying Fibroma

Etiology and Pathogenesis

Ossifying fibroma is a slow-growing, well-circumscribed, benign tumor of bone that probably arises from cells of the periodontal ligament.

Epidemiology

This benign tumor occurs in the mandible more frequently than the maxilla. It is usually diagnosed in the third to fourth decades of age, but has a broad age range and a female predilection.

Clinical, Radiographic, and Histologic Manifestations

Radiographically, the tumor has a well-circumscribed margin (Figure 6-24). The cementifying fibroma has been reclassified under the category of ossifying fibroma.[29] The ossifying fibroma is a benign fibro-osseous lesion that is histologically composed of cellular fibrous connective tissue containing varying amounts of osteoid, rounded cementoid calcifications and irregularly shaped bone trabeculae.

Differential Diagnosis

The clinical/radiographic differential diagnosis includes enostosis, osteoblastoma/osteoid osteoma, complex odontoma, and perhaps dense bone island/idiopathic osteosclerosis, depending on the size and radiographic appearance.

Management

Treatment involves conservative surgical excision of the tumor.

Juvenile Ossifying Fibroma

Juvenile ossifying fibroma is a controversial lesion that is separated from ossifying fibroma based on the patient's age (most are children and young adults), location of lesion, and clinical behavior. This tumor exhibits more aggressive behavior and a greater propensity for recurrence than ossifying fibroma.

Cemento-Osseous Dysplasias

Etiology and Pathogenesis

The etiology and pathogenesis of these conditions are unknown. The lesions begin as radiolucencies that become more radiopaque with time; large calcified masses become a characteristic histologic feature.[30] Three forms of this dysplastic process involving bone of the jaws are described: periapical cemento-osseous dysplasia, focal cemento-osseous dysplasia, and florid cemento-osseous dysplasia.

Epidemiology

Periapical cemento-osseous dysplasia and florid osseous dysplasia are most commonly reported in black women over the age of 40 years. Focal cemento-osseous dysplasia is also reported to occur frequently in middle-aged white women.

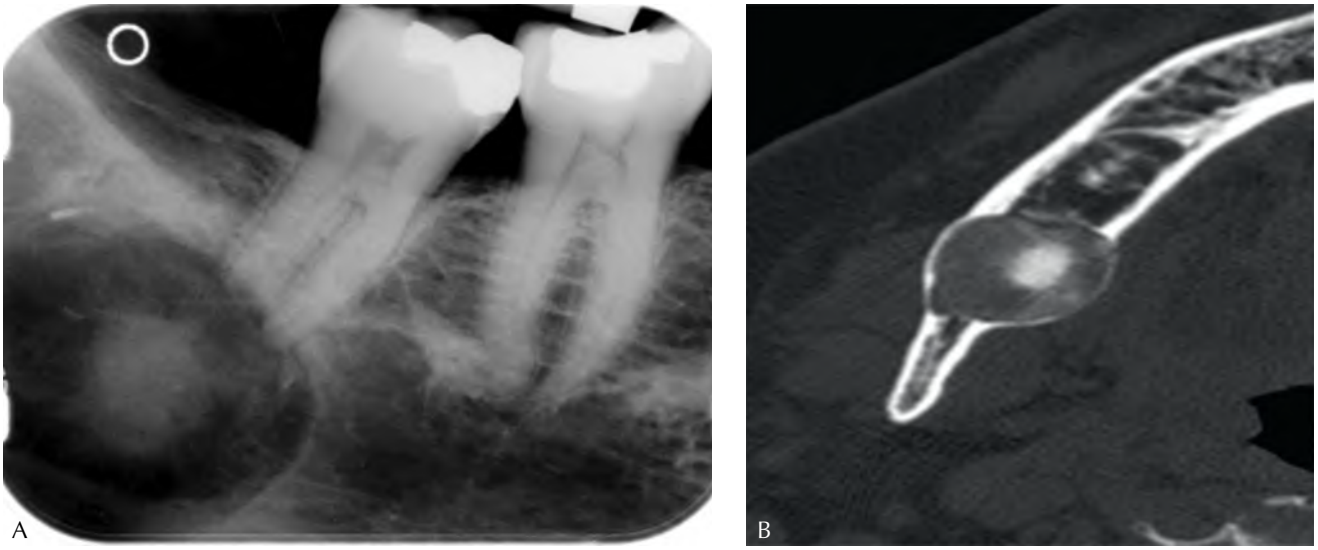

Figure 6-24 Ossifying fibroma in a 64-year-old female. (A) Periapical and (B) cropped axial CT bone window images show a well-circumscribed, mixed radiolucent-radiopaque entity of the posterior right mandible. The entity has concentric expansion and remodeled the overlying buccal and lingual cortices.

Clinical and Histopathologic Manifestations

Periapical and florid types are generally most appropriately diagnosed on the basis of the clinical and radiographic features. The focal type requires a biopsy to establish a definitive diagnosis. Periapical cemento-osseous dysplasia, previously called cementoma, is a lesion that occurs at the apical aspect of vital mandibular anterior teeth. The condition is asymptomatic and does not require treatment.

Focal cemento-osseous dysplasia differs from the periapical form since it occurs at the apical aspect of posterior teeth. Florid cemento-osseous dysplasia presents as an exuberant form of cemento-osseous dysplasia, involving more than one and often multiple quadrants of the maxilla and mandible. Cystic changes similar to simple bone cysts may be seen in association with florid cemento-osseous dysplasia (Figure 6-25A). The calcified masses of the dysplastic bone do not resorb with the alveolar process in edentulous patients (Figure 6-25B). In patients with tissue-borne removable dentures, secondary infection may occur from mucosal perforation and subsequent communication between the dysplastic bone and oral cavity. Additionally, the affected bone becomes sclerotic with little vasculature, complicating the healing process.

Differential Diagnosis

The differential diagnosis of periapical cento-osseous dysplasia when the lesion is radiolucent includes dental pulp–related periapical inflammatory disease, and establishment of tooth vitality is critically important. Florid cemento-osseous dysplasia may resemble Paget's disease; however, florid cemento-osseous dysplasia is limited to the gnathic bones. The differential for focal cemento-osseous dysplasia could include numerous lesions, depending on whether it is radiolucent or demonstrates opacity.

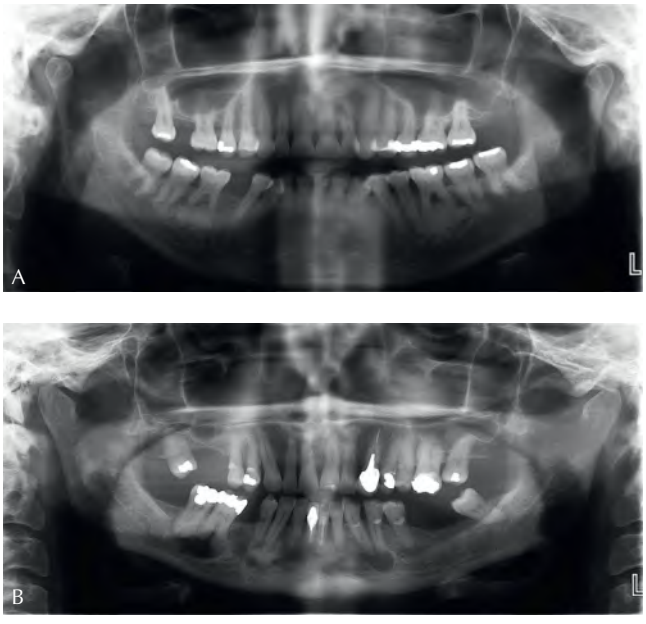

Figure 6-25 Florid cemento-osseous dysplasia (A) without and (B) with simple bone cyst association.

Management

Surgery (e.g., extractions, placement of implants) should be avoided due to potential poor healing and the increased risk of osteomyelitis associated with the affected bone, especially once the bone is sclerotic. Asymptomatic patients should be counseled and followed regularly for prophylactic dental care. This will help to eliminate odontogenic or periodontal disease and any associated surgical intervention.

LANGERHANS CELL HISTIOCYTOSIS (HISTIOCYTOSIS X)

Etiology and Pathogenesis

Langerhans cell histiocytosis, formerly called histiocytosis X, comprises a group of conditions that are characterized histologically by a monoclonal proliferation of large mononuclear cells accompanied by a prominent eosinophilic infiltrate.[31] The mononuclear cells have been identified as Langerhans cells (the most peripheral cell of the immune system) by their immunologic staining characteristics and the presence of a cytoplasmic inclusion called the Birbeck granule. Historically, the clinical spectrum of Langerhans cell histiocytosis includes (1) single or multiple bone lesions with no visceral involvement (eosinophilic granuloma); (2) a chronic disseminated form that includes the classic Hand–Schüller–Christian triad of skull lesions, exophthalmos, and diabetes insipidus; and (3) an acute disseminated form (Letterer–Siwe disease) that affects multiple organs and has a poor prognosis. Langerhans cell histiocytosis is currently classified by the clinical extent and severity of disease at diagnosis (Table 6-1).[31] Studies have shown that 40–60% of lesions have a *BRAF* mutation. This finding has lent support to the theory that this should be considered a neoplastic condition rather than one of reactive etiology as previously accepted.

Epidemiology

Each of the forms of Langerhans cell histiocytosis tends to affect patients at different ages, with the eosinophilic granuloma affecting older children and young adults, the chronic disseminated form affecting young children, and the acute disseminated form affecting infants and children under the age of 2 years.

Clinical, Radiographic, and Histologic Manifestations

Single or multiple eosinophilic granulomas with no systemic or visceral involvement are the most common presentation. Both the maxilla and the mandible may be affected in Langerhans cell histiocytosis, both with and without systemic involvement. Early lesions present radiographically as well-defined, noncorticated radiolucencies. With time, the

Table 6-1 Current clinical classification of langerhans cell histiocytosis.

Single organ system disease
Unifocal
Multifocal
Multiorgan system disease
No organ dysfunction
Organ dysfunction
• Low-risk, excellent prognosis organs: skin, bone, lymph node, pituitary
• High-risk, poor prognosis organs: lung, liver, spleen, hematopoietic

lesions enlarge and coalesce with one another, resulting in more bone destruction (Figure 6-26). Involvement of the alveolar process may mimic periodontal disease, but Langerhans cell histiocytosis starts at the mid-root level. The gingival soft tissues may also be involved, and this may resemble periapical or periodontal inflammatory disease.

Differential Diagnosis

This includes disorders causing alveolar bone loss in children. Aggressive periodontitis, Papillon–Lefèvre syndrome, cyclic neutropenia/agranulocytosis, and Burkitt's lymphoma could all be considered in the differential diagnosis. Each of these, as well as Langerhan's histiocytosis, can cause a significant destruction of bone around the teeth, leading to a radiographic appearance of "teeth floating in air."

Management

The treatment varies, based on the clinical presentation of the disease. Solitary eosinophilic granuloma may be treated by surgical curettage. Low-dose radiation therapy has been used successfully for lesions that are multiple, less accessible, or persistent. The older the patient with Langerhans cell histiocytosis and the less visceral involvement, the better the prognosis. Langerhans cell histiocytosis is a life-threatening disease in infants and very young children.

Figure 6-26 Langerhans cell histiocytosis. Multiple, well-defined, noncorticated radiolucencies have coalesced to give the appearance of diffuse mandibular bone destruction.

GIANT CELL LESIONS OF BONE

Giant cell lesions include the peripheral giant cell granuloma (see "Benign Soft Tissue Tumors") and the central giant cell granuloma, aneurysmal bone cyst, and cherubism (discussed here). These conditions are all non-neoplastic lesions that are characterized by a similar histologic appearance. Common to all of them is the presence of numerous multinucleated giant cells in a background of mesenchymal cells that contain round to ovoid nuclei. Extravasated red blood cells and hemosiderin deposits are commonly found in these lesions, as are reactive bone trabeculae. The aneurysmal bone cyst contains varying-sized blood-filled spaces, frequently admixed with trabeculae of bone. The bone lesions of cherubism are similar to those of the central giant cell granuloma.

Central Giant Cell Granuloma (Central Giant Cell Lesion)

Etiology and Pathogenesis

As already noted, the majority of these lesions are thought to be non-neoplastic.

Epidemiology

Central giant cell granuloma occurs more frequently in the mandible than the maxilla, generally anterior to the first molar, and often crossing the midline. Most central giant cell granulomas are diagnosed before age 30 years.

Clinical, Radiographic, and Histologic Manifestations

The radiographic features vary from small, well-circumscribed radiolucencies mimicking periapical inflammatory disease to large, destructive, multilocular radiolucencies (Figure 6-27). The lesions have been reported to perforate the corticle plate and extend into the soft tissue adjacent to the bone. Complaint of pain is an inconsistent feature of these lesions.

Laboratory Findings

The diagnosis of a central giant cell granuloma requires an evaluation for hyperparathyroidism (see also Chapter 22, "Disorders of the Endocrine System and of Metabolism"). Serum calcium, phosphorus, and alkaline phosphatase levels should be obtained prior to surgical removal of a giant cell granuloma, and if abnormal, parathyroid hormone (PTH) levels should be assessed. Lesions radiographically and histologically identical to the giant cell granuloma occur in primary and secondary hyperparathyroidism, and treatment of the lesion in these cases involves treatment of the hyperparathyroidism rather than treatment of the giant cell granuloma. Primary hyperparathyroidism is a result of uncontrolled PTH due to a parathyroid gland abnormality. Secondary hyperparathyroidism develops, usually in patients

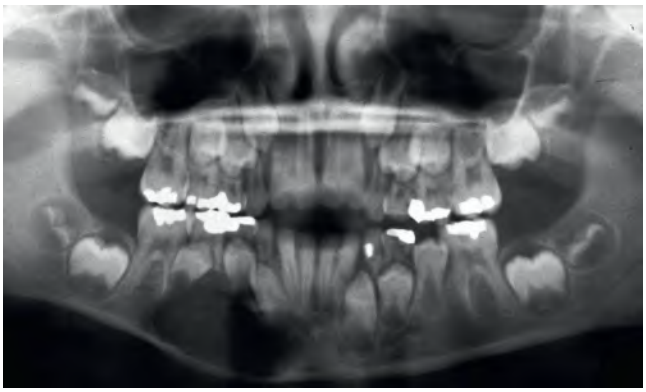

Figure 6-27 Giant cell granuloma. A panoramic radiograph of a giant cell granuloma in a child with a mixed dentition.

with chronic renal disease, due to an increase in PTH production in response to chronic low levels of serum calcium.

Differential Diagnosis

The radiographic differential is rather extensive considering this can appear as a small unilocular radiolucency or a larger multiloculated lesion. For the multilocular lesions ameloblastoma, odontogenic keratocyst, odontogenic myxoma, and central hemangioma are all considerations depending on the presentation.

Management

Treatment usually involves conservative curettage. Other treatment modalities include systemic calcitonin, intralesional injections of corticosteroids, and use of RANKL inhibitors like denosumab. Recurrence rates ranging from 11 to 49% have been reported.

Aneurysmal Bone Cyst

Etiology and Pathogenesis

The term *aneurysmal bone cyst* is a misnomer, since this lesion is not a true cyst and exhibits no epithelial lining. It does contain varying-sized blood-filled spaces. While most lesions are generally believed to be reactive, primary aneurysmal bone cysts have been found to result from oncogenic activation of the *USP6* gene on chromosome 17p13.[32]

Epidemiology

The lesion occurs less frequently in the jaws than in the long bones, but when in the jaws it usually involves the mandible rather than the maxilla. Tissue histologically consistent with aneurysmal bone cyst can be seen in association with other bone diseases, such as fibrous dysplasia. Consequently, aneurysmal bone cysts have been categorized as either primary, for those occurring alone, or secondary, for those occurring in association with another bone disease. Both sexes are equally affected and 80% of aneurysmal bone cysts occur in patients younger than 30 years.

Clinical, Radiographic, and Histologic Manifestations

The clinical signs and symptoms are nonspecific. Pain has been reported (although not consistently) and enlargement of the involved bone is common. The radiographic appearance varies from unilocular to multilocular (Figure 6-28).

Management

Treatment depends on the size of the lesions and includes curettage, enucleation, and resection. Recurrence is attributed to incomplete removal.

Cherubism

Etiology and Pathogenesis

Cherubism is inherited as an autosomal dominant trait, with a penetrance of nearly 100% in males and 50–75% in females. Genetic overexpression of *SH3BP2* on chromosome 4p16 for the 3BP2 protein is the accepted cause of the disease.[33] Other patterns of inheritance and the occurrence of cherubism in association with other syndromes have been described.

Epidemiology

Cherubism is a rare disease that usually presents in early childhood.

Clinical, Radiographic, and Histologic Manifestations

Cherubism is characterized by bilateral painless swellings (mandible and maxilla) that cause fullness of the cheeks;

Figure 6-28 Aneurysmal bone cyst. An aneurysmal bone cyst presenting as a multilocular radiolucency in the angle of the mandible of a 31-year-old woman.

firm, protuberant, intraoral, alveolar masses; and missing or displaced teeth.[33] Submandibular lymphadenopathy is an early and constant feature that tends to subside after the age of 5 years and usually has regressed by the age of 12 years. Maxillary involvement can often produce a slightly upward turning of the child's eyes, revealing an abnormal amount of sclera beneath them. It was the upward "looking toward heaven" cast of the eyes combined with the characteristic facial chubbiness of these children that prompted the term *cherubism*. The clinical appearance may vary from barely discernible posterior swellings of a single jaw to significant deformation from anterior and posterior expansion of both jaws, with concomitant difficulties in mastication, speech, swallowing, and respiration.

Disease activity declines with advancing age. Radiographically, the lesions are multiple well-defined multilocular radiolucencies in the mandible and maxilla. They are irregular in size and usually cause marked destruction of the alveolar bone. Numerous displaced and unerupted teeth appear to be floating in radiolucent spaces. Histologically, the lesions of cherubism resemble the central giant cell granuloma, but may exhibit eosinophilic deposits surrounding blood vessels throughout the lesion.

Laboratory Findings

Serum calcium and phosphorus are within normal limits, but serum alkaline phosphatase may be elevated.

Differential Diagnosis

When considering multiquadrant, multilocular radiolucencies in children, Gorlin syndrome (nevoid basal carcinoma syndrome) and Noonan syndrome should be in the differential.

Management

A variety of treatments have been recommended: no active treatment and regular follow-up, extraction of teeth in the involved areas, surgical contouring of expanded lesions, or complete curettage. Long-term longitudinal investigations have reported that the childhood lesions become partially or completely resolved in the adult.

PAGET'S DISEASE OF BONE (OSTEITIS DEFORMANS)

Etiology and Pathogenesis

The etiology of Paget's disease is not well understood. The possibility of an infective viral etiology is suggested by the ultrastructural demonstration of intranuclear inclusions in the abnormal osteoclasts, both in Paget's disease and in the cells of Paget's disease–associated osteosarcoma. Also of note is a significant decrease in the number of new cases in areas of previous high prevalence over the past two decades. However, a viral etiology remains controversial. In recent years, genetic mutations affecting osteoclastogenesis, such as inactivation of *TNFRSF11B* for osteoprotegerin and mutation of *SQSTM1* for the NFKappaB signaling pathway, have been found in some cases of Paget's disease of bone.

It has been reported that close to 30% of patients with Paget's disease have a first-degree relative who has also been affected. This supports the case that both genetic and environmental factors may be playing a role in the disease. About 40% of familial cases have been found to have a mutation of the *SQSTM1* gene.

Epidemiology

Paget's disease of bone affects about 3% of the population over 45 years of age and is rare in patients younger than 40 years. It has a predilection for those of Anglo-Saxon ancestry. Paget's disease is exceeded only by osteoporosis in numbers of patients affected by a metabolic bone disease. Malignant transformation to osteosarcoma and giant cell tumor occurs in less than 1% of patients.

Clinical, Radiographic, and Histologic Manifestations

Paget's disease of bone is a chronic disease of the adult skeleton characterized by focal areas of excessive bone resorption followed by bone formation. Histologically, the involved bone demonstrates prominent reversal lines that result from the resorption and deposition of bone. There is also replacement of the normal bone marrow by vascular fibrous connective tissue. Although some patients with Paget's disease have no symptoms, many experience considerable pain and deformity. The narrowing of skull foramina can cause ill-defined neuralgic pains, severe headache, dizziness, and deafness. The bony lesions of Paget's disease produce characteristic deformities of the skull, jaw, back, pelvis, and legs that are readily recognized both clinically and radiographically. Enlargement of the affected bone is common. Irregular overgrowth of the maxilla may lead to the facial appearance described as "leontiasis ossea," and edentulous patients may complain that their dentures no longer fit. Radiographically, there are patchy radiolucent and radiopaque changes that have been described as a "cotton wool" appearance. Other radiographic findings of the jaw bones include loss of the lamina dura, root resorption, and hypercementosis. CT and Tc 99m diphosphonate bone scanning are used to define the extent of bone involvement.

Laboratory Findings

Urinary levels of calcium and hydroxyproline (a measure of collagen metabolism) and serum alkaline phosphatase levels

(a measure of osteoblastic activity) are useful for diagnosing Paget's disease and for monitoring bone resorption and deposition during treatment.

Management

Craniofacial disorders, associated medical problems (e.g., cardiac failure, hypercalcemia), and the incidence of malignant transformation have encouraged the use of a variety of new treatments.[34] These agents include antibiotics (i.e., intravenous mithramycin, an effective inhibitor of osteoclastic activity), hormones of human and animal origin (high-dose glucocorticoids and porcine, salmon, and human calcitonin administered subcutaneously or by nasal spray or suppository), salts such as the diphosphonate etidronate (which effectively reduces bone resorption), and cytotoxic agents such as plicamycin and dactinomycin.

In addition to cosmetic issues, dental concerns include poor healing of dental extraction sites and excessive postsurgical bleeding from the highly vascular bone that is characteristic of this disease. Bone that exhibits unusually rapid change or enlargement suggests the possibility of malignant transformation. In view of the rarity of a giant cell tumor in the jaws except as a complication of Paget's disease, the finding of this lesion in a patient who is older than 40 years of age should raise the possibility of previously undiagnosed Paget's disease.

CYSTS OF THE JAWS AND ADJACENT SOFT TISSUES

Cysts are defined as fluid-filled epithelium-lined pathologic cavities. Odontogenic cysts are those derived from tooth-forming tissues and/or associated with teeth. Odontogenic and nonodontogenic cysts occur in the oral soft tissues and in both maxilla and mandible. The cysts included here are those that are most common in the jaws and adjacent soft tissues.[35,36]

Odontogenic Cysts

Radicular Cyst (Periapical Cyst)

Etiology and Pathogenesis

A radicular cyst is a true cyst that occurs in association with the root of a nonvital tooth. It is the most commonly occurring cyst in the oral region. An inflammatory response occurs in the periapical tissue, resulting in resorption of bone and formation of granulation tissue that is infiltrated by acute and chronic inflammatory cells. The epithelial lining for the radicular cyst is thought to develop as a result of proliferation of the rests of Malassez entrapped in the inflamed granulation tissue. Histologically, the radicular cyst appears as a squamous epithelium-lined cyst lumen surrounded by inflamed fibrous connective tissue.

Epidemiology

The majority of radicular cysts are seen in adults and the anterior maxilla is the most common location for these cysts.

Clinical and Radiographic Manifestations

Most radicular cysts are asymptomatic and discovered on radiographic examination. Symptoms tend to present when the cyst becomes acutely inflamed. On imaging, they appear as well-circumscribed radiolucencies at the apex or lateral to a tooth root (Figure 6-29). These cysts respond in a negative way to electric and thermal pulp testing.

Differential Diagnosis

Any well-circumscribed unilocular radiolucency adjacent to the root of a tooth could be in the differential. Periapical cemento-osseous dysplasia, periapical granuloma, and periapical scar are included, as is lateral periodontal cyst for the lateral radicular cyst. However, more aggressive lesions such as odontogenic keratocyst, ameloblastoma, and even lymphoma may initially present as a small unilocular radiolucency, therefore submission of removed tissue for microscopic examination is essential.

Management

The radicular cyst is treated by endodontic therapy, apicoectomy, or extraction and curettage of the periapical tissues. A residual cyst forms when the tooth is removed and all or part of a radicular cyst is left behind. Radiographically, the residual cyst appears as a well-circumscribed radiolucency

Figure 6-29 Radicular (periapical) cyst.

located at the site of a previously extracted tooth. Either biopsy or excision of the lesion with histologic examination of the tissue is necessary for diagnosis and the treatment is based on the diagnosis. The treatment of a residual cyst involves conservative surgical excision. The cyst does not recur, since the tooth associated with the pathogenesis of the cyst has been removed.

Dentigerous Cyst (Follicular Cyst)

Etiology and Pathogenesis

The dentigerous cyst arises from the epithelium of the dental follicle and remains attached to the neck of the tooth, enclosing the crown within the cyst.

Epidemiology

Some unerupted teeth (e.g., third molars and canines) appear to be more susceptible than others to the development of such cysts. Neoplastic changes such as plexiform ameloblastoma and carcinoma have been reported to occur within segments of the wall of dentigerous cysts. This potential for neoplastic change, infiltration beyond the cyst wall, and the occasional finding of other odontogenic tumors in association with a dentigerous cyst fully justify the need for histopathologic examination of all material derived from jaw cysts.

Clinical and Radiographic Manifestations

A dentigerous or follicular cyst is diagnosed on the basis of its very specific location. The dentigerous cyst forms around the crown of an unerupted or impacted tooth, which may be part of the regular dentition or a supernumerary tooth. Dentigerous cysts have the potential for attaining a large size and also tend to resorb the roots of adjacent teeth. Histologically, the epithelial lining varies from cuboidal to squamous and from very thin to hyperplastic.

Differential Diagnosis

Ameloblastoma, odontogenic keratocyst, and hyperplastic dental follicles should all be considered in the differential. Early calcifying lesions, such as calcifying odontogenic cyst, could also be considered.

Management

Enucleation of the cyst with extraction of the tooth is the most common treatment, with low risk of recurrence. If the cyst is associated with a tooth being considered for eruption, such as with an impacted canine, partial removal of the cyst wall may be indicated along with opening to the oral cavity and potential bracketing of the tooth for orthodontic movement. Larger dentigerous cysts may be decompressed prior to enucleation.

The eruption cyst is the soft tissue analogue of the dentigerous cyst; it presents clinically as a bluish gray swelling of the mucosa over an erupting tooth, most commonly first permanent molars and maxillary incisors. These are also referred to as eruption hematomas. If any treatment is needed, excision of a wedge of the mucosa to expose the tooth crown is usually adequate.

Odontogenic Keratocyst (Keratocystic Odontogenic Tumor)

Etiology and Pathogenesis

In 2005, the World Health Organization (WHO) classified the odontogenic keratocyst as the keratocystic odontogenic tumor. *This decision was then reconsidered by the WHO and reversed in 2016, returning the classification to odontogenic keratocyst (OKC).* Reasons to consider this lesion as a cystic neoplasm include its aggressive clinical course, its tendency for recurrence, its association with certain genetic abnormalities, and its occurrence in the nevoid basal cell carcinoma (Gorlin–Goltz) syndrome.[37]

Epidemiology

The posterior mandible is the most common site of occurrence. However, the odontogenic keratocyst may occur in any location in the maxilla or mandible.

Clinical, Radiographic, and Histologic Manifestations

Radiographically, the OKC may present as a small, asymptomatic, unilocular radiolucency (Figure 6-30A). However, larger, multilocular radiolucencies are common presentations of this cystic neoplasm (Figure 6-30B). The lesions tend to grow along the medullary space of the jaw bone prior to causing expansion of the cortical plate. The odontogenic keratocyst is characterized by its unique histologic appearance. The lumen is lined by epithelium that is generally 8–10 cell layers thick and surfaced by parakeratin. The interface between the epithelium and connective tissue is devoid of rete ridges and the basal cell layer is palisaded and prominent. The parakeratin forms a wavy, corrugated surface.[37] Budding of the cyst lining into the connective tissue is also described as a feature of this cystic neoplasm.

Differential Diagnosis

Early lesion may be unilocular and depending on location a number of lesions would be considered in the differential. Multilocular radiolucencies are typically in the differential with OKC, therefore ameloblastoma, central giant cell granuloma, odontogenic myxoma, and calcifying epithelial odontogenic tumor (early lesions prior to calcifications becoming apparent on imaging) would be included, among others.

Management

Complete removal of the OKC is necessary to prevent recurrence and may be difficult due to the thin, fragile nature of the cyst wall. Treatment ranges from decompression and enucleation to peripheral ostectomy, and chemical cauterization to resection.

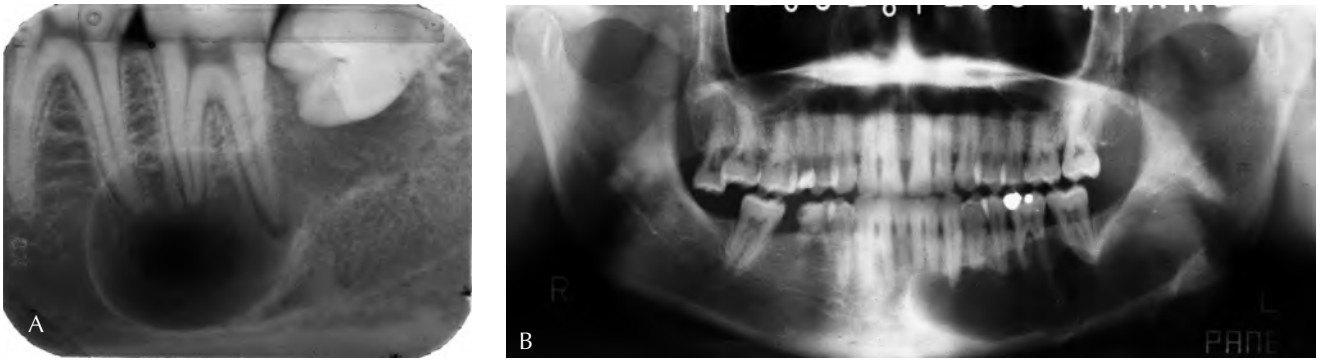

Figure 6-30 Keratocystic odontogenic tumor. (A) A keratocystic odontogenic tumor presenting as a well-circumscribed radiolucency mimicking a periapical inflammatory lesion. (B) A keratocystic odontogenic tumor presenting as a large radiolucency in the mandible.

Figure 6-31 Keratocystic odontogenic tumor in nevoid basal cell carcinoma syndrome. The multiple radiolucencies seen in this patient with the syndrome ere histologically shown to be keratocystic odontogenic tumors.

The OKC can occur as an isolated cyst or as a component of the nevoid basal cell carcinoma syndrome (Figure 6-31). This syndrome is inherited as an autosomal dominant trait that exhibits high penetrance and variable expressivity. Mutation of the *PTCH1* gene on chromosome 9q22.3-31 has been shown to be the cause of the syndrome. In addition to keratocystic odontogenic tumors (usually multiple), components of the syndrome include (among many others) basal cell carcinomas developing at an early age in non-sun-exposed skin, mild hypertelorism, enlarged calvarium, calcification of the falx cerebri, and rib abnormalities. Pitting of the soles and palms (local areas of undermaturation of the epithelial basal cells) is an additional finding in about half of individuals affected by the syndrome. Despite the syndrome's name, multiple basal cell carcinomas occur in only 50% of cases. Appropriate treatment for OKC is simple curettage or marsupialization of the cysts.

Lateral Periodontal Cyst (Botryoid Odontogenic Cyst)

Although the lateral periodontal cyst has a distinct and characteristic histologic appearance, the cyst is named for its location.

Etiology and Pathogenesis

These developmental cysts are believed to be derived from remnants of the dental lamina.

Epidemiology

These cysts are most commonly found in adults.

Clinical, Radiographic, and Histologic Manifestations

Lateral periodontal cysts most often present as an asymptomatic unilocular (rarely multilocular) radiolucency, lateral to the root of a vital tooth (Figure 6-32). They are located in the mandibular premolar/canine/lateral incisor area 75% of the time.[38] Divergence of the affected roots is not uncommon. Histologically, the lateral periodontal cyst exhibits a very thin lining of stratified squamous epithelium with focal epithelial thickenings.

Differential Diagnosis

Any unilocular radiolucency in a position lateral to the tooth root would be considered in the differential. This would include lateral radicular cysts, early adenomatoid odontogenic tumors, as well as small ameloblastomas and odontogenic keratocysts.

Management

These cysts are treated by conservative surgical excision. A few cases of recurrence of lateral periodontal cysts have been reported.

The gingival cyst is the soft tissue analogue of the lateral periodontal cyst. The botryoid odontogenic cyst is a variant of the lateral periodontal cyst and clinically may appear multilocular.

Calcifying Odontogenic Cyst (Gorlin Cyst)

Etiology and Pathogenesis

The etiology of the cystic and solid variants of this lesion have been debated for some time. It is now generally considered that the solid variant is a benign tumor (the WHO classifies this as a dentinogenic ghost cell tumor) and the more common variant is a cystic lesion, and both are thought to arise from the dental lamina.[39] These lesions can be seen in

Figure 6-32 A lateral periodontal cyst presenting as a well-circumscribed radiolucency between the roots of a mandibular lateral and cuspid.

association with odontomas (~20% of reported cases) and other odontogenic tumors.

Epidemiology

A rare lesion making up less than 1% of odontogenic cysts. It is seen over a large age range, but most are seen in the second to fourth decades of life. Calcifying odontogenic cysts have about equal prevalence in the maxilla and mandible and approximately two-thirds are seen in the canine/incisor area.

Clinical, Radiographic, and Histologic Manifestations

It is usually a well-defined lesion that can present either as a unilocular or a multilocular radiolucency.[39] Calcifications are seen radiographically as radiopaque areas within a radiolucent lesion. Odontomas have been seen in association with calcifying odontogenic cysts. The calcifying odontogenic cyst is usually a nonaggressive cystic lesion lined by odontogenic epithelium that resembles that of the ameloblastoma, but with characteristic ghost cell keratinization. A solid, noncystic variant histologically resembling the calcifying odontogenic cyst has been described.

Differential Diagnosis

Early lesions with no calcifications would be in the differential with other well-circumscribed unilocular radiolucencies such as dentigerous cyst, early odontogenic keratocyst, and ameloblastoma. Once calcifications appear on imaging, the differential changes and would include adenomatoid odontogenic tumor and calcifying epithelial odontogenic tumor.

Management

The calcifying odontogenic cyst is generally treated by surgical enucleation and usually does not recur. The solid variant has been reported to exhibit more aggressive behavior and a higher recurrence rate and therefore needs more aggressive surgical management, such as peripheral ostectomy or resection.

Glandular Odontogenic Cyst (Sialo-odontogenic Cyst)

Etiology and Pathogenesis

Since 1987, the glandular odontogenic cyst has been recognized as a distinct developmental cyst of the jaws, bearing a histologic resemblance to the botryoid odontogenic cyst and mucoepidermoid carcinoma.[40]

Epidemiology

Clinically, the glandular odontogenic cyst commonly affects middle-aged adults, with no sex predilection. The anterior mandible is a frequent site of occurrence.

Clinical, Radiographic, and Histologic Manifestations

Patients may be asymptomatic or have a painless jaw swelling at presentation. Radiographically, the glandular odontogenic cyst can manifest as a well-defined unilocular or multilocular radiolucency. Histologically, key diagnostic features of the cyst lining include eosinophilic cuboidal (hobnail) cells, clear cells, intraepithelial microcysts, and epithelial spheres.

Differential Diagnosis

Well-circumscribed unilocular radiolucencies would be in the differential with lesions like radicular cyst, but larger lesions may appear multilocular and be in the differential with ameloblastoma, odontogenic keratocyst, and central giant cell granuloma.

Management

The glandular odontogenic cyst is locally aggressive and tends to recur after surgery.

Buccal Bifurcation Cyst

The buccal bifurcation cyst is exceedingly rare and recognized as an inflammatory odontogenic cyst of the pediatric population. Clinically, the cyst typically manifests as a swelling buccal to the furcation of the mandibular first or second molar. The cyst may also present bilaterally. The affected tooth is vital, but may have a deep periodontal pocket. Radiographically, the buccal bifurcation cyst appears as a well-defined unilocular radiolucency centered on the furcation of the mandibular molar (Figure 6-33A). An occlusal radiographic projection will show the cyst tipping the roots of the affected molar lingually

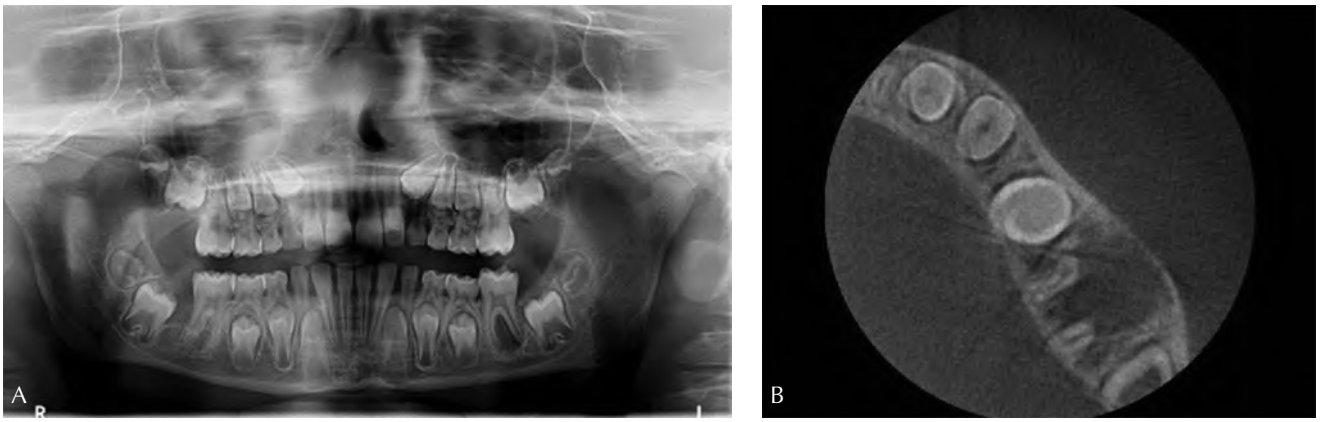

Figure 6-33 Buccal bifurcation cyst. (A) Panoramic and (B) axial cone beam computed tomographic images of a buccal bifurcation cyst associated with the mandibular left first molar. The cyst has tipped the molar roots to the lingual mandibular cortex.

(Figure 6-33B). Histologic features of the buccal bifurcation cyst consist of a nonspecific, inflamed cyst lining. The buccal bifurcation cyst should not recur after curettage.

Nonodontogenic Cysts

Nasopalatine Canal (Duct) Cyst

Etiology and Pathogenesis

The nasopalatine canal (duct) cyst is a developmental cyst derived from remnants of epithelium-lined vestigial oronasal duct tissue.

Epidemiology

The nasopalatine canal cyst is the most common nonodontogenic cyst of the oral cavity and has a mean age of diagnosis in the fifth decade.[41]

Clinical, Radiographic, and Histologic Manifestations

Lesions are often asymptomatic and found on routine imaging, but larger lesions can lead to expansion of the bone and/or soft tissue in the palate. The cyst is located within the nasopalatine canal and presents as a unilocular radiolucency between the roots of vital maxillary central incisors (Figure 6-34).[41] The cyst lining varies from squamous to respiratory (pseudostratified ciliated columnar in about one-third of cases) epithelium. Blood vessels and nerve tissue, contents of the nasopalatine canal, are frequently seen in the connective tissue wall of the cyst.

Differential Diagnosis

The clinical evaluation involves differentiating this cyst from a normal nasopalatine foramen and a radicular cyst. The cyst of the incisive papilla is the soft tissue analogue of the nasopalatine canal cyst.

Management

The cyst is treated by conservative excision and does not recur if completely removed.

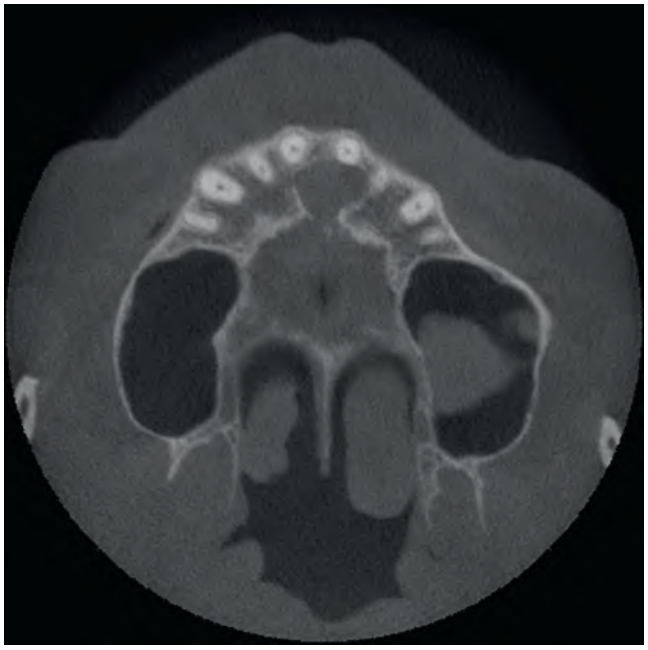

Figure 6-34 Nasopalatine canal (duct) cyst. Axial cone beam computed tomographic image shows a histologically proven nasopalatine canal (duct) cyst arising within the nasopalatine canal.

The nasoalveolar cyst is a soft tissue cyst of uncertain pathogenesis with no alveolar bone involvement. The cyst is observed in older adults, with a 4:1 female predilection. Clinically, the cyst presents as a swelling in the mucolabial fold. The cyst lining varies from squamous to respiratory (pseudostratified ciliated columnar) epithelium. Treatment is surgical excision, and recurrence is rare.

Pseudocysts

Simple (Traumatic, Hemorrhagic) Bone Cyst

The simple bone cyst is a pathologic cavity in bone that is not lined with epithelium. The cause is uncertain, although traditionally an association with trauma has been suggested. The

lesion is found most often in young patients, with an equal distribution between males and females. The lesion presents radiographically as a well-defined radiolucency that characteristically demonstrates a scalloping pattern around the roots of teeth. The lesion is usually asymptomatic and discovered on routine radiographs. Surgical intervention reveals a void within the bone, and healing generally follows intervention.

ODONTOGENIC TUMORS

The classification of odontogenic tumors that is most commonly used divides these tumors into three categories based on the type of cell that forms the tumor: epithelial, mesenchymal, and mixed epithelial and mesenchymal. Odontogenic tumors are derived from tooth-forming tissues, and the developmental stages of tooth formation are emulated in the various odontogenic tumors.

Epithelial Odontogenic Tumors

Ameloblastoma

Etiology and Pathogenesis

The ameloblastoma is the best known of the epithelial odontogenic tumors. The microscopic appearance of this tumor includes tumor cells resembling ameloblasts, with no formation of calcified material. *BRAF* (B-raf proto-oncogene serine/threonine kinase) gene mutations have been identified in ameloblastoma, as have a number of other mutations.[42] The efficacy of therapy targeted to these tumors is still being investigated, but may be helpful in cases where surgery is not an option.

Epidemiology

The ameloblastoma is most commonly seen in the posterior mandible, but may also arise in the maxilla and anterior aspect of the jaws. The radiographic appearance ranges from a unilocular to a multilocular radiolucency (Figure 6-35). Ameloblastomas are rare in children, with most cases occurring in patients between 20 and 50 years of age. A unicystic variant of the ameloblastoma tends to occur during teenage years and has been reported to exhibit a less aggressive behavior.

Figure 6-35 Ameloblastoma. Panoramic image shows a multilocular presentation of a histologically proven ameloblastoma.

Clinical, Radiographic, and Histologic Manifestations

Ameloblastoma is typically asymptomatic when small and shows up as an incidental finding on routine imaging. It is often associated with impacted teeth. Larger lesions can cause jaw expansion, perforation of the cortical plate, and even invasion into surrounding soft tissue. If left untreated ameloblastoma can lead to significant facial deformity. Microscopically, all ameloblastomas show a fibrous stroma, with islands or masses of proliferating epithelium that resemble the odontogenic epithelium of the enamel organ (i.e., palisading of cells around proliferating nests of odontogenic epithelium in a pattern similar to ameloblasts). Follicular, plexiform, and acanthomatous histologic variants of this tumor show basal cells, stellate reticulum, and squamous metaplasia. These histologic variants show no correlation with either the clinical appearance of the lesion or its behavior, and variation may be seen between different sections of the same tumor.[42]

Differential Diagnosis

Unilocular ameloblastoma may present like radicular cysts or resemble a dentigerous cyst, especially those lesions associated with an impacted tooth. For multilocular lesions odontogenic keratocyst, central giant cell granuloma, and odontogenic myxoma, among others, are include in the differential.

Management

Complete removal of the tumor is required to prevent recurrence; the plan for reconstruction often influences the extent of surgery. Rare examples of metastatic foci of an ameloblastoma in lungs or regional lymph nodes have been reported. Fewer than 20% of unicystic ameloblastomas have been reported to recur after curettage, whereas over 75% of solid ameloblastomas will recur unless treated by resection. Attempts have been made to marsupialize unicystic tumors. Recurrence is associated with incomplete removal of the tumor.

Adenomatoid Odontogenic Tumor

Etiology and Pathogenesis

Adenomatoid odontogenic tumor (AOT) is a benign tumor of odontogenic epithelium that exhibits behavior very different from the ameloblastoma. This tumor is characterized histologically by a very distinct capsule surrounding the tumor and structures resembling ducts ("adenomatoid") within the epithelium.[43]

Epidemiology

Approximately 70% of AOTs occur in females younger than 20 years and 70% involve the anterior jaw. Association with an impacted canine is common and the maxilla is affected more often than the mandible.

Clinical, Radiographic, and Histologic Manifestations

Early lesion can appear radiolucent, but as the lesion grows calcification arises within the lucency, leading to a mixed radiolucent-radiopaque lesion.[43] While often associated with impacted teeth, adenomatous odontogenic tumors may also present between the roots of teeth and may cause divergence of the roots as the lesion expands.

Differential Diagnosis

Early lesions without calcifications may resemble dentigerous cysts or lateral periodontal cysts. Once calcification is observed, calcifying odontogenic cyst and calcifying epithelial odontogenic tumor can present with a similar radiographic appearance.

Management

Adenomatoid odontogenic tumors often have a fibrous capsule, which means they are easily separated from the bone and rarely recur even with conservative curettage.

Calcifying Epithelial Odontogenic Tumor (Pindborg Tumor)

Etiology and Pathogenesis

The rare calcifying epithelial odontogenic tumor (CEOT) was first described by Dr. J. J. Pindborg in the 1950s. Since then only about 350 cases have been reported in the literature.[44] The lesion is thought to arise from rests of odontogenic epithelium.

Epidemiology

The CEOT has a presentation similar, in location and age of the patient, to ameloblastoma. The average age of presentation is in the fourth to fifth decades.

Clinical, Radiographic, and Histologic Manifestations

CEOT differs from other epithelial odontogenic tumors in that the epithelium does not resemble the epithelium of the tooth-forming apparatus.[44] It is composed of sheets of polyhedral epithelial cells with very little stroma. The cells of this tumor may be quite pleomorphic, with large nuclei. Foci of hyalin amyloid material and calcifications exhibiting concentric rings are frequently seen in this tumor. It is important for the pathologist to recognize this distinctive tumor so that it is not misdiagnosed as a squamous carcinoma. It is locally invasive and may present as a unilocular or multilocular swelling in the molar–ramus region. Larger lesions may expand the cortical bone.

Differential Diagnosis

Early lesions may present as small unilocular radiolucencies such as radicular cyst or lateral periodontal cyst. Multilocular radiolucent lesions would be in the differential with ameloblastoma, central giant cell granuloma, and odontogenic myxoma. For those lesions with calcifications, calcifying odontogenic cyst and AOT should be in the differential.

Management

Treatment is by enucleation or local block excision; the recurrence rate is reported to be 20%.

Squamous Odontogenic Tumor

The squamous odontogenic tumor is a rare lesion composed of multiple islands of squamous epithelium. The squamous epithelium does not exhibit the ameloblast-like features seen in the ameloblastoma. It is reported to occur equally within the maxilla and mandible. Radiographically, this tumor does not have distinctive features. The radiolucent area may resemble periodontal bone loss or periapical inflammatory disease. Conservative surgical excision is the treatment of choice for this tumor.

Mesenchymal Odontogenic Tumors

Odontogenic Myxoma

Etiology and Pathogenesis

Odontogenic myxoma is a benign tumor thought to arise from odontogenic ectomesenchyme.

Epidemiology

The mandible is the most common location (particularly the posterior mandible) of odontogenic myxomas and there is a slight female predilection. The mean age at presentation is in the third decade.[45]

Clinical, Radiographic, and Histologic Manifestations

Myxomas are slow-growing and invasive tumors that can become very large and distend the maxilla or mandible. Characteristically, a myxoma appears radiographically as a unilocular or multilocular lesion and is clinically and radiographically indistinguishable from other lesions that present with a similar radiographic appearance (Figure 6-36). Myxomas are tumors composed of very loose cellular connective tissue containing little collagen and large amounts of an intercellular substance that is rich in acid mucopolysaccharide. This lesion usually consists of very small rounded and angular cells lying in an abundant mucoid stroma that is reminiscent of dental pulp. Since similar lesions are very rare in other bones and since some oral myxomas contain tiny epithelial remnants that resemble inactive odontogenic epithelium, tumors with this histologic appearance that occur in the jaw bone are assumed to be odontogenic in origin.[45]

Differential Diagnosis

Ameloblastoma, odontogenic keratocyst, central giant cell granuloma, and central hemangioma are all included in the differential.

Management

Treatment is similar to that recommended for ameloblastoma.

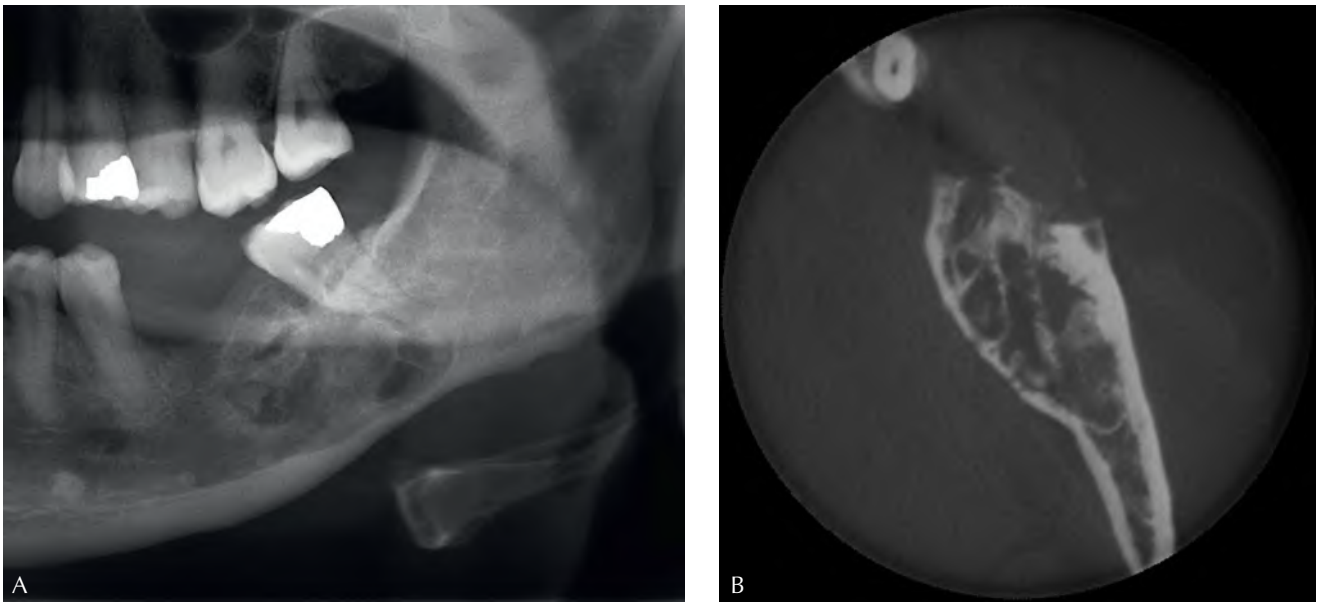

Figure 6-36 Odontogenic myxoma. (A) Cropped panoramic and (B) axial cone beam computed tomographic images show a well-defined multilocular radiolucency with long straight septa, characteristic of odontogenic myxoma.

Central Odontogenic Fibroma

The central odontogenic fibroma is a tumor composed of mature fibroblastic tissue admixed with nests and strands of odontogenic epithelium in varying amounts. It is an uncommon, slow-growing, and nonaggressive lesion. These tumors are usually well-defined unilocular radiolucencies. They are generally small, yet they may cause root resorption. Treatment is conservative excision.

Cementoblastoma

The cementoblastoma is a cementum-producing lesion that is fused to the roots of a vital tooth. The tumor often occurs in young adults and is associated with a mandibular molar or premolar.[46] Pain is a frequent complaint. Early in its development, this tumor presents as a periapical radiolucency that may be indistinguishable from a periapical inflammatory lesion. Later, the cementoblastoma demonstrates a pathognomonic appearance, a well-defined radiopaque mass surrounded by a radiolucent halo that incorporates the root of the tooth (Figure 6-37). Treatment involves removing both the tooth and the attached cementoblastoma. The cementoblastoma does not recur.

Figure 6-37 Cementoblastoma. Periapical image shows classic radiographic presentation of cementoblastoma fused to the root of the mandibular left first molar.

Mixed Odontogenic Tumors

Ameloblastic Fibroma

Etiology and Pathogenesis

The ameloblastic fibroma is a well-circumscribed tumor that is composed of mesenchymal tissue resembling dental papillae and small islands of odontogenic epithelium resembling dental lamina. A defined capsule may or may not be present with this tumor.

Epidemiology

Most cases of this tumor are in patients under 20 years of age, particularly very young children, and congenital cases have been reported. The most common location is the mandibular premolar and molar region.

Clinical, Radiographic, and Histologic Manifestations

Radiographically, an ameloblastic fibroma presents as a radiolucency that may be well defined, poorly defined, unilocular, or multilocular. When tooth-like formations are associated with this tumor, it is called an ameloblastic fibro-odontoma.

Management

The tumor is treated by surgical excision, and the recurrence rate is low.

Compound and Complex Odontomas

Etiology and Pathogenesis

Compound and complex odontomas are nonaggressive lesions that are more likely to be hamartomatous than neoplastic. Odontogenic cysts and other tumors may also be associated with odontomas.

Epidemiology

Most odontomas are identified in adolescents and young adults. The compound odontoma is most commonly seen in the anterior maxilla and the complex odontoma in the posterior mandible. A compound odontoma consists of a collection of numerous small teeth. Complex odontomas appear as radiopaque masses of varying radiodensity. Despite its designation as a hamartoma, the compound odontoma is considered the most common of the odontogenic tumors.

Clinical, Radiographic, and Histologic Manifestations

It is usually diagnosed by the radiographic identification of multiple small tooth structures. The complex odontoma appears radiographically as a radiopaque mass. It consists of a mass of enamel, dentin, cementum, and pulp that does not morphologically resemble a tooth. Histologic examination of the tissue is generally needed to establish the diagnosis.

Differential Diagnosis

Depending on the appearance of the odontoma, radiopaque lesions such as osteoblastoma, osteoid osteoma, enostosis, and idiopathic osteosclerosis may be included in the differential.

Management

Treatment of the compound or complex odontoma requires surgical excision. These lesions are not expected to recur.

BENIGN NONODONTOGENIC TUMORS OF THE JAWS

Osteomas and Gardner Syndrome

Etiology and Pathogenesis

Osteomas are benign tumors of bone that are composed of mature cancellous or cortical bone.

Epidemiology

Most are initially diagnosed in young adults.

Clinical, Radiographic, and Histologic Manifestations

They can form within the bone as a well-circumscribed radiopacity or on the surface of bone as either a sessile or polypoid bony-hard mass. Osteomas are asymptomatic and are generally undetected unless they are discovered on routine radiographic evaluation or cause facial asymmetry.

Differential Diagnosis

Dense bone island/idiopathic osteosclerosis and complex odontomas may mimic the radiographic appearance of osteomas. If the location is adjacent to teeth, condensing osteitis could also be considered.

Management

Osteomas can be followed with periodic radiographic evaluation to look for any alterations in size or shape. If multiple osteomas are identified in a child or young adult, evaluation for Gardner's syndrome (see below) should be considered.

Maxillary and mandibular tori were described earlier in this chapter. Although they are histologically identical to osteomas, they do not have unlimited growth potential and are not considered neoplasms.

The most significant feature of osteomas of the jaw is the association with Gardner's syndrome.[47] Gardner's syndrome is caused by mutations of the *APC* gene and inherited as an autosomal dominant trait with nearly 100% penetrance. A specific gene mutation responsible for Gardner's syndrome has been identified. Adenomatous polyps of the colon develop in the second and third decades in individuals with Gardner's syndrome. These polyps ultimately exhibit malignant transformation to adenocarcinoma. Patients with Gardner's syndrome develop multiple osteomas of the maxilla and mandible (Figure 6-38) that precede the diagnosis of colonic polyps. Other components of Gardner's syndrome include supernumerary teeth, impacted teeth, skin cysts, and fibrous tumors of the skin.[47]

Osteoblastoma and Osteoid Osteoma

Etiology and Pathogenesis

Benign tumor of osteoblasts.

Epidemiology

Osteoblastoma and osteoid osteoma occur much more commonly in other bones than the jaws. In the jaws, more than two-thirds of lesions are seen before the age of 30 years and there is a higher prevalence in males. The mandible is the most common site of occurrence.[48]

Clinical, Radiographic, and Histologic Manifestations

They are clinically, radiographically, and histologically very similar lesions. The size of the lesion is a distinguishing feature (Table 6-2). The pain associated with an osteoid osteoma

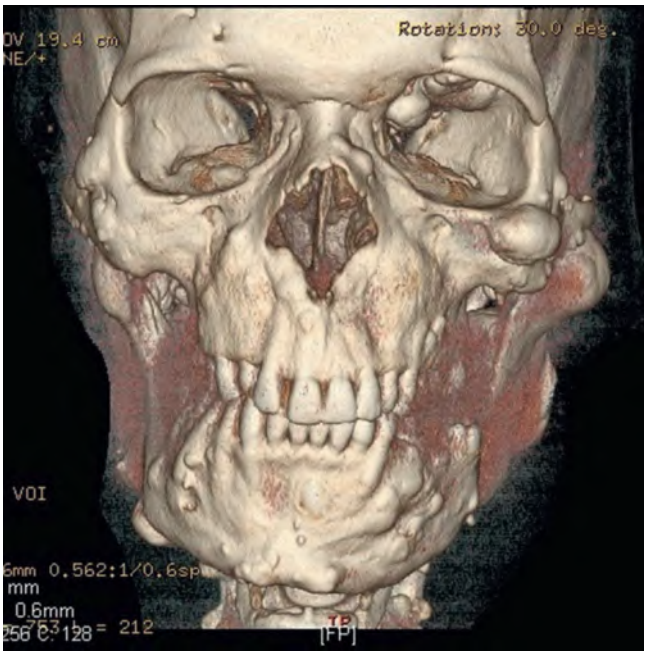

Figure 6-38 Osteomas in Gardner syndrome. Three-dimensional computed tomographic reconstructed image shows multiple craniofacial osteomas in a 30-year-old male diagnosed with Gardner syndrome.

Table 6-2 Distinguishing between osteoid osteoma and osteoblastoma.

	Osteoid Osteoma	Osteoblastoma
Size	Less than 2 cm	More than 2 cm
Symptoms	Nocturnal pain alleviated by aspirin	Dull, localizable ache not relieved by aspirin
Radiographic	Often central radiopaque nidus with a sclerotic border (target appearance)	Twice as common in mandible as maxilla
Most common location	Femur and tibia	Vertebrae

responds to aspirin and other nonsteroidal anti-inflammatory drugs,[48] whereas the pain associated with an osteoblastoma does not. Radiographically, the osteoblastoma presents as a radiolucency that may be either well or poorly defined, with patchy areas of radiopacity within the lesion. The osteoid osteoma is more likely to present with a surrounding zone of sclerosis. Histologically, they both resemble the cementoblastoma, but are not attached to a tooth. They are composed of sheets or irregular trabeculae of bone that exhibit prominent reversal lines. The bone is lined by osteoblast and osteoclast-like cells that contain multiple and large hyperchromatic nuclei. The central portion of the osteoid osteoma contains a concentration of nerve tissue.[48] These tumors are generally treated by conservative excision.

Differential Diagnosis

Depending on the location of the lesion and the amount of calcification, ossifying fibroma, dense bone island/idiopathic osteosclerosis, and complex odontomas may be considered in the differential diagnosis.

Management

Curettage or surgical excision is the most common therapy, with low risk of recurrence.

Chondroma and Chondromyxoid Fibroma

Cartilaginous tumors of the jaws are very rare. Any tumor-containing cartilage in the oral cavity and jaws must be evaluated very carefully by the pathologist to exclude malignancy. However, benign tumors of cartilage occurring in the jaws have been reported rarely. The chondromyxoid fibroma is composed of spindle-shaped and stellate-shaped cells in a myxoid and cartilaginous stroma.[49] The major concern with cartilaginous tumors in the jaws is to ensure that the diagnosis is correct. Benign cartilaginous tumors are treated by conservative excision. Multiple chondromas are components of Ollier's disease (multiple enchondromas) and Maffucci's syndrome (multiple enchondromas with soft tissue hemangiomas).

Desmoplastic Fibroma

Etiology and Pathogenesis

The desmoplastic fibroma of bone is a rare tumor that has been reported to occur in the jaws.[50] It is composed of uniform-appearing fibroblasts and abundant collagen fibers. The degree of cellularity may vary, but the cells of the desmoplastic fibroma do not show atypia and mitoses are not present.

Epidemiology

Most tumors have occurred in the mandible in patients under 30 years of age.

Clinical and Radiographic Manifestations

Painless enlargement of the mandible with an associated unilocular radiolucency is the most common presentation. Radiographically, the tumor may be well or poorly defined and occasionally multilocular.

Differential Diagnosis

Due to the wide range of radiographic appearances, a differential diagnosis is very broad.

Management

This tumor can behave in an aggressive fashion; accordingly, treatment is based on the extent and rate of tumor growth.

Burket's Oral Medicine, Thirteenth Edition. Edited by Michael Glick, Martin S. Greenberg, Peter B. Lockhart, and Stephen J. Challacombe.

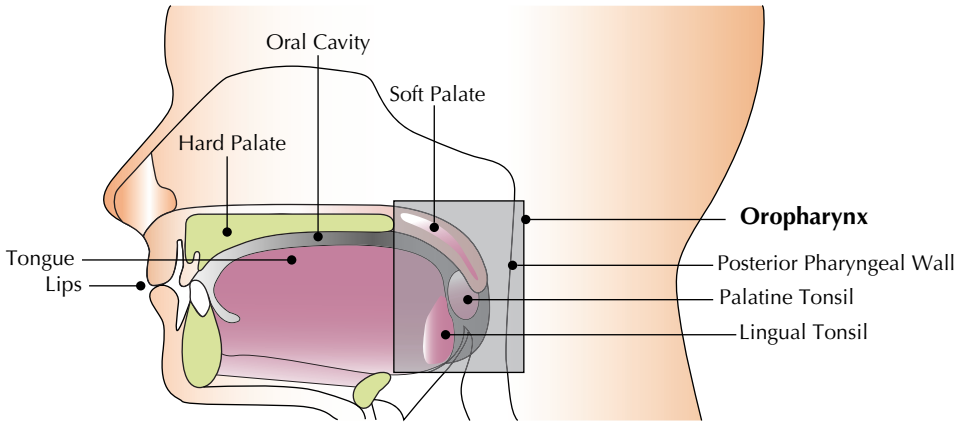

Figure 7-1 The oral cavity and oropharynx. *Source:* Copyright © 2011 American Dental Association. All rights reserved. Reproduced with permission of Elsevier.

Oral cancer is a broad term that includes a number of malignant diagnoses that present in the oral region. Even though the management and prognosis may be different among types and stages of oral cancer, the condition always has a dramatic impact on the patient's life. The cancer and its therapy are associated with morbidities that may negatively affect quality of life, both during cancer therapy, in the immediate period after treatment, and continuing throughout the life of the patient.

Older literature often combines oral squamous cell carcinoma (OSCC) and oropharyngeal carcinoma (OPC), making the evaluation of epidemiology, pathogenesis, and outcomes difficult to assess between the two diseases, and it is now recognized that OSCC and OPC must be evaluated individually. To develop a uniform baseline for discussion, the anatomic domains are presented in Figure 7-1. The oral cavity includes the lips, the labial and buccal mucosa, the anterior two-thirds of the tongue, the retromolar pad, the floor of the mouth, the gingiva, and the hard palate. The oropharynx includes the palatine and lingual tonsils, the posterior one-third (base) of the tongue, the soft palate, and the posterior pharyngeal wall. The nasopharynx extends above the oropharynx and the glottis and larynx below.

This chapter will provide a review of various types of oral and oropharyngeal malignant diseases, with a focus on OSCC and OPC. It will also review other cancers in the head and neck, including nasopharyngeal cancer, paraneoplastic syndromes, and head and neck malignant disease in AIDS. This is a topic that is highly relevant to all healthcare professionals caring for patients during all phases of cancer treatment, from detection to diagnosis, precancer treatment dental care and prevention, and managing oral and dental care for cancer survivors.

EPIDEMIOLOGY

OSCC and OPC represent the sixth most common cancer worldwide.[1] The global incidence of OSCC and OPC is 4.2% of all cancers (754,252) per year, which is expected to increase by 62% to 856,000 by 2035.[2] Worldwide over 354,864 new cases and 177,384 deaths were attributed to OSCC in 2018.[3]

In the United States, OSCC and OPC affect 10.8 of every 100,000 individuals, and 7.2 of every 100,000 individuals will have oral cancer.[2] The estimated new oral and oropharyngeal cancer cases in the United States for 2019 were calculated to be 53,000, with estimated deaths of 10,860.[4] During their lifetime 1.1% of the US population will be diagnosed with oral cavity and oropharyngeal cancer. The American Cancer Society (Cancer.Net) reports that 5-year survival in the United States is now over 62%.[5] This is an improvement in the relative survival compared to 1950–1954, during which relative survival was calculated to be 46%.[6]

The statistics are similar throughout North America but vary around the world; for example, in Hungary the incidence is up to 21.1 cases per 100,000 population.[7] In Southeast Asia the prevalence of oral cancer is high. Oral cancer is ranked one of the sixth most frequent malignancies in Asia, where nearly 274,300 new cases occur annually. The incidence rate is more than 10 per 100,000[8] and it may reach an annual incidence rate of 21.4 per 100,000 individuals in some districts of India.[9,10] Cultural habits, including betel quid chewing, alcohol consumption, and reverse smoking, as well as low socioeconomic status and low consumption of fruits and vegetables, contribute to this high prevalence. The trend differs among countries in this region (it increases in Pakistan and decreases in the Philippines and Sri Lanka) and even varies among provinces of the same country (Thailand).[8]

The majority of oral cancers are squamous cell cancers. Other malignant diseases that can occur in the oral cavity include tumors of the salivary glands, lymph nodes, bone, and soft tissue.

Approximately 95% of oral cancer occurs in people older than 40 years, with an average age at diagnosis of approximately 60 years.[11] OSCC at a young age and even in pediatric patients has however been reported.[12]

The majority of oral cancers involve the lateral borders and base of the tongue. The lips, gingiva, dorsal tongue, palate,

and salivary glands are less common sites. Primary squamous cell carcinoma (SCC) of bone is rare; however, a tumor may develop from epithelial rests and from epithelium of odontogenic lesions, including cysts and benign lesions. Individuals who have had a previous cancer are at high risk of developing a second primary oral cancer. African Americans in the United States have a lower risk of developing OSCC and OPC than Caucasians (9.6 vs. 11.2 per 100,000 population).[13]

Data published specifically for OPC associated with human papillomavirus (HPV) infection showed increased incidence, most of which is related to a rise in incidence in Caucasian males.[14,15] In contrast, the incidence in black males has not increased.[2] Analysis of tissues in national registries during the years 1984–2004 showed that the increase in the population-level incidence of oropharyngeal cancers in the United States since 1984 is caused by HPV infection.[16,17] HPV is primarily associated with OPC, with many fewer HPV-positive tumors in the oral cavity, nasopharynx, and larynx. Despite the changing risk factors for OPC, there is no evidence that detection of high-risk HPV can predict the development of oropharyngeal cancer accurately, as the majority of individuals clear the virus. Interesting findings suggest that tonsillectomy may reduce the incidence of OPC, and decreasing tonsillectomies conducted between 1970 and 2009 may also reflect the period of increasing HPV infection and OPC.[18]

A risk prediction model incorporating OSCC/OPC risk factors, including age, sex, race, smoking, alcohol, lifetime sexual partners, and HPV infection, predicted the following 1-year risks: 21.1/100,000 for older individuals (65–69-year-olds), 13.9/100,000 for men, 10.4/100,000 for Caucasians, 18.0/100,000 for smokers >20 pack years, 18.4/100,000 for heavy alcohol users, and 140.4/100,000 for oncogenic HPV, showing the relative risks of each component of the model.[19] Risk of oral cancer is moderately increased in immunocompromised patients (transplants and HIV infection), was associated with duration of immunosuppression, and was highest in those HIV infected.[20]

Tumors of the salivary glands, the majority of which involve the parotid glands, represent less than 5% of all head and neck tumors. Approximately two-thirds of these are benign mixed tumors (pleomorphic adenomas). In order of decreasing frequency, malignant salivary gland tumors are mucoepidermoid carcinoma, adenoid cystic carcinoma, adenocarcinoma, SCC, malignant pleomorphic adenoma, undifferentiated carcinoma, lymphoma, melanoma, and a mixed group of sarcomas. Malignant salivary gland tumors are more common in the submandibular, sublingual, and minor salivary glands than in the parotid glands.[21]

ORAL CANCER CLASSIFICATION

Oral cancer nomenclature reflects the histopathologic characteristics of the lesion. In order to facilitate communication between healthcare providers, a classification system was established by the World Health Organization/International Agency for Research on Cancer (WHO/IARC).[22] The classification system was most recently updated in 2017 based on advances in technology and outcome data.

According to the WHO/IARC classification of tumors, the morphology of the cells and the tissue architecture as seen in light microscopy are used to define the neoplasm, which may correlate with the biology and behavior of the cancer.

Publications within the WHO/IARC classification of tumors reference books ("Blue Books," 4th edition) refer to cancer of the oral cavity, oropharynx, cancer of the salivary glands, and odontogenic tumors. Notable changes in this 2017 update underscore the distinct pathologic differences between OSCC and OPC. Tumors of the oropharynx (base of tongue, tonsils, and adenoids) are further delineated into HPV-positive and HPV-negative SCC. HPV-positive tumors are no longer graded histologically. These changes underscore the epidemiologic trends demonstrated by the changing demographics, anatomic site, and prognostic outcomes that make up the current landscape of head and neck cancer.

SQUAMOUS CELL CARCINOMA OF THE ORAL CAVITY AND OROPHARYNX

Etiology and Risk Factors

The incidence of oral cancer is age related, which may reflect time for the accumulation of genetic changes and duration of exposure to initiators and promoters. These include chemical and physical irritants, viruses, and hormonal effects. In addition, decreased immunologic surveillance over time may be another explanation for the age relation. Furthermore, immunosuppressed patients following solid organ and hematopoietic stem cell transplantations, patients treated with chemotherapy, and HIV patients have an increased risk.

Tobacco and Alcohol

Tobacco products and alcohol are acknowledged risk factors for oral and oropharyngeal cancer. Tobacco contains potent carcinogens, including nitrosamines, polycyclic aromatic hydrocarbons, nitrosodiethanolamine, nitrosoproline, and polonium. Tobacco smoke contains carbon monoxide, thiocyanate, hydrogen cyanide, nicotine, and metabolites of these constituents. Nicotine is a powerful and addictive drug. Epidemiologic studies have shown that up to 80% of oral cancer patients were smokers.[11] In addition to the risk of primary cancers, the risk of recurrent and second primary oral cancers is related to continuing smoking after cancer treatment. Of patients who were observed for 1 year, 18% developed a recurrence or a second primary oral cancer, and those who

continued to smoke had a 30% risk.[23] The effect of smoking on cancer risk diminishes 5–10 years after quitting.

Most studies have focused on cigarette use; however, other forms of tobacco use have been associated with oral cancers. Benign hyperkeratosis and epithelial dysplasia have been documented after short-term use of smokeless tobacco products, and it is implied that chronic use will be associated with an increasing incidence of malignant lesions.[11,24] The potential risk of oral cancer with cannabis is unclear as data are inconsistent, with some reports suggesting decreased risk of cancer associated with the anti-inflammatory and antioxidant properties of cannabinoids. Route of ingestion (smoking, vaping, or edible formulation) and potential contaminants along with confounding variables make the relationship between cannabis and head and neck cancer currently indeterminate.[25,26]

All forms of alcohol, including "hard" liquor, wine, and beer, have been implicated in the etiology of oral cancer. While this topic is difficult to study for many reasons, several studies identified subpopulations in which alcohol is not a risk factor for oral cancer, such as nonsmoking, non-betel-chewing participants or those with the MTHFR TT genotype in Asians.[27,28] In contrast, other studies identified subpopulations at a higher risk for oral cancer following high-dose long-lasting exposure to alcohol, such as participants with ADH1C*1/*2 (Caucasians), ADH1C*1/*2 or ADHA1C*2/*2 (Asians), and ALDH2*2 (Asians).[29] The combined effects of tobacco and alcohol result in a synergistic effect on the development of oral cancer. The mechanisms by which alcohol and tobacco act synergistically may include dehydrating effects of alcohol on the mucosa, increasing mucosal permeability, and the effects of potential carcinogens in alcohol or tobacco. Various enzymatic pathways were suggested as having a role in the mechanism of the synergistic effect of smoking and alcohol on the oral mucosa. Alcohol in small amounts has been shown to have cardioprotective effects and increases high-density lipoprotein levels. The definition of moderate alcohol intake is likely related to individual factors, therefore making population-level recommendations for safe intake not possible.[24]

Areca Nut and Betel Leaf

People who use betel quid, pa(a)n masala, Gutk(ha)a, Catechu gum, or Supari, with or without added tobacco, are at a higher risk for developing oral cancer. In parts of Asia and Southeast Asia (e.g., India, Taiwan), use is historically widespread and accounts for the higher incidence of oral cancer. This habit is often continued in immigrant communities in the United States and Canada and providers outside of India and Asia should be familiar with the effects of this carcinogen: oral submucous fibrosis of the buccal mucosa and periodontium may develop secondary to alkaloid damage to fibroblasts. The resulting fibrosis may cause a decreased intraoral aperture, interfering with speech, swallowing, and oral care, which may lead to an increase in periodontal disease risk. Submucous fibrosis is considered a premalignant condition and other deleterious health effects including increased risk of non-head and neck primary cancers have been reported.[30]

Human Papillomavirus

HPVs are DNA viruses that infect various epithelial surfaces. There are more than 120 types of HPV. HPV 16, 18, 31, 33, and 35 are considered high-risk subtypes due to their association with malignant tumors. HPV 16 alone is associated with about 90% of HPV-positive oropharyngeal cancers. The virus penetrates the host cell and integrates into the host cell genome, where it can replicate. Malignant transformation occurs through the expression of two HPV viral oncogenes, E6 and E7, which downregulate p53 and Rb, two critical cell regulators of cell cycle progression. HPV-related head and neck squamous cell carcinoma (HNSCC) continue to express p16, unlike HPV-negative tumors, which makes p16 a marker for HPV infection.[31] There are many unanswered questions about the biology of HPV infection, which include clearance versus persistence of virus, latency and carcinogenesis, site localization, recurrence, and second primary cancers. This is discussed further in the section on oncoviruses.

HPV is transmitted by direct contact, primarily by means of vaginal, anal, and oral sex. Risk of developing HPV-positive oropharyngeal cancer increases with an increasing number of self-reported lifetime sexual partners (oral and vaginal), younger age at first sexual activity, and history of having a same-sex partner; in addition, the level of risk can vary according to tumor site.[32] It is important to note that these findings are related to oropharyngeal carcinoma, whereas in oral cancer HPV is not well defined as a risk factor.

Nutritional Factors

Low consumption of fruits and vegetables and high consumption of meat, tobacco, and alcohol is associated with an increased risk of cancer. Foods high in vitamins A, C, E, and selenium have antioxidant protective effects, particularly for epithelial cancers. High abdominal adipose composition combined with low consumption of nutritionally dense foods is a concern for increased cancer rates in Western countries.[33]

Lycopene and beta carotene may play a role in reducing the risk of premalignant lesions of the oral cavity. This hypothesis is based on population studies in which deficiency was associated with a risk of SCC, and on studies of vitamin A and carotenoid supplementation, as well as on studies of reduction in carcinogenesis in animal models.

Some reports have demonstrated that vitamin A may cause regression of premalignant leukoplakia.[34]

Other Risk Factors

There is conflicting evidence on the causality of other risk factors related to oral health, including alcohol-based mouthwashes, poor dental status, denture use, chronic mucosal trauma, and microorganisms. These factors combined with exposure to known carcinogens likely work in a synergistic fashion. The role of local trauma in the development of oral cancer remains controversial.[35,36] It is possible that chronic trauma, in the presence of other risk factors and carcinogens, may promote the transformation of epithelial cells, as has been demonstrated in animal studies.

In lip cancer, sun exposure, fair skin, pipe smoking, and alcohol are identified risk factors.[37] Recurrent herpes simplex virus of the lip has not been associated with increased cancer risk.

Environmental exposure to indoor and outdoor pollution from wood smoke and coal combustion, leading to inhaled toxins such as mercury, lead, sulfur dioxide, nitrogen, and other particulates, is related to numerous deleterious health effects globally. The IARC has classified air pollution as a carcinogen and it is a leading environmental cause of cancer deaths.[38]

Certain inherited cancer syndromes show an increased risk for oral cancer. For example, oral cancer is one of the cancers that are typical for patients with Fanconi anemia. Cowden syndrome, xeroderma pigmentosum, and dyskeratosis congenita were reported in association with oral cancer as well.[39]

Patients undergoing allogeneic hematopoietic stem cell transplantation (HSCT) are at increased risk of developing secondary neoplasms, particularly leukemias and lymphomas, which may manifest in the oral tissues. Likewise, OSCC has been reported as having up to a 20-fold increase in risk in these patient populations.[40–42] OSCC after an extended period of immunosuppression post transplantation is documented as having similar molecular changes as seen in nonmedically induced immunosuppression.[43] Oral cancer may behave more aggressively in patients post HSCT with chronic graft-versus-host disease and associated immunosuppression. Other immunosuppressed patients show increased risk for oral cancer as well, such as patients after liver transplantation.[44]

Oral Potentially Malignant Disorders

The WHO listed several oral conditions as having the potential to transform into oral cancer, including lichen planus, leukoplakia, discoid lupus erythematosus, inherited disorders, tobacco-related lesions, erythroplakia, actinic cheilitis, and submucous fibrosis.[23] Under the term "leukoplakia," it is worthwhile mentioning proliferative verrucous leukoplakia, which behaves more aggressively than other leukoplakias and has a high risk of progression to SCC.[45] Within the oral cavity, leukoplakia, erythroleukoplakia, and speckled leukoplakic lesions may have dysplastic elements within the clinically identifiable lesion. Keratotic epithelium with dysplasia has a 3–5 times increased risk of malignant transformation with severe dysplasia.[46]

The classification of oral potentially malignant disorders (OPMDs) takes into account that a field change in clinically normal-appearing tissues may occur in a patient with a diagnosed OPMD. Most patients will not have a specific diagnosis and many may have an isolated lesion. Clinical and histologic features may help the oral medicine provider stratify risk for malignant progression. These high-risk factors include large size, nonhomogeneous texture, red or speckled in color, tongue or floor of mouth location, tobacco use, and histologic severe dysplasia.

Pathogenesis

Carcinogenesis is a genetic process that leads to a change in molecular function, cell morphology, and, ultimately, cellular behavior. Carcinogenesis is not limited to the epithelium but involves a complex epithelial, connective tissue, and immune function interaction.

Major genes involved in OSCC include oncogenes and tumor suppressor genes (TSGs). Regulatory genetic molecules may be involved as well.[47] The genetic changes may be reflected in allelic loss or addition at chromosome regions corresponding to proto-oncogenes and TSGs, or epigenetic changes such as deoxyribonucleic acid (DNA) methylation or histone deacetylation. Extracellular enzymes, cell surface molecules, and immune function play a role in the development and spread of oral cancer; viruses and carcinogens are involved as well.[48]

While the principal studies have been related to epithelial changes, some of the components listed can constitute a complex environment that suggests an epithelium-connective tissue theoretical model. For example, the interplay of extracellular enzymes, cell surface molecules, growth factors, and the immune system leads to epithelial–connective tissue interaction. According to this model, mucosal differentiation and maturation of epithelial cells represent an epithelial and connective tissue bidirectional process that may be involved in carcinogenesis.

Oncogenes

Oncogenes may encode for growth factors, growth factor receptors, protein kinases, signal transducers, nuclear phosphoproteins, and transcription factors. Although proto-oncogenes increase cell growth and effect differentiation and are likely involved in carcinogenesis, few have been

consistently reported in HNSCC. Proto-oncogenes associated with HNSCC include ras (rat sarcoma), cyclins, myc (myelocytomatosis), erb-b (erythroblastosis), bcl (B-cell lymphoma), int-2, CK8, CK19, and epidermal growth factor receptor (EGFR).[47,49] Each of these oncogene families has several genes and isoforms with potential roles in carcinogenesis. For example, the ras family has three genes (Hras, Kras, Nras) and represents one of the most mutated oncogenes in human cancer, including oral cancer.[50]

Tumor Suppressor Genes

TSGs negatively regulate cell growth and differentiation. Functional loss of TSGs is common in carcinogenesis and in OSCC. Both copies of a TSG must be inactivated or lost for loss of function (the "two-hit" hypothesis). Chromosomes are numbered (1 to 23), and the arms of each chromosome are divided by the centromere into a short arm (designated P) and a long arm (designated Q). TSGs have been associated with sites of chromosome abnormalities where loss of genetic nucleic segments has been reported to commonly involve chromosome arms 3p, 4q, 8p, 9p, 11q, 13q, and 17p. TSGs involved in HNSCC are P53, Rb (retinoblastoma), and p16INK4A. Other candidates include FHIT (fragile histidine triad), APC (adenomatous polyposis coli), DOC1 VHL (gene for von Hippel-Lindau syndrome), and TGF-R-II (gene for transforming growth factor type II receptor).[47]

Gene-Regulating Proteins

Part of the oncogenic gene regulation is performed by transcription factors. These are proteins binding to DNA sequences to permit or inhibit co-binding to RNA polymerase, which in turn regulates the activation of the DNA-segment respective gene. Transcription factors that were identified from oral tumors and their potential contribution to oral cancer are listed in Table 7-1.[50]

Table 7-1 Commonly involved oncogenic transcription factors propelling oral cancer.

OTF	Oncogenic potential in OSCC
AP-1	Overexpression, nuclear expression increased according to degree of dysplasia, lymph node metastasis, increased transcriptional activity
NF-κB	Differential expression, activation, proliferation, malignant transformation, invasion
c-Myc	Overexpression, DNA amplification, DNA binding activity, progression of oral cancer
STAT	Early overexpression and activated form of transcription factor, active in OSCC
β-catenin	Nuclear overexpression, oral cancer progression, metastasis
Snail	Overexpression, activation, invasion, correlated with EMT
HIF1α	Overexpression, progression, expression correlates with poor prognosis, invasion
Mutated p53 (GOF)	Inactivated protein, GOF of mutant p53 propel mitosis by expressing cyclin A and cyclin B, GOF leads to shorter disease-free survival, prevention apoptosis after DNA damage, chemoresistance, disease progression

EMT, epithelial–mesenchymal transition; GOF, gain of function; OSCC, oral squamous cell carcinoma; OTF, oncogenic transcription factor.

Loss of Heterozygosity

Loss of heterozygosity (LOH) or allelic loss has been studied in oral premalignant lesions and predicts the malignant risk of low-grade dysplastic oral epithelial lesions.[51] The importance of allelic loss has been shown in retrospective and cross-sectional studies and confirmed in a prospective study of patents with dysplasia, where lesions with allelic loss at 3p, 9p, and 17p predict risk of progression to SCC, even in histologically benign tissue or tissue with mild dysplasia. This is of importance, as the majority of potentially malignant oral lesions (hyperplasia, mild and moderate dysplasia) do not progress to cancer. Lesions that progress to SCC appear to differ genetically from nonprogressing lesions, even though they may not demonstrate different histomorphologic findings.

Molecular analysis therefore may become necessary in diagnosis. LOH on 3p and/or 9p is seen in virtually all progressing cases. LOH on 3p and/or 9p has a 3.8 times relative risk of developing SCC, and if additional sites of LOH are present (4q, 8p, 11q, 13q, or 17p), there is a 33-fold increase in risk of progression to cancer. Accumulation of allelic loss is seen in progressing lesions, and the majority of progressing dysplasias have LOH on more than one arm (91% vs. 31% of nonprogressing dysplasias); 57% have loss on more than two arms (vs. 20% of dysplasias without progression). LOH on 4q, 8p, 11q, 13q, and 17p is common in severe dysplasia and carcinoma in situ as well as SCC.[52,53]

Hypermethylation

The role of promoter hypermethylation of CpG islands is being investigated in OSCC, as methylation of epigenetic DNA has been shown to result in a loss of function in some genes involved in cell cycle regulation and DNA repair that may lead to loss or change in TSGs involved in carcinogenesis. Changes in DNA methylation of six genes and a significantly higher frequency of methylation in a number of TSGs, including cyclin A1 and p16 promoter sequences, have been seen. Mitochondrial DNA (mtDNA) content increases with oxidative damage as possible compensation to mitochondrial dysfunction. MtDNA as assessed by polymerase chain reaction for specific mitochondrial genes was

shown to increase with severity of dysplasia and in SCC. These findings support the model of accumulation of genetic alterations as mucosal disease progresses from benign to dysplasia and potentially to SCC, and the contention that mtDNA increases with histologic grade.[54,55]

MicroRNA

MicroRNAs are small segments of nonencoding single-stranded RNAs that mediate gene expression at the post-transcriptional level by mRNA degradation or translational repression. Aberrant microRNA may disrupt the normal regulation and lead to malignancy. MicroRNAs function either as oncogenes or as tumor suppressors and are suggested to play a role in oral cancer.[56]

Extracellular Enzymes

SCC primarily spreads by direct local extension and by regional extension, primarily via the lymphatics. Regional spread in the oral mucosa may occur by direct extension and possibly by submucosal spread and results in wide areas of involvement. Production of type I collagenase, heparanase, prostaglandin E_2, and interleukin-1 and connective tissue growth factor (CTGF) may affect the extracellular matrix, and motility of epithelial cells may allow invasion.[57,58] Changes in the basement membrane, such as the breakdown of laminin and collagen, occur with invasion. Matrix metalloproteinase (MMP) and tissue inhibitor of metalloproteinase play a role in cancer initiation and development and have prognostic significance.[59] The initiation or progression of oral cancer may also be associated with polymorphism of the vascular endothelial growth factor (VEGF) gene.[60,61] Understanding the biology of invasion by malignant cells may lead to additional approaches to diagnosis and management.

Cell Surface Changes

Changes in cell surface receptors and major histocompatibility class I and class II antigens have been seen and may indicate that immune surveillance and immune function may be affected in patients with oral cancer. Other cell surface changes include a loss of cytoplasmic membrane binding of lectins, which has been shown to correlate with the degree of cellular atypia.

Intercellular adhesion molecules may play a role in tumorigenesis and perineural invasion. Integrin is a cell adhesion receptor and is often associated with altered expression in tumors as well as with malignant transformation. Alterations in cell-bound immunoglobulins and circulating immune complexes are detectable, but the importance of these changes is unclear.

Immunosuppression

The development of malignant disease at a higher rate in immunosuppressed patients indicates the importance of an intact immune response. Mononuclear cell infiltration correlates with prognosis, and more aggressive disease is associated with limited inflammatory response. Total numbers of T cells may be decreased in patients with head and neck cancer. In addition, the mixed lymphocyte reaction is reduced in some patients, and a diminished migration of macrophages has been demonstrated. Clusters of differentiation 8 (CD8) lymphocytes (T-suppressor cells) predominate tumor infiltrates, suggesting that immunosuppression is associated with progression of disease. Programmed cell death-1 (PD-1) is currently the target of many cancer immunotherapy agents aimed at interference with specific immune checkpoints. This immunoinhibitory receptor is part of the cytotoxic T-lymphocyte antigen family.[62]

Oncoviruses

An estimated 12% of cancers can be caused by an oncovirus, including Epstein–Barr virus (EBV), HPV, human T-cell lymphotropic virus-1 (HTLV-1), Merkel cell polyomavirus (MCPyV), hepatitis B and C viruses (HBV and HCV), and Kaposi sarcoma (KS) herpesvirus (HHV8). As discussed previously, HPV is the most critical oncovirus in the pathogenesis of head and neck cancer and has dramatically changed the demographics and treatment approach as well as outcomes of OPC. HPV-related lesions are increasingly reported at other head and neck sites, including the oral cavity.[63] Up to 80% of OPC and 26% of OSCC have been associated with high-risk HPV, showing a continuing trend to increasing HPV in SCC.[64] HPV prevalence in the OSCC group was higher than in potentially malignant disorder participants or the control group. The most common HPV subtypes detected in OPC are HPV 16 and 18 (68% and 34%, respectively). Other types of HPV detected in OSCC were HPV 6, 11, 31, 33, 35, and 56.[65]

EBV and HHV8 are of particular importance to understanding head and neck cancer. EBV infection is noted in malignant transformation of nasopharynx and specific salivary gland cancers. This is discussed further in the section on nasopharyngeal carcinoma. HHV8 or KS herpesvirus, which historically affected older European males, became a global concern during the AIDS epidemic of the 1980s. KS continues to impact immunosuppressed individuals and can occur in the oral cavity. (Figures 7-2 and 7-3).

PRESENTING SIGNS AND SYMPTOMS

Unfortunately, patients are most often identified after the development of symptoms associated with advanced stages of disease. Discomfort is the most common symptom that leads a patient to seek care and may be present at the time of diagnosis in oral cavity tumors. However, oropharynx cancers

Figure 7-2 Bilateral involvement of the anterior and posterior hard palate with purple discolorations consistent with Kaposi sarcoma.

Figure 7-3 Gingival involvement by Kaposi sarcoma, with discoloration and enlargement and soft tissue mass on the maxillary tuberosity.

Figure 7-4 Irregular erythroleukoplakia of the left lateral border of the tongue.

often present with an awareness of a mass in the neck.[66] Dysphagia, odynophagia, otalgia, limited movement, oral bleeding, neck masses, and weight loss may occur with advanced disease.[67] Paresthesia or dysesthesia, especially when it is unilateral, is a red flag that may indicate neural involvement and requires that cancer be ruled out. Loss of function involving the tongue can affect speech, swallowing, and diet.

Possible tissue changes may include a red, white, or mixed red and white lesion; a change in the surface texture producing a smooth, granular, rough, or crusted lesion; or the presence of a mass or ulceration (Figures 7-4, 7-5, 7-6, 7-7, 7-8, and 7-9). The lesion may be flat or elevated and may be minimally palpable or indurated. The high-risk sites for oral carcinoma include the lower lip, the anterior floor of the mouth, and the lateral borders of the tongue.

The clinical presentation may take a different shape in verrucous carcinoma, a subtype of OSCC with characteristic clinical findings. It can be described clinically as grainy, papillary, verruciform, fungating, or cauliflower-like. Verrucous carcinoma may develop from the progression of proliferative verrucous leukoplakia and develop into carcinoma.[45,68,69]

Lymphatic spread of oral carcinoma most commonly involves the submandibular and digastric nodes and the upper cervical nodes, and can involve the remaining nodes of the cervical chain. The nodes most commonly involved are those that are ipsilateral to the primary tumor, although the closer the tumor is to the midline and the more posterior in the oral cavity or oropharynx, the more common is the involvement of the bilateral and contralateral nodes.

Lymph node involvement may not occur in an orderly fashion. Lymph nodes associated with cancer become enlarged and firm to hard in texture, and with progression may become fixed. The fixation of nodes to adjacent tissue due to invasion of cells through the capsule is a late occurrence and evidence

Figure 7-5 Previously treated squamous cell carcinomas are at risk of recurrent squamous cell carcinoma. This case was treated with surgery and postoperative radiation therapy and presented with an area of erythroleukoplakia that was diagnosed as recurrent squamous cell carcinoma.

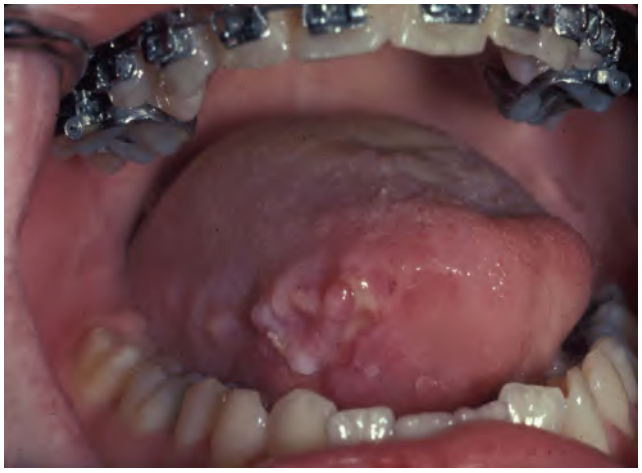

Figure 7-6 Indurated and ulcerated lesion of the right anterior tongue in a 15-year-old girl, persisting after removal of orthodontic appliances, proven to be squamous cell carcinoma on biopsy.

Figure 7-7 Nonpainful, irregular indurated exophytic and ulcerated buccal mass; histopathology revealed squamous cell carcinoma.

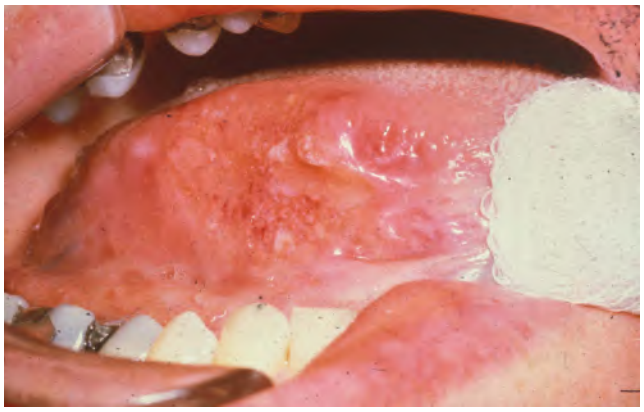

Figure 7-8 Eroded, erythroleukoplakic, indurated lesion in the right posterior third of the lateral border of the tongue, diagnosed as squamous cell carcinoma.

of aggressive disease. The fixation of the primary tumor to adjacent tissue overlying bone suggests the involvement of the periosteum and possible spread to bone. Nodes are not tender unless they are associated with secondary infection or an inflammatory response is present, which may occur after a biopsy. Spread of tumor is critical for prognosis and for selection of treatment. The understaging of nodes by cursory assessment or the overstaging of nodes following a biopsy, when an inflammatory component may be present, impacts the selection of treatment. Therefore, accurate node examination is needed before biopsy.

It is essential to have an understanding of the differentiation between OSCC and OPC with respect to cervical nodal metastasis. Staging by the AJCC 8th edition (see later) takes into account the high rate of nodal metastasis in HPV-related OPC. Tonsillar and oropharyngeal SCC is more likely to be diagnosed after regional metastasis has occurred, with 12% localized and 67.5% regional metastasis at diagnosis. Metastasis of OSCC at diagnosis is localized in 31.7% or regional in 45.2%. The stage at initial diagnosis is similar across all sexes and ethnic backgrounds for OPC and is related to the molecular behavior of HPV-related tumors, rather than delayed diagnosis or racial or socioeconomic barriers to care.[70]

DIAGNOSIS AND HISTOPATHOLOGY

Diagnosis is primarily based on histopathology. Within the epithelial tumors, SCC is the most prevalent oral malignancy. It has several subtypes based on histopathology. Some of the variants may have a unique clinical presentation.

For the diagnosis of OSCC, dysplasia involves the full thickness of the epithelium and the basement membrane is violated. Dysplasia describes a range of cellular abnormalities that

include changes in cell size and morphology, increased mitotic figures, hyperchromatism, changes in nuclear size and the nuclear–cytoplasmic ratio, and alteration in normal cellular orientation and maturation. Well-differentiated carcinoma retains some anatomic features of epithelial cells, including their ability to produce keratin, whereas poorly differentiated carcinoma involves a loss of the anatomic pattern and function of epithelium. Tumors may be associated with a mixed inflammatory infiltrate. Inflammatory and reactive lesions can be difficult to differentiate from dysplasia, and the experience of the pathologist becomes important with a need for clinical reassessment and repeat investigation. Invasion of lymphatics, blood vessels, and perineural spaces is of critical importance, but is difficult to determine.[71]

Histologically, verrucous carcinoma is characterized by piling up of keratin on the surface, with downgrowth of club-shaped fingers of hyperplastic epithelium with a pushing front rather than infiltration into the connective tissue. Dysplasia may be mild. Usually, a dense infiltrate of lymphocytes and plasma cells is present. Verrucous carcinoma rarely spreads to lymph nodes and typically remains locally destructive.[72,73] The difficulty in diagnosis and treatment is due to a benign histology or mild dysplastic changes that may be seen despite progressive and recurrent disease.

The term basaloid squamous carcinoma (BSC) has been introduced for tumors of which the major portion is composed of a solid growth of basaloid cells with small cystic spaces containing periodic acid–Schiff– and alcian blue–positive material. The histologic hallmark of the neoplasm is that of an OSCC in intimate relationship with a basaloid component. Immunohistochemical findings may be helpful in distinguishing BSC from histopathologically similar tumors.[74] HPV-associated cancers of the oral cavity are more likely to have basaloid features.[75]

Spindle cell carcinoma, also referred to as sarcomatoid SCC, is a rare variant of SCC. The histologic criteria of spindle cell carcinoma is the demonstration of epithelial changes ranging from prominent dysplasia to frank OSCC in conjunction with a dysplastic spindle cell element or evidence of direct transition of epithelial cells to dysplastic spindle cells. Osteoid-appearing material within the spindle cell component can be found.[76]

A few cases of adenoid SCC of the oral mucosa have been reported, also known as acantholytic SCC. This is mostly seen in the skin and very rarely in the oral cavity. The adenoid structure results from loss of cohesion of the epidermoid tumor cells. It may show pseudovascular morphology.[77] Other variants such as carcinoma cuniculatum and intraoral sebaceous carcinoma have been reported and may be confused with more common variants such as mucoepidermoid carcinoma.

While histopathology is the gold standard in diagnosis, it is a subjective assessment of tissue, with inter- and intrarater variability. However, phenotypic changes appear following molecular change, and it is expected that as molecular markers become defined, they will provide additional information and may ultimately become the gold standard in diagnosis.

Staging and Grading of Oral Cancer: Tumor–Nodes–Metastasis System

The American Joint Committee on Cancer (AJCC) Tumor–Nodes–Metastasis (TNM) staging system is the most widely used system for clinical and pathologic staging of cancer. Staging reflects prognosis, and is therefore a determinant of treatment strategy.[78] T describes the primary tumor, N indicates the presence of regional lymph node metastasis, and M indicates distant metastasis. The staging system for oral and oropharyngeal cancer combines the T, N, and M categories to classify lesions as stages I through IV and IVA though IVC. The AJCC classification is currently in its 8th edition, which has made significant changes to the TNM staging of head and neck cancers with the aim of improving the reproducible differentiation between stage groups. Major changes from AJCC 7 include newly added staging algorithms for nasopharynx cancer and HPV-mediated oropharynx cancer that reflect the unique biology of these diseases. Changes have also been made to the staging of oral cancer, taking depth of invasion (DOI) and extranodal extension (ENE) into consideration.

There are separate TNM classifications for cancer of the mucosal lip and oral cavity (Table 7-2), HPV-positive and -negative oropharyngeal carcinoma (Table 7-3), and salivary gland carcinomas. The classifications use the same principles with adjustment to the specific anatomic regions.

Adjunctive Diagnostic Aids and Screening Tools

Early detection of potentially malignant and malignant lesions is associated with improved treatment outcomes and a reduction in morbidity of treatment. Patient history and thorough head and neck and intraoral examinations are prerequisites. The definitive test for diagnosis remains tissue biopsy. Several aids to the oral examination were suggested in the past, including light technologies, vital tissue staining using toluidine blue (TB), and computer-assisted cytology of oral brush biopsy specimens.[79] Additional markers based on blood and saliva samples are under investigation for use in early detection, diagnosis, and surveillance for recurrence. There is no consensus regarding the standardization of collection, storage, processing, and analysis of salivary biomarkers and this is not currently a feasible clinical tool.[80] It is imperative to

Table 7-2 Staging of cancer of the mucosal lip and oral cavity.

Primary Tumor (T)		
TX	Primary tumor cannot be assessed	
Tis	Carcinoma in situ	
T1	Tumor ≤2 cm with depth of invasion (DOI*) ≤5 mm	
T2	Tumor ≤2 cm with DOI* >5 mm and ≤10 mm; or Tumor >2 cm and ≤4 cm, with DOI* ≤10 mm	
T3	Tumor >2 cm and ≤4 cm with DOI* >10 mm; or Tumor >4 cm with DOI* ≤10 mm	
T4	Moderately advanced or very advanced local disease	
T4a	Moderately advanced local disease Tumor >4 cm with DOI* > 10mm; or Tumor invades adjacent structures only (e.g., through cortical bone of the mandible or maxilla, or involves the maxillary sinus or skin of the face) NOTE: Superficial erosion of bone/tooth socket (alone) by gingival primary is not sufficient to classify a tumor as T4	
T4b	Very advanced local disease Tumor invades masticator space, pterygoid plates, or skull base and/or encases the internal carotid artery	
*DOI is depth of invasion and not tumor thickness.		
Regional Lymph Nodes (N)		
Clinical N (cN)		**Pathological N (pN)**
NX	Regional lymph nodes cannot be assessed	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral lymph node, 3 cm or smaller in greatest dimension, extranodal extension (ENE)(-)	Metastasis in a single ipsilateral lymph node, 3 cm or smaller in greatest dimension, ENE(-)
N2	Metastasis in a single ipsilateral node larger than 3 cm but not larger than 6 cm in greatest dimension and ENE(-); or Metastases in multiple ipsilateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(-); or Metastases in bilateral or contralateral lymph nodes, none larger than 6 cm in greatest dimension, and ENE(-)	Metastasis in a single ipsilateral node, 3 cm or smaller in greatest dimension and ENE(+); or Larger than 3 cm but not larger than 6 cm in greatest dimension and ENE(-); or Metastases in multiple ipsilateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(-); or Metastases in bilateral or contralateral lymph nodes, none larger than 6 cm in greatest dimension, and ENE(-)
N2a	Metastasis in a single ipsilateral node larger than 3 cm but not larger than 6 cm in greatest dimension, and ENE(-)	Metastasis in single ipsilateral node 3 cm or smaller in greatest dimension and ENE(+); or A single ipsilateral node larger than 3 cm but not larger than 6 cm in greatest dimension, and ENE(-)
N2b	Metastases in multiple ipsilateral nodes, none larger than 6 cm in greatest dimension, and ENE(-)	Metastases in multiple ipsilateral nodes, none larger than 6 cm in greatest dimension, and ENE(-)
N2c	Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension, and ENE(-)	Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension, and ENE(-)
N3	Metastasis in a lymph node larger than 6 cm in greatest dimension and ENE(-); or Metastasis in any node(s) and clinically overt ENE(+)	Metastasis in a lymph node larger than 6 cm in greatest dimension and ENE(-); or Metastasis in a single ipsilateral node larger than 3 cm in greatest dimension and ENE(+); or A single contralateral node of any size and ENE(+)

Source: Reproduced with permission from AJCC: HPV-Mediated (p16+) Oropharyngeal Cancer and Oropharynx (p16-) and Hypopharynx. In Amin MB, Edge SB, Greene FL, et al. (Eds.). *AJCC Cancer Staging Manual*, 8th edn. New York: Springer; 2017: 113–136.

note that these techniques are adjunctive aids for screening and tools for early detection, and are not a replacement for surgical tissue sample collection and histopathologic diagnosis. The development of noninvasive screening techniques may have impact at the population level with regard to cancer control and detection. Providers implementing these aids in clinical practice should be aware of the utility and limitations of each test in their clinical setting.[81]

Vital Tissue Staining with Toluidine Blue

Vital staining with TB may be used as an adjunctive aid in the assessment of potentially malignant oral mucosal lesions. TB is a metachromatic dye that has an affinity to binding with DNA. TB staining has been correlated with LOH profiles in tissue biopsy. TB can be applied directly to suspicious lesions or used as an oral rinse. The assessment of dye uptake depends on clinical judgment and experience (Figure 7-10). Positive retention of TB, particularly in areas

Figure 7-9 Asymptomatic erythroplakia in the floor of the mouth in a patient presenting due to toothache, diagnosed on biopsy as squamous cell carcinoma.

Figure 7-10 Irregular erythroleukoplakia, following application by toluidine blue. Inferior of lesion and superior stained site were biopsy-proven squamous cell carcinoma.

of leukoplakia, erythroplakia, and uptake in a peripheral pattern of an ulcer, may indicate the need for biopsy or assist in identifying the site of biopsy. False-positive dye retention may occur in inflammatory and ulcerative lesions, but false-negative retention is uncommon.

TB is currently cleared by the US Food and Drug Administration (FDA) as an adjunctive marking aid to a chemiluminescence light device, and not marketed as a stand-alone diagnostic tool. TB has been suggested by the Council on Scientific Affairs of the American Dental Association for use in high-risk patients and high-risk clinical settings by experienced providers, but no guidance was possible for use in the general practice setting due to the lack of clinical study in these settings.[82]

Visualization Adjunctive Tools

Chemiluminescent devices such as ViziLite® (Den-Mat Holdings, Lompoc, CA, USA) generate light based on chemical reaction. The suspected area of mucosa appears brightly lit. Other products like VELscope® (Apteryx Imaging, Akron, OH, USA) generate fluorescent light using an LED source, sometimes combined with optical filtration of the viewfinder to enhance natural tissue fluorescence. These products are promoted to assist the practitioner in discovering mucosal abnormalities, specifically OPMDs, and to evaluate the margins of a resection site. There is no consensus regarding the sensitivity and specificity of these devices and their ability to detect early disease.

There is an increasing interest in the use of confocal microscopy and optical coherent tomography systems to provide tissue diagnosis in real time, noninvasively, and in situ. Such a diagnostic approach is available in dermatology and is anticipated to be developed for oral mucosal application in the future. Other imaging modalities are being studied due to the need for improved detection and to assist in diagnosis and treatment.[83]

Cytopathology

Brush cytology, such as the OralCDx® system (OralScan Laboratories, Suffern, NY, USA), combines the cytobrush with a computer-assisted analysis of the cytologic sample, assessing the cell morphology and keratinization. The final diagnosis is made by an examining pathologist on the basis of standard histomorphologic criteria. Further developments in cytology include molecular evaluation of exfoliated cells for molecular markers of dysplasia or carcinoma to improve the diagnostic and prognostic value. Liquid-based cytology has renewed some interest in this noninvasive technique, as it may improve its sensitivity and specificity. This may be combined with biomarkers to improve accuracy, but validated and standardized methods of interpretation have not been established.[84]

Molecular Analysis

Improved technological advances allow for expeditious and cost-effective molecular analysis of HNSCC tumors and have led to the development and implementation of novel molecular targets for therapeutic suppression and/or enhancement.[85] Molecular markers from tissue specimens have elucidated HNSCC HPV-negative and HPV-positive cancers arising from different anatomic locations as well as genomic profiles, molecular characteristics, and therefore clinical prognosis.[86] The Cancer Genome Atlas Network (TCGA) and Hammerman et al. (2015) collated the molecular landscape of HPV-positive and HPV-negative HNSCC. HPV-positive tumors often demonstrate mutations in genes E6 and E7, TP53/RB1, TRAF3, FGFR2/3, CD8, DC56, ICOS, LAG3,

HLA-DR. Alterations in HPV-negative tumor genes commonly noted were TP53, CDKN2A/RB1, HRAS, CASP8, EGFR, ERBB2, FGF1, FAT1, AJUBA, NOTCH1, TP63, NFE2L2, and KEAP1.[87,88]

Imaging

Routine radiology, computed tomography (CT), nuclear scintiscanning, magnetic resonance imaging (MRI), and ultrasonography can provide evidence of bone involvement or can indicate the extent of some soft tissue lesions. The selection of the appropriate imaging modality is dependent on the type and location of the suspected tumor. Positron emission therapy (PET) using the radiolabeled glucose analogue 18-fluorodeoxyglucose (^{18}FDG) offers a functional imaging approach for the entire body (Figures 7-11 to 7-17).

Acquisition of a Tissue Specimen

In addition to standard surgical biopsy techniques, tissue can be acquired for histopathology by using fine-needle aspiration (FNA) or core needle biopsy (CNB). Open biopsy of enlarged lymph nodes is not recommended; in such cases, FNA biopsy should be considered. FNA/CNB also may aid in the evaluation of suspicious masses in other areas of the head and neck, including masses that involve the salivary glands, tongue, and palate, or when there is a contraindication to conventional biopsy (e.g., thrombocytopenia). Ultrasound may assist in guiding FNA/CNB.

Treatment

The principal objective of treatment is to cure the patient of cancer with the least possible morbidity of care and maintaining quality of life. The choice of treatment depends upon tumor-specific factors, the site and size of the primary lesion, the presence or absence of metastases, and generalized prognostic data. Current trends in treatment plan recommendations are grounded in fundamentals of patient-centered care, which take into account the patient's personal preference, current performance status, and ability and willingness to tolerate therapeutic modalities based on cultural, individual, and biopsychosocial-motivated beliefs and attitudes.

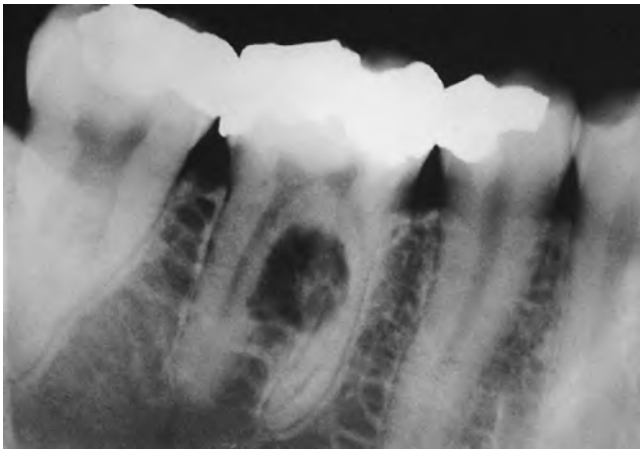

Figure 7-11 Periapical radiograph demonstrating bone destruction in the furcation of the first molar tooth and associated resorption of the root. A subsequent biopsy specimen demonstrated squamous cell carcinoma, which was diagnosed as a primary intra-alveolar lesion.

Figure 7-12 Periapical radiograph demonstrating an irregular radiolucency involving the bone of the apical region of the mandibular anterior teeth, without a change in root anatomy. The teeth tested vital. The radiographic finding was the first indication of involvement of the bony squamous cell carcinoma.

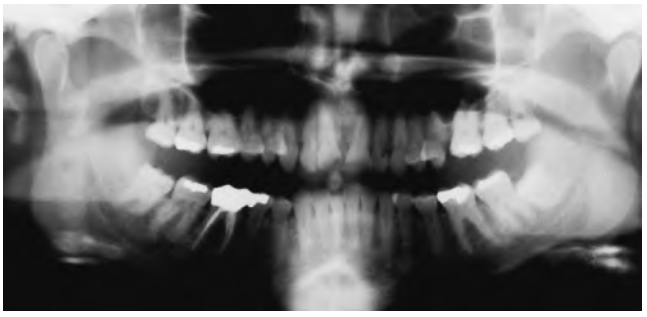

Figure 7-13 Panoramic radiograph taken at the time of diagnosis of squamous cell carcinoma.

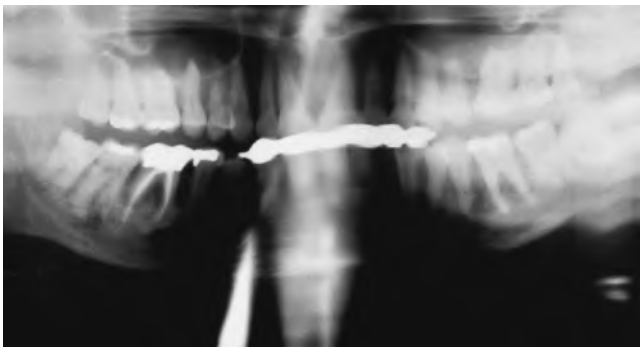

Figure 7-14 Massive bone destruction of the mandible, shown after five years of follow-up in a case of squamous cell carcinoma (see Figures 7-11 and 7-12) extending to the molar regions bilaterally. The anterior teeth had been lost due to progressive destruction of the anterior mandible and floor of the mouth.

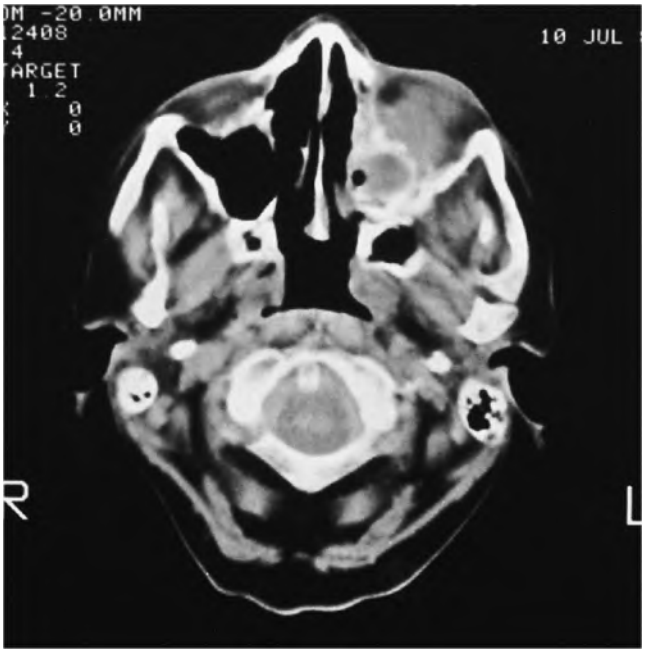

Figure 7-15 Computed tomographic scan demonstrating destruction of the medial wall of the antrum and opacification of the antrum. Additional views suggested that the opacification represented a tissue mass that was consistent with tumor.

First-line definitive therapy may include surgery, radiation therapy, with or without chemotherapy/targeted therapy, for curative intent for oral and oropharyngeal carcinoma. Immunotherapy as an adjunct to principal therapeutic modalities of surgery, radiation, and chemoradiotherapy is now included in treatment options. In general, the larger the primary tumor and the more advanced the disease, the more multimodality treatment is recommended for upfront, initial therapy. Often the combined treatment includes all three modalities: radiotherapy, surgery, and chemotherapy.

Figure 7-16 Panoramic radiograph showing bony destruction of the molar region of the right mandible due to invasion of contiguous tumor. Paresthesia of the right lip was present at the time of diagnosis.

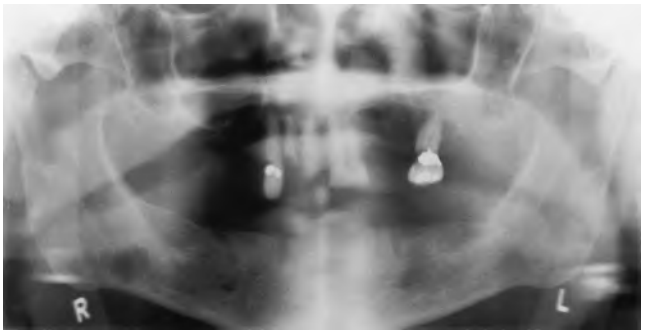

Figure 7-17 Panoramic radiograph demonstrating a destructive lesion of the right mandible overlying the mandibular canal. Anesthesia of the mandibular nerve and jaw pain were present. The bone biopsy specimen was consistent with metastatic colon carcinoma, which was subsequently diagnosed.

Continuing study of clinical outcomes, both survival and survivorship, will shed new light on the preferred combined treatment protocol.

Treatment recommendations are also impacted by the ability to preserve oropharyngeal function including speech, swallowing, and esthetics. Furthermore, the support available to the patient throughout therapy, a thorough assessment of the potential complications of each therapy, and the experience of the oncologic team may influence multidisciplinary treatment planning decisions. Initial therapy provides the best chance of curative therapy; if the patient experiences a recurrence or metastasis after first-line therapy, the options for treatment may be limited, and the likelihood of cure is reduced. However, in the era of immunotherapy, novel options for improving overall survival for recurrent and metastatic head and neck cancer are emerging.[89]

Targeted therapies for use in HNSCC have been limited to cetuximab in the definitive setting and have a low response rate in the metastatic setting. Limited development of available targeted therapies has driven investigations of tumors'

ability to evade innate immunosurveillance, and many researchers and institutions have shifted resources to immunotherapy pathways such as checkpoint inhibitors and immune effectors.

Multidisciplinary Care Model

National Comprehensive Cancer Network (NCCN) 2019 guidelines for treating patients with head and neck cancer note that all patients need access to multidisciplinary team members who have expertise in providing disease- and treatment-specific care. These team members and support services include head and neck surgery, radiation oncology, medical oncology, plastic and reconstructive surgery, specialized nursing care, dentistry/prosthodontics, physical medicine, speech and swallowing therapy, social work, clinical nutrition, pathology, diagnostic and interventional radiology, and additional adjunctive services. Cancers of the labial mucosa, oral cavity, oropharynx, hypopharynx, nasopharynx, glottic larynx, supraglottic larynx, ethmoid sinus, maxillary sinus, and salivary gland tumors all require dental evaluation as part of their initial work-up, which includes history and physical, biopsy, clinically indicated imaging and multidisciplinary consultation as indicated.[90]

Oral Complications

NCCN guidelines note that outcomes are improved when patients are treated at high-volume centers by providers with expertise in head and neck cancer management and prevention of complications. The oral medicine/dental provider with specific and comprehensive training and experience plays an integral role in the planning of post-treatment reconstruction along with the head and neck surgeon. In addition to prosthetic reconstruction, the oncologic dentist's role in the multidisciplinary treatment team includes diagnosing and treating existing dental conditions and providing patient-centered education and preventive care strategies. Complications from cancer treatment can be secondary to direct tissue damage, as well as to the surgical resection and reconstruction of the resulting defect, and can be in the form of both short- and long-term complications. Oral hard and soft tissues experience both transient and permanent changes from head and neck radiation, including mucositis, xerostomia/hyposalivation, dysgeusia and ageusia, trismus, delayed healing, osteoradionecrosis, and an increase in the risk of dental decay and periodontitis. The frequency of tissue necrosis is related to the treated volume, fraction size, and total dose of radiation therapy, the proximity of the radioactive implant to bone, and the presence of comorbid risk factors including dental status.[91]

SURGICAL ONCOLOGY

Though the principles and tenets of surgical oncology for head and neck cancers have not changed dramatically in the last two decades, advancements in technology, surgical approaches, and science have led to improved patient outcomes, particularly in respect to quality of life, surgical candidacy, and post-treatment function. As there is increasing histopathologic, genomic, and immunologic data to help characterize and predict the behavior of head and neck cancers, there has been a paradigm shift toward personalized medicine and tailoring cancer treatment and therapies to each individual patient and their particular cancer. Despite advances in radiation therapy, chemotherapy, targeted therapy, and immunotherapy, the backbone of treatment for resectable malignant tumors of the oral cavity remains upfront surgery with tailored adjuvant therapy.

Robotic Surgery

Perhaps the most important technological advances in ablative head and neck cancer surgery within the last decade has been the advent of robotic-assisted surgery for the treatment of oropharynx cancer. Historically, SCC of the oropharynx was treated via open approaches including lip split mandibulotomy, lateral pharyngotomy, transhyoid pharyngotomy, or transoral oropharyngectomy. There was a paradigm shift toward organ preservation for the treatment of oropharynx cancer in the mid-1990s after data from the Veterans Affairs Laryngeal Cancer Study Group trial emerged demonstrating efficacy of radiotherapy and chemoradiotherapy in patients with T1–T3 SCC of the larynx.[92] These data were quickly extrapolated and radiation or concurrent chemoradiotherapy was widely used for the treatment of SCC of the oropharynx. Unfortunately, full-dose radiation to the oropharynx (66–70 Gy) used in the definitive setting substantially increased the risk of long-term dysphagia, xerostomia, and osteoradionecrosis of the mandible.

In the early 2000s it was noted that long, stable demographic trends shifted and the incidence of oropharynx SCC increased.[93] It was not until 2010 when this particular subset of oropharyngeal SCC driven by HPV was described and contrasted to HPV-negative oropharyngeal SCC. These data from the Radiation Therapy Oncology Group (RTOG) 0129 study demonstrated a significant survival benefit in patients with HPV-positive oropharynx SCC (84.2% 3-year survival) compared to patients with HPV-negative oropharynx SCC (57.1% 3-year survival).[94] The majority of these cases present with small primary tumors in the lymphoid-bearing tissue of the base of the tongue or palatine tonsil and cervical metastasis to level II. Despite the high incidence of nodal metastasis, the prognosis and response to treatment are dramatically

better than the HPV-negative counterpart. In 2019, the incidence of HPV-associated head and neck cancer has surpassed the incidence of HPV-associated gynecologic/cervical cancers.

Since patients with HPV-positive oropharynx cancer are generally younger and respond more favorably to treatment, there has been an ongoing effort to de-escalate and de-intensify therapy for this subgroup of patients to reduce the late radiation-induced toxicity and morbidity. In 2008, the FDA approved the use of the da Vinci surgical robot (Intuitive, Sunnyvale, CA, USA) for the treatment of oropharynx SCC. This is well suited to HPV-positive oropharynx cancers of the base of the tongue or palatine tonsils, as traditional surgical access generally required open approaches including lip split and mandibulotomy.[95,96] The surgical robot is introduced through the oral cavity with the aid of a suspended retractor. Just like endoscopic techniques, robotic-assisted surgery allows for minimally invasive approaches and "wristedness." The da Vinci robot allows for 7 degrees of freedom and 90 degrees of articulation, which enable movements that are not possible with conventional endoscopic or traditional surgery. This allows for access to the oropharynx with the use of high-definition angled endoscopes for surgical removal of malignant tumors via a strictly transoral approach (Figures 7-18, 7-19, 7-20, 7-21, and 7-22). The major benefit to this approach is to de-intensify or eliminate radiotherapy and improve short- and long-term swallowing

Figure 7-18 Traditional lip split mandibulotomy for right base of tongue cancer. This requires pharyngeal reconstruction with a vascularized flap.

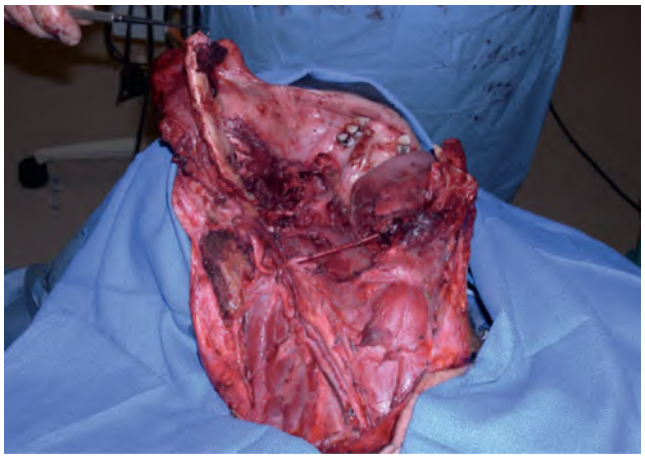

Figure 7-19 Neck dissection for right base of tongue cancer, as in Figure 7-18.

Figure 7-20 Initial set-up for FK-WO TORS retractor (Olympus Medical, Center Valley, PA, USA) in place with patient oroendotracheally intubated.

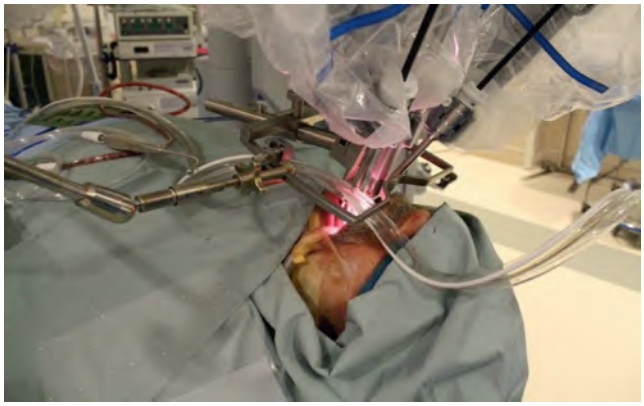

Figure 7-21 The da Vinci surgical robot (Intuitive, Sunnyvale, CA, USA) is docked and all three arms (endoscope, monopolar cautery, and Maryland forceps) are advanced into the oral cavity.

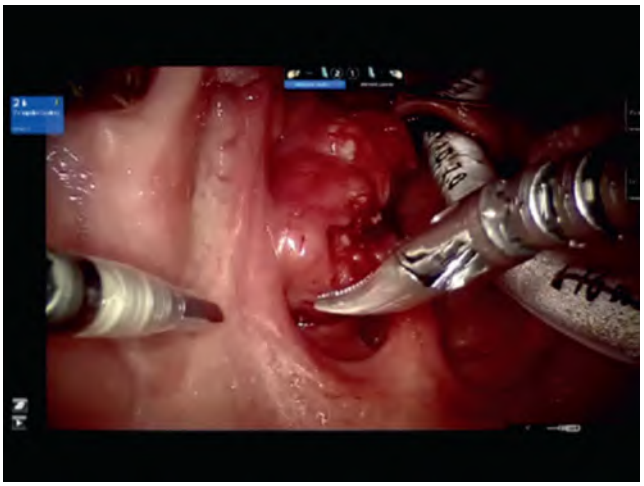

Figure 7-22 Robotic console view of left tonsil cancer immediately prior to resection.

outcomes. In addition, transoral robotic surgery (TORS) for the treatment of early-stage oropharynx SCC has shown superiority in functional outcomes, including less dysphagia and significantly lower rates of feeding tube dependence, when compared to concurrent definitive chemoradiation. TORS is considered first-line treatment for many patients with HPV-associated oropharynx cancer, and 5-year overall survival rates are greater than 91%.

Advances in Ablative Oral Cavity Surgery

Since its inception in head and neck surgical oncology, the use of computer-assisted surgery has not only revolutionized maxillofacial reconstruction, it has allowed for more precise surgical ablation with less invasive approaches. The earliest iteration of this was three-dimensional (3D) printing and stereolithography using CT scans and associated Digital Imaging and Communications in Medicine (DICOM) data to 3D print models of a patient's anatomy in 1998 (Medical Modeling, Golden, CO, USA). This can be used as a 3D reference when planning ablative surgeries for oral head and neck cancers. 3D models are particularly helpful in T4 oral cavity cancers of the maxilla or mandible that encroach on the skull base, infratemporal fossa, or masticator space, as these house essential neurovascular structures and are traditionally difficult to visualize. Surgical ablative plans can be digitally created in a virtual environment, usually via web meeting with a biomedical engineer who can effectively manipulate the DICOM data. The computer surgical plan can also be exported into intraoperative navigation software to allow for precise replication of the digital surgical design and osteotomies.[97] More commonly, the virtually and digitally planned resection is processed to design 3D-printed cutting jigs that are patient specific and allow for guided bony cuts and osteotomies for cancer resection. These have been shown to be highly accurate and reproducible.[98] The use of 3D-printed, virtually designed, patient-specific cutting jigs and implants allows for predictable osteotomies and osteosynthesis without wide access.[99] Maxillectomy and mandibulectomy can often be carried out via a transoral approach without the need for transcervical or transfacial skin access when computer-assisted surgery and design are utilized.

Microvascular Reconstruction

Undoubtedly, the most important advance in surgery in regard to the treatment of oral head and neck cancer has been the advent and refinement of microvascular reconstructive techniques. Microvascular free flap, or free tissue transfer, is best described as an autogenous transplant that is harvested from the patient's own body and may include bone, muscle, skin, fascia, or any combination of these paired with its perfusing artery and draining vein. This is transplanted to the head and neck and used to reconstruct acquired oncologic defects and re-vascularized by anastomosing its vessels to those in the head and neck. Prior to the 1990s, the majority of surgical reconstruction of oral cavity defects was limited to skin grafts, healing by secondary intention, and local-regional flap reconstruction. In most cases, these were not adequate reconstructions by modern standards, as they were only partially effective in restoring form and function. Prior to the advent of microvascular surgery, a patient undergoing composite resection for a floor-of-mouth SCC would almost certainly be severely deformed, tracheostomy and gastrostomy tube dependent, and functionally debilitated. Primary reconstruction of oncologic defects at the time of ablative surgery is routinely carried out with the use of microvascular free flaps. As these techniques have been refined, flap reconstruction success rates at high-volume centers are greater than 95%. Free tissue transfers are inherently robust and resistant to infection, necrosis, fistula, and devitalization due to the active blood supply and drainage. The importance of radiotherapy in the adjuvant setting for oral cavity cancers cannot be understated, and with the use of free tissue transfer patients are sufficiently healed to start radiotherapy within the six-week postoperative window, which seems to be maximally beneficial.

Although free flaps may be harvested from almost every part of the human body, several are used most commonly for reconstruction of oral cavity defects. The radial forearm free flap, a fasciocutaneous flap based on the radial artery and its venae comitantes, is the most frequently used soft tissue free flap for oral reconstruction. This is thin, pliable, and easy to harvest, with a long robust vascular pedicle for microvascular anastomosis. In most cases, it is the flap of choice for reconstruction of partial or hemiglossectomy defects due to its size match. The volar aspect of the forearm generally cannot be closed primarily, so a skin graft is required to reconstruct the donor site defect on the wrist. Alternatively, the flap can be taken as an ulnar forearm free flap based on the ulnar vessels (Figures 7-23, 7-24, 7-25, and 7-26).

Figure 7-23 Hemiglossectomy specimen for tongue squamous cell carcinoma.

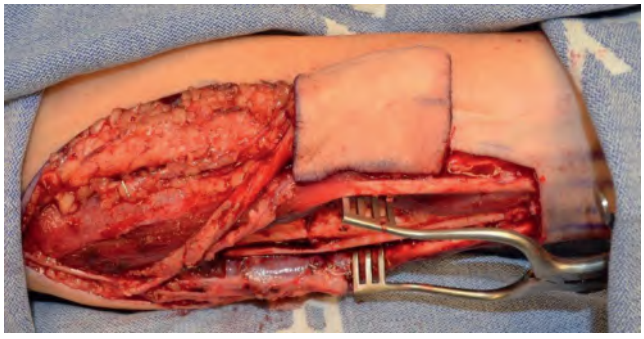

Figure 7-24 Ulnar forearm flap harvest.

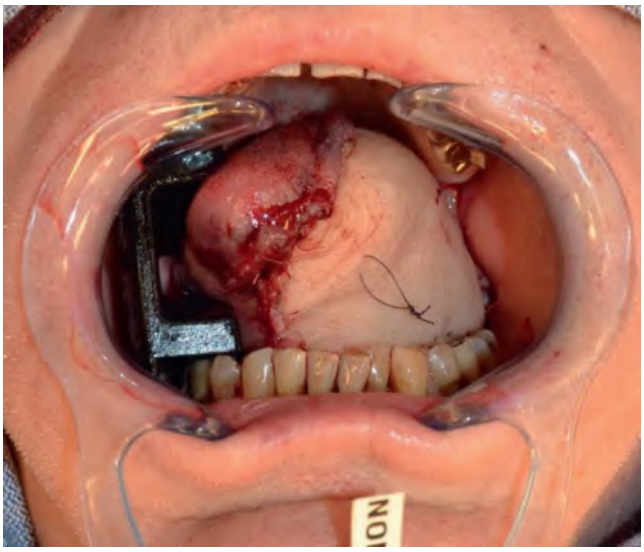

Figure 7-25 Flap inset after microvascular anastomosis.

Figure 7-26 Six months after radiation with excellent speech and deglutition.

Alternatively, when a larger volume of tissue is required, such as for those undergoing total glossectomy, an anterolateral thigh free flap may be favored. This is based on the descending branch of the lateral femoral circumflex artery and its venae comitantes. A large volume of skin, subcutaneous tissue and fat, and vastus lateralis muscle may be harvested and vascularized on its pedicle. One major advantage of this flap over the radial forearm flap, other than the size, is the ability to close the donor site primarily without the use of a skin graft (Figures 7-27, 7-28, and 7-29).

The workhorse of oromandibular and palatomaxillary hard and soft tissue reconstruction since the 1990s has remained the microvascular fibula free flap. The long bony length, long vascular pedicle of the peroneal arteries and veins, plasticity, and sufficient bone stock for dental implantation have made this the first-line composite hard and soft tissue flap for reconstruction of the jaws at most centers.[99] The fibula flap was also the first to be used in computer-assisted design and reconstruction.[100] The fibula can be harvested with or without a vascularized skin paddle or muscle, depending on the reconstructive need. The skin that is harvested with the fibula in most patients is thin and pliable and readily movable along the long axis of the bone. Like the radial forearm flap, the lateral calf skin defect from osteocutaneous fibula flap harvest generally requires a split-thickness skin graft to close (Figures 7-30, 7-31, 7-32, 7-33, and 7-34).

The subscapular system free flap is the most versatile flap used for head and neck reconstruction. As the subscapular artery and vein traverse the axilla, they give rise to multiple branches that supply the lateral border of the scapula bone, the scapular tip, the latissimus dorsi muscle, the serratus anterior muscle, the skin of the back overlying the scapula, and segments of the ribs. Any combination of these tissues can be harvested, all connected to the subscapular artery and vein. Large volumes of skin and latissimus muscle are available for harvest to reconstruct massive oral, head, and neck defects. Though the scapula bone is not as robust or long as the fibula, it still provides excellent bone stock for maxillomandibular reconstruction, and in some cases suitable for

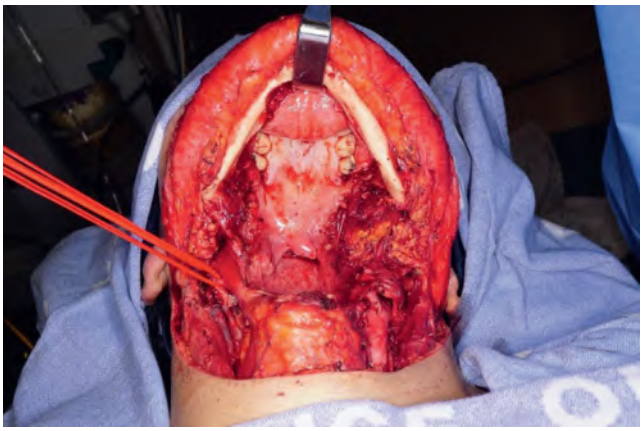

Figure 7-27 Total glossectomy defect viewed from the neck.

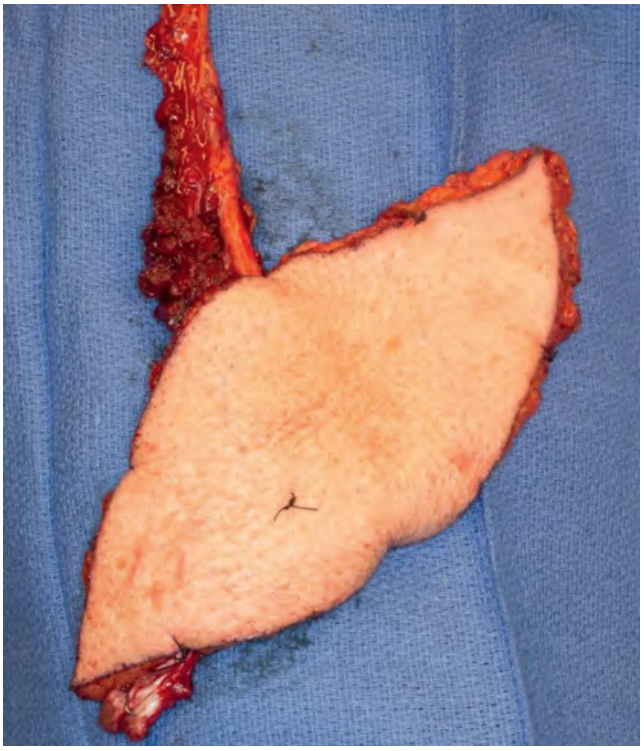

Figure 7-28 8 × 20 cm anterolateral thigh flap harvested.

future dental implantation. Unlike the fibula, the scapula donor site can be closed, primarily because the skin of the back has laxity and may be widely undermined when needed. Its major disadvantage is its location on the body, as scapula harvest requires a patient to be positioned on their side in a lateral decubitus position, which can be cumbersome and time consuming to set up in the operating room. In addition, it is incredibly difficult and awkward for both the ablative and reconstructive surgeons to work simultaneously. In most cases, the patient is repositioned mid-case after the ablative surgery is complete, increasing overall surgical time. Due to

Figure 7-29 Reconstruction of tongue and floor of mouth with anterolateral thigh free flap.

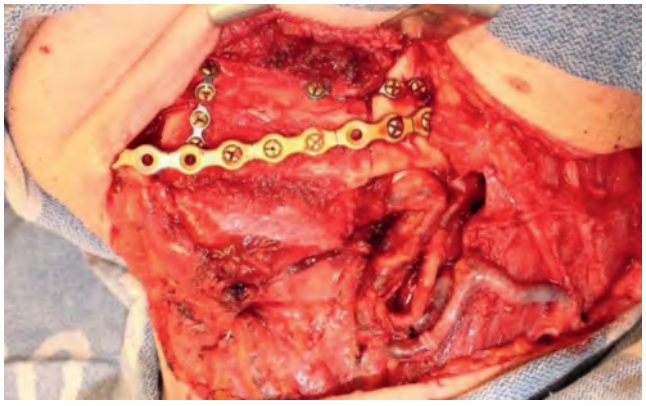

Figure 7-30 Fibula flap to reconstruct lateral mandibular defect with completed arterial and venous anastomosis to the neck.

these considerations, the subscapular system/scapula flap is used in cases where massive soft tissue volume is needed, or in patients with severe peripheral vascular disease of the lower extremities where fibula flap harvest is not possible (Figures 7-35, 7-36, and 7-37).

Management of the Neck

Imaging

OSCC has a high propensity for regional lymph node metastasis. Approximately 20–45% of patients with early-stage oral cancer who present without clinical or radiographic evidence of regional disease will, in fact, harbor occult cervical metastasis.[101] The presence of a pathologically positive metastatic cervical lymph node in patients with oral head and neck cancer is a significant negative prognostic factor with up to a 50% reduction in 5-year survival rates. Work-up

and staging of the cervical lymphatics in patients with biopsy-proven oral cavity SCC are necessary. Clinical neck examination is an important tool; however, it is limited by low sensitivity in ruling out cervical metastasis. Contrast-enhanced CT scan is the most widely used imaging modality in the United States, as it has high sensitivity, specificity, reproducibility, and transferability. MRI has similar specificity and sensitivity; however, it can be more difficult to read and harder to tolerate, as image acquisition times are significantly longer than for a CT scan. The most specific technique for interrogation of the cervical lymphatics preoperatively is ultrasound-guided FNA biopsy, but this requires technical proficiency from the ultrasonographer and interventional radiologist and may not always be reproducible.

Patients with clinically positive cervical metastasis (cN+) found on clinical exam, CT, MRI, PET, or ultrasound who are undergoing surgery for oral cavity carcinoma should receive a therapeutic neck dissection to remove the affected nodes and at-risk nodes for cervical metastasis in an en bloc fashion. This generally necessitates a modified radical neck dissection with removal of cervical basins I–V. Care should be taken particularly with oral cavity cancers to completely remove all level I lymph nodes and perifacial nodes around the marginal mandibular nerve and facial artery as it crosses the mandible. In contrast to the radical neck dissection described by George Crile in the early 1900s, the modified radical neck dissection initially described by Suarez and Bocca in 1967 preserves the spinal accessory nerve, the internal jugular vein, and the sternocleidomastoid muscle in the majority of cases. The structures sometimes require sacrifice if there is gross tumor invasion from a lymph node with extranodal tumor extension. The oncologic outcomes are similar; however, there is a significant decrease in morbidity associated with the preservation of critical neurovascular and muscular structures.

The more difficult treatment dilemma is how to manage patients with oral cavity cancer and a clinically negative neck (cN0). Decisions regarding the treatment approaches for these patients have been debated extensively, which has produced numerous investigations. Fortunately, in the last five years evidence has emerged demonstrating a survival benefit when the cN0 is treated with elective selective neck dissection in patients with OSCC. Two prospective clinical trials demonstrated decreased risk of death or cancer recurrence in patients with T1 and T2 oral cavity cancer with cN0 necks undergoing elective neck dissection. A critical histopathologic factor in determining the risk of cervical recurrence in both studies was tumor DOI, thickness of tumor cells past the basement membrane. In 2015, D'Cruz et al. found, in post-hoc analysis, that the protective effect of elective neck dissection on recurrence and death was lost when tumor DOI from the primary site was 3 mm or less.[102] Similar analysis was undertaken in 2019 by Hutchinson et al. in a prospective multicenter study. The outcomes confirmed previous reports, but also demonstrated a positive survival benefit even in patients with tumor DOI of 3 mm or less (hazard ratio of 0.81).[103]

It is evident that elective neck dissection is beneficial from an oncologic and survival standpoint in the treatment of cN0 early-stage OSCC, particularly when the tumor DOI is 3 mm or greater. This should be carried out as a selective neck dissection, selecting the highest at-risk nodal basins for dissection, in an en bloc fashion. For oral cavity cancers, the highest risk of cervical metastasis is in levels I, II, and III. There is some evidence to support the phenomenon of "skip metastasis," or isolated metastatic lymph nodes in level IV, in tongue cancer. Lymphadenectomy of levels I, II, III (supra-omohyoid), and possibly level IV with preservation of the spinal accessory nerve, sternocleidomastoid, and internal jugular vein is standard practice for elective selective neck dissection.

Sentinel Lymph Node Biopsy

Sentinel lymph node biopsy is a minimally invasive technique to interrogate cervical lymphatics in patients with OSCC and offers the potential of reduced morbidity compared to selective neck dissection. Outcomes from investigations within the last decade have supported its use for early-stage OSCC, but consensus among surgeons has yet to be achieved. The concept of sentinel lymph node and lymphatic mapping was first used reliably and accurately to predict regional cancer spread by Morton et al. in 1992 in patients with stage I cutaneous melanoma. Since then, sentinel lymph node biopsy has been a critical part of the treatment of melanoma with clinically negative regional disease. Multiple single-center pathologic validation studies on sentinel lymph node biopsy suggest that it is efficacious for the identification of sentinel lymph nodes, may detect occult metastasis, and accurately predicts a status of lymphatic basins with negative predictive values ranging between 90 and 98%.[101,104] Results of the American College of Surgeons Oncology Group validation trial Z0360 demonstrated a negative predictive value of 96%.[105] Sentinel lymph node biopsy is an excellent alternative to observation of the clinically negative neck; however, it is unclear whether or not a negative sentinel lymph node biopsy results in the same survival benefit as elective neck dissection for early-stage OSCC.

Indications for sentinel lymph node biopsy of the oral cavity are biopsy-confirmed T1 or T2 oral SCC with clinically negative neck disease based on physical exam and advanced imaging. Estimation of tumor thickness and DOI is also critical in selecting these patients, since thicker tumors as previously described would benefit more from an elective neck dissection. A punch biopsy taking a tangential core of the primary tumor is sometimes helpful in identifying DOI on biopsy prior to surgery, in order to decide between a sentinel lymph node biopsy or elective neck dissection for the cN0 neck.

Patients undergoing this procedure will have the tumor injected with a nuclear radio tracer, usually technetium 99-m labeled sulfur colloid. This may be done by the surgeon or the nuclear medicine physician hours prior to surgery. Multiple planar images are taken in the nuclear medicine suite via a gamma camera to complete the lymphoscintigraphy as the tracer descends through the lymphatics. Single photon-emission CT (SPECT) can also be used, as this provides a 3D anatomic image combined with nuclear imaging to localize the draining lymph nodes. Radiotracer will accumulate in the first draining echelon of lymph nodes, or the sentinel node, and be evident on the SPECT scan or lymphoscintigram. This can then be targeted for removal during surgery with the use of an intraoperative gamma probe. Once the lymph node is confirmed to be the sentinel node intraoperatively, it is sent for histopathology and serial step sectioning to identify metastasis or micrometastasis. In patients with a positive sentinel lymph node, further treatment is usually necessary in the form of a neck dissection and/or postoperative radiotherapy.

Computer-Assisted Surgical Planning

Since 2009, oral and maxillofacial surgeons have been at the forefront of developing technology for computer-aided head and neck ablative surgery and reconstructive surgery.[100] Improvements in imaging technology, imaging software, and biomedical engineering have allowed for surgeons to virtually and digitally carry out procedures and transfer those plans to the operating room. Ongoing evolution of this technology allows for precise and accurate surgical ablation and reconstruction, aiding surgeons to achieve results that were previously difficult or impossible. Perhaps the greatest impact of this technology is the ability to preplan, visualize, and pre-navigate a complex operation prior to entering the operating room. Surgeons without years of clinical experience can achieve reconstructive success, since much of the trial and error may be done in the virtual environment during the web meeting.

Data is acquired using high-resolution medical-grade or cone-beam CT scans with 1 mm cuts or finer. These DICOM images are uploaded to a third-party digital planning company. The DICOM data are segmented and rebuilt in a 3D fashion by biomedical engineers. A web meeting between the surgeon and biomedical engineer with shared viewing screens demonstrates the patient anatomy based on the high-resolution CT data. 3D anatomy can be easily manipulated in the virtual environment and appropriate surgical planning is carried out, including osteotomies for resection, mapping the position of nerves and teeth, and reconstruction of defects using bone flaps such as a fibula, scapula, or iliac crest flap. Since all the data are patient specific, the final surgical plan can be exported as a stereolithography (STL) file used to design patient-specific cutting jigs to carry out

osteotomies, or patient-specific permanent titanium 3D-printed surgical plates and implants. These data may then be exported into surgical navigation software in order to facilitate and confirm adequate osseous positioning in the intraoperative setting.

Multiple validation studies have demonstrated the accuracy, precision, and effectiveness of computer-aided surgical planning.[106,107] It allows surgeons to achieve extremely complex reconstructive designs while decreasing operating room time. As with most technology, there is a learning curve required to effectively use these methods to achieve the desired outcomes. 3D-printed cutting guides and jigs that are patient specific must be adapted to the mandible or maxilla precisely. If one portion of the operation is misguided or poorly executed, there may be compounding error as the reconstructive portion is based on accurate surgical ablation. If the virtual design plan is aborted, modifications must be made intraoperatively (Figures 7-38, 7-39, 7-40, and 7-41).

Dental Reconstruction

As previously mentioned, one major benefit of computer-assisted surgery and computer-aided surgical simulation is the ability to create complex reconstructions as well as incorporate guided dental implant placement into osseous free flaps. Historically, the goal of head and neck reconstruction of cancer defects with microvascular free flaps was simple: to keep the flap perfused and the patient alive. As technology and science evolve, the goal of the surgeon and patient has become to return to as close to the precancer state as possible. The use of endosseous dental implants plays an integral role in the comprehensive treatment and reconstruction of head and neck cancer patients. With computer-assisted design and planning, as well as advances in microvascular reconstruction, immediate dental implant placement into bone flaps at the time of ablative and reconstructive surgery

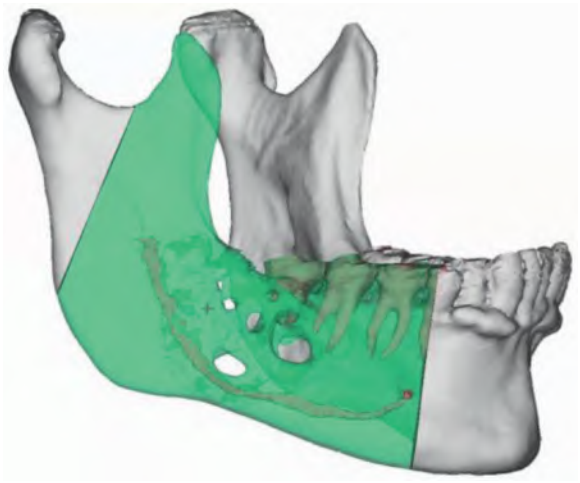

Figure 7-38 Squamous cell carcinoma of the right mandible with highlighted virtual mandibulectomy in green. The patient-specific fibula computed tomographic scan is being used to start the virtual reconstruction.

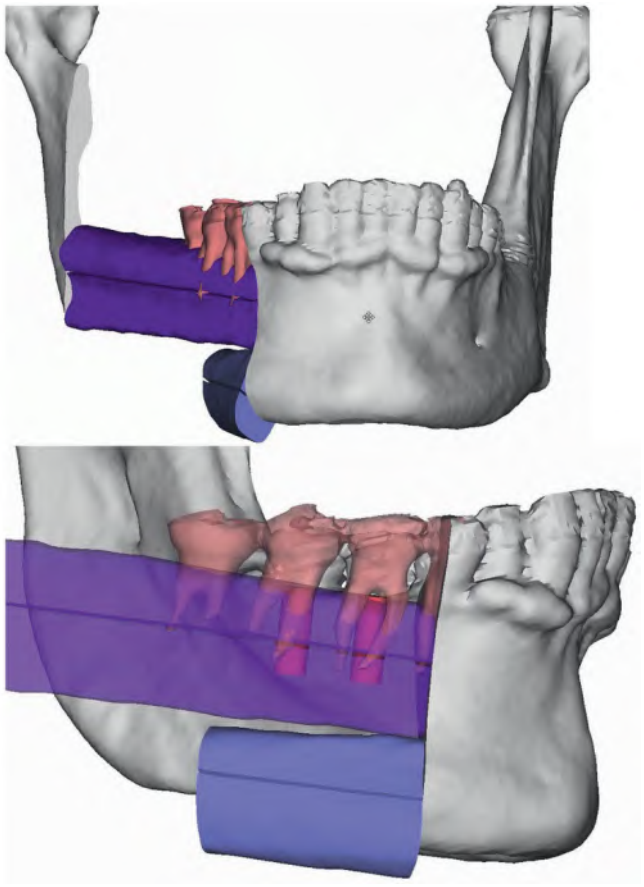

Figure 7-39 Two fibula segments are used to reconstruct the alveolus and basal mandible, with planned endosseous dental implants into the fibula.

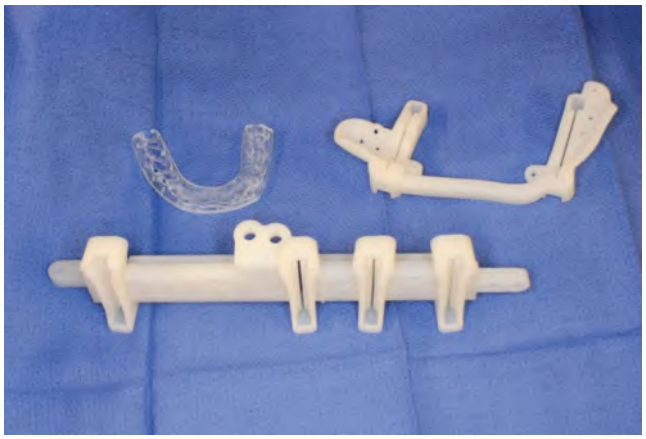

Figure 7-40 Once the plan is finalized, patient-specific 3D-printed occlusal splints, mandible cutting guides, and fibula cutting jigs are manufactured.

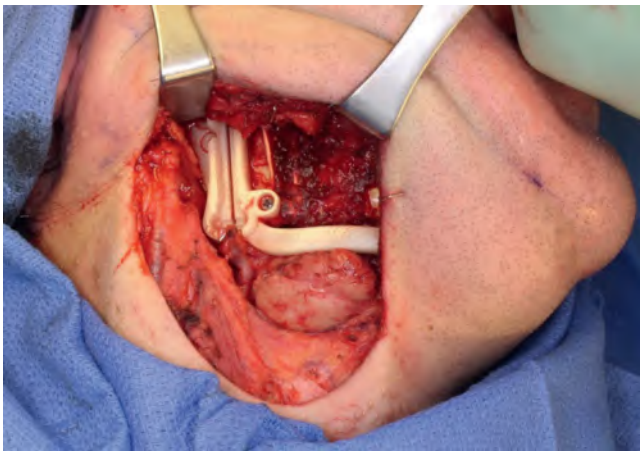

Figure 7-41 Mandibular cutting jig in place prior to osteotomy.

is possible. Traditionally, dental implants have been placed six months to a year after the patient has completed cancer therapy. More recently, placement of dental implants into the fibula flap at the time of mandibular or maxillary reconstruction has been shown to be as successful and safe (94% implant success, 98% restorability success).[108] The fibula is an extremely dense cortical bone with little to no marrow space and most analogous to type I mandibular bone with a predominantly periosteal blood supply. Unlike traditional dental implant placement into the jaws, implants in a fibula should be placed through both cortices and care should be taken to slightly overprepare and screw-tap the bone to prevent fracture or pressure necrosis.

A major advantage of simultaneous dental implant placement during ablative and reconstructive surgery is that it can be done while still pedicled to the leg, working outside of the confines and constraints of the oral cavity. With computer-aided surgical simulation, implants can be planned at precise positions and angulations for optimal restorability in the virtual environment. The fibula bone flap can be planned and adjusted to support those implants for a dentally and occlusally driven reconstruction. This plan is carried out in the operating room using the fibula cutting guide and cutting jig with implant guide sleeves prior to the segmentation of the fibula flap and transfer to the head neck region. Often, the implants are buried and then exposed 4–6 months later to ensure complete osseointegration for prosthetic fabrication.

A comprehensive surgical reconstruction for OSCC is not complete until both the tissue and dentition resected with cancer surgery are replaced. Without the definitive restorative approach, including dental prosthetics, patients may feel psychologically and socially debilitated. In most cases, it may take up to 18 months and multiple procedures for a patient to undergo complete dental restoration after mandibulectomy or maxillectomy. In 2012, surgeons first described the "jaw in a day" technique that addresses exactly this problem.[109] Planning in a fully digital workflow, the patient can undergo mandibulectomy or maxillectomy and reconstruction with a fibular free flap, along with immediately loaded dental implants and a hybrid prosthesis. This eliminates the multiple interim procedures and lag time to dental reconstruction. Currently, this technique is used primarily in patients that do not require a skin paddle transplant with their fibula, as the thickness of the skin may prevent complete seating of the prosthesis. In order to circumvent this, an osseous fibula flap is harvested and used to reconstruct the jaw. The native soft tissue and gingiva are closed over the fibula flap and around the immediately loaded dental implants. This technique offers patients a single-stage solution to reconstruct bone, soft tissue, and teeth during a mandibulectomy or maxillectomy, and hopefully represents a preview into the advances and direction of future oncologic surgical approaches (Figures 7-42, 7-43, 7-44, 7-45, 7-46, 7-47, and 7-48).

RADIATION ONCOLOGY

Radiation oncologists work closely with a multidisciplinary team of physicists, dosimetrists, radiation therapists, nurses, dietitians, dentists, and social workers. Radiation therapy may be administered with intent to cure, as a single modality, as part of combined radiation–surgery and/or chemotherapy management, or for palliation.[110] Radiotherapy with intent to cure causes early and late toxicities. In palliative care, radiation may provide symptomatic relief from pain, bleeding, ulceration, and oropharyngeal obstruction.

Radiation kills cells by interaction with water molecules in the cells, producing charged molecules that interact with

biochemical processes in the cells and by causing direct damage to DNA. The affected cells may die or remain incapable of division. Due to a greater potential for cell repair in normal tissue than in malignant cells and a greater susceptibility to radiation due to the higher growth fraction of cancer cells, a differential effect is achieved. To achieve therapeutic effects, radiation therapy is delivered in daily fractions for a planned number of days. The relatively hypoxic central tumor cells are less susceptible to radiotherapy, but may become better oxygenated as peripheral cells are affected by radiation and thus become more susceptible to subsequent fractions of radiation. In general, the more differentiated the tumor, the less rapid will be the response to radiotherapy. Exophytic and well-oxygenated tumors are more radiosensitive, whereas large invasive tumors with small growth fractions are generally less responsive. Radiotherapy fractionation can be used to improve oncologic outcomes by intensifying treatment with altered fractionation or by combining systemic therapy, which may sensitize certain tumors to radiotherapy.

The biologic effect of radiation depends on the dose per fraction, the number of fractions over time, the total treatment time, the total dose of radiation, and the type of radiation used (e.g., electron, neutron, proton).[111] Methods for representing the factors of dose, fraction size, and time of radiation with a single calculation using the time–dose fraction (TDF) and the nominal standard dose (NSD) calculations have been described. When comparing studies of radiation effect and when describing the results of studies of cancer patients treated with radiotherapy, reporting the total

Figure 7-47 Immediate postoperative reconstruction.

dose is inadequate because of the importance of fraction size and the time of therapy (which are not available for comparison). The use of the TDF or the NSD will facilitate the understanding of the relative biologic effect (RBE). The tolerance of the vascular, neurologic, and connective tissues to radiation influences both the success of tumor control and the development of treatment complications. The late complications of radiotherapy are due to effects on vascular, connective, and slowly proliferating parenchymal tissues. Late effects are related to the number of fractions, fraction size, total dose, tissue type, and volume of tissue irradiated and whether combined with chemotherapy. An increase in fraction size or a reduction in the number of fractions with the same total dose results in increased late complications, including tissue fibrosis and soft tissue and bone necrosis. As specificity of treatment planning improves, doses can be minimized. High-risk primary treatment sites may receive a dose of 72 Gy, while postoperative radiotherapy doses may be de-escalated to 66 Gy for high-risk sites and as low as 50 Gy for low-risk sites such as negative margins and cervical lymph nodes without extranodal extension.[110]

Radiation can be used preoperatively, postoperatively, or with a planned split-course approach, although there is controversy on the best approach. The advantages of preoperative radiation are the destruction of peripheral tumor cells, the potential control of subclinical disease, and the possibility of converting inoperable lesions into operable lesions. The disadvantages include delayed surgery and delayed postsurgical healing. The addition of chemotherapy following a combination of radiotherapy and surgery is used to treat cells that remain at the margin of resection and to reduce the potential for regional and systemic spread. Local control of the primary disease appears to be similar with preoperative or postoperative radiotherapy, but in some series the incidence of metastases was lower in the postoperative group.

Intensity-modulated radiotherapy (IMRT) uses radiation beams of varying intensity, which provides the ability to conform the prescription dose to the shape of the target tissues in three dimensions, reducing the dose to surrounding normal tissues. During the optimization process, each beam is divided into small "beamlets" whose intensity can be varied so that the optimal dose and distribution are obtained. The resultant intensity profile of each beam is complex. Rapid dose gradients outside the target result in sparing of normal tissues. IMRT and other advanced beam therapies are ideally suited for head and neck malignancies given the proximity of these tumors to critical structures, including the brainstem, optic chiasm, and salivary glands. IMRT has been shown to have comparable disease control to standard radiotherapy in head and neck oncology, with reduced acute and late toxicity. IMRT versus conventional radiotherapy has been demonstrated to improve quality of life and long-term severity of complications such as xerostomia in numerous studies and systematic reviews.[112,113]

Technical advances such as IMRT, newer faster forms of image-guided IMRT (IGRT), adaptive radiotherapy, and proton beam therapy reduce the size of the high-dose field of irradiation and limit the exposure of adjacent vital structures, including the salivary glands, but increase the

Figure 7-48 Postoperative panorex.

volume of tissue irradiated at low dose. Adaptive radiotherapy accounts for patient- and treatment-related morphologic changes such as severe weight loss or swelling to reduce an excessive dose to vital tissues. IMRT with meticulous treatment planning is recommended to reduce long-term treatment complications, in particular xerostomia, by reducing mean doses to less than 26 Gy to the parotid glands. Despite the improved outcomes for parotid function, most patients continue to experience xerostomia and salivary hypofunction post radiotherapy to some degree. This is likely a result of the difficulty in dose reduction in the region of the submandibular and sublingual glands.[114]

Radiation Sources

For treatment of superficial tumors, radiation with low penetration may be used. Low-kilovolt radiation (50–300 kV) can be used in the treatment of skin and lip lesions. Electron beam therapy provides superficial radiation and has largely replaced low-kilovolt x-ray machines because electrons produce a rapid dose build-up and fall-off of dose; thus, the depth of penetration can be relatively controlled. Electrons are useful in providing radiation to skin lesions, parotid tumors, and cervical nodes. Deep-seated tumors may be treated with heavy-particle irradiation, such as neutron beam radiation, which is considered for salivary gland tumors and central nervous system malignancies.

Proton Therapy

Protons are charged particles that can deliver a more concentrated and precise radiation dose to targeted tumor volumes, while minimizing exit doses to adjacent healthy tissue due to the heavy mass of protons. The homogeneous beam is more susceptible to artifact interference such as surgical hardware or metallic dental restorations. Intensity-modulated proton therapy (IMPT) with multifield optimization is often necessary in head and neck cancer treatment due to the inherent anatomic complexity of the region, which may lead to increased uncertainty of proton beam range.[115] Proton beam therapy is available at some centers, but a substantial upfront cost presents a barrier to widespread use and implementation. IMPT in head and neck cancer continues to be evaluated.[116] It is theorized that IMPT reduces damage to adjacent tissues and improves long-term sequelae such as xerostomia; however, early studies report mixed outcomes.[117]

Cancer Treatment Planning

Simulation is the first step in treatment planning, including immobilization via a thermoplastic face mask and CT, MRI, or PET scan to fabricate a radiotherapy treatment plan. Diagnostic-quality CT and MRI are used for computer-based treatment algorithms to target tumor volume and minimize critical normal adjacent structures. The radiation treatment plan is determined by the tumor site and size, relation to vital structures, volume to be radiated, radiation technology available, number of treatment fractions, total number of days of treatment, and tolerance of the patient. The dose to the eye, optic chiasm or spinal cord, salivary glands, alveolar bone, and soft tissue can be limited through the selection of the radiation source, field set-up, and shielding, and by moving the uninvolved tissue out of the field.

The current approach to treatment with the greatest potential to spare high-dose irradiation to vital tissue adjacent to the tumor includes IMRT, IGRT, or IMPT. For repeated doses of radiation to be applied to the site of treatment, the patient and the area of treatment are immobilized, using various techniques and materials, including head holders, bandages, laser positioning using head and neck "landmarks" or tattoos, and custom acrylic shells. Custom shells provide the best means of immobilization and positioning of patients that are critical in IMRT, IGRT, and proton beam therapy. These techniques may be combined with an oral device to position the mandible, allowing the maxilla or mandible to be moved into or out of the radiation field. An oral device can also position the tongue in or out of the treatment field.

Treatment planning requires localization of the tumor, and tumor margins can be marked with radiopaque gold seeds or lead wire, or based on real-time CT such as is incorporated into IGRT. If a shell is used, markings can be placed on the shell or by a marking on the skin (Figures 7-49 and 7-50). The 3D contours of the radiation field as planned by computer modeling and alterations can be made as needed. IGRT provides accurate and ongoing tumor contours and margin delineation during radiotherapy.

Modern radiation therapy is now using smaller margins around the tumor with the use of elaborate treatment algorithms. More complex set-ups include boost fields and sequential-field set-ups to maximize therapeutic effects and reduce complications (Figure 7-51).

CHEMOTHERAPY

Chemotherapy has been integrated into treatment algorithms for multiple types of head and neck cancer, including previously untreated locally advanced and recurrent or metastatic oral cavity and oropharynx cancer. Advances in systemic therapy have been made with the recognition of two distinct etiologies for HNSCC: environmental carcinogenesis (tobacco/alcohol/areca nut) and HPV. Three contexts are defined with regard to the chemotherapeutic management of HNSCC:

- Adjuvant postoperative concurrent chemoradiotherapy (CCRT).

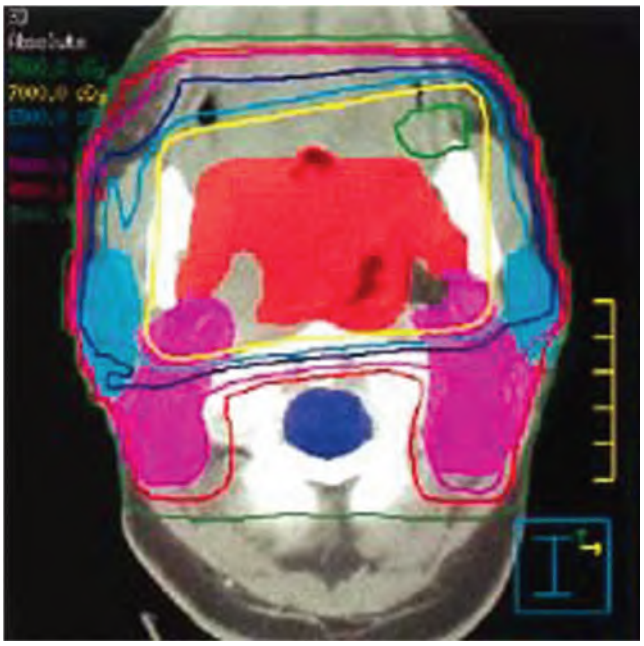

Figure 7-49 Conventional radiation is delivered in few fields and may result in high-dose exposure across the region of exposure. Exposure to vital structures such as midbrain, optic nerves, and salivary gland may be included in the high-dose volume.

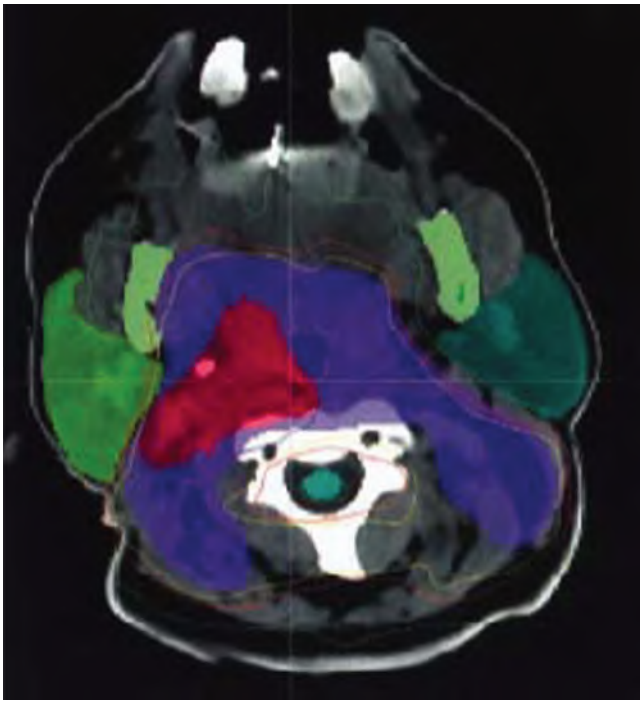

Figure 7-50 Intensity-modulated radiotherapy allows control of contours of radiation fields, tailoring of dose to enable high dose to tumor volumes, and shaping of fields to result in reduced dose to vital tissues such as brainstem, optic nerves, and salivary gland.

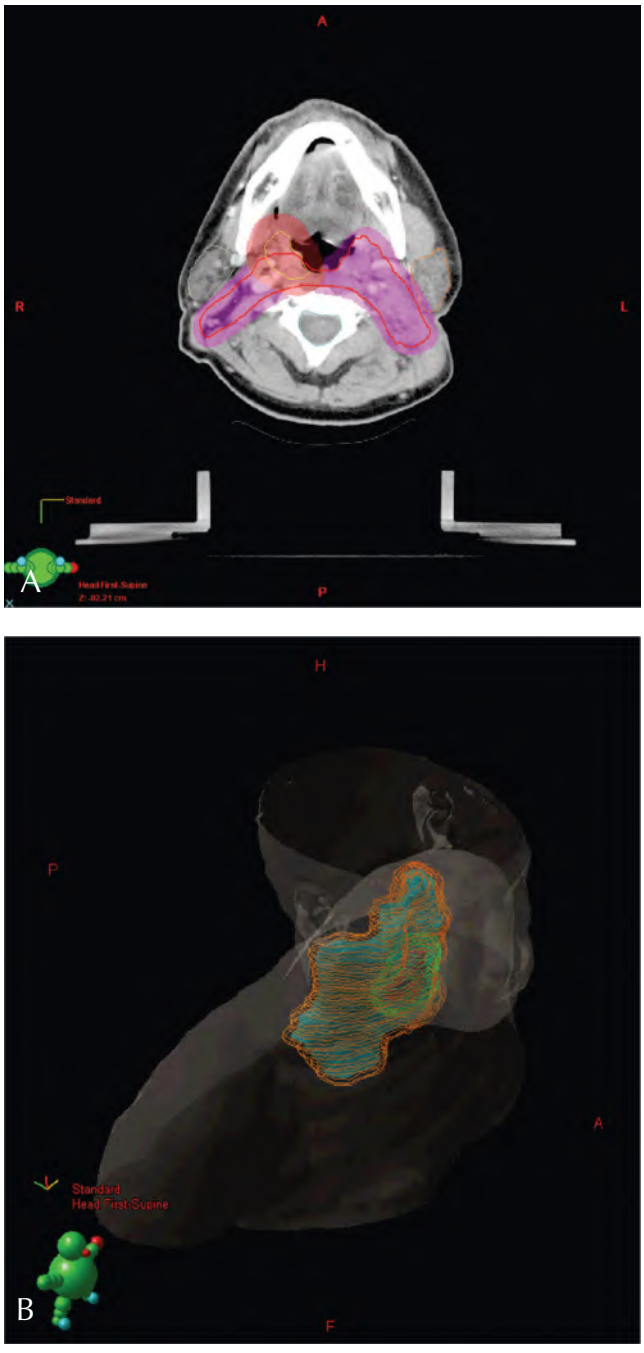

Figure 7-51 (A) Two-dimensional representation of intensity-modulated radiotherapy (IMRT) dosing to unilateral tumor, with minimal dose to salivary glands and spinal cord, and high-treatment dose to tumor and parapharyngeal lymph nodes. (B) Three-dimensional reconstruction of treatment fields using IMRT, where doses are contoured in three dimensions to maximize tumor dose and minimize dose to vital and uninvolved structures.

- Definitive CCRT, sometimes preceded by induction chemotherapy known as sequential therapy, for management of locally advanced or unresectable disease.
- Recurrent or metastatic disease.

The choice of treatment is determined by multiple factors, including the anatomic site of the primary tumor, disease stage at presentation (stage III and higher with positive surgical margins and ENE/extracapsular extension (ECE) being of importance), and the overall performance status of the patient, including their ability to tolerate various treatment modalities as well as their goals of therapy.

Systemic Therapy for Previously Untreated, Locally Advanced Head and Neck Squamous Cell Carcinoma

See Table 7-4.

Primary Definitive Concurrent Chemoradiotherapy

In patients with unresectable HNSCC, chemotherapy in addition to definitive radiotherapy has been shown to improve disease-free survival (DFS) and overall survival (OS). The Head and Neck Intergroup conducted a phase III randomized trial comparing radiotherapy alone, radiotherapy with concurrent bolus cisplatin every three weeks or a split course of single daily fractionated radiotherapy, and three cycles of concurrent fluorouracil and bolus cisplatin. The results established cisplatin–radiotherapy as the standard of care for this treatment group.[118] Cetuximab is a chimeric human/murine immunoglobulin (Ig) G1 and inhibitor of EGFR that is overexpressed in HNSCC, along with its ligand transforming growth factor-alpha (TGF-a). In combination with radiotherapy, cetuximab has been shown to be an alternative for patients unable to tolerate the toxicities of cisplatin.[119] Cetuximab is currently the only FDA-sanctioned targeted therapy for HNSCC.

Adjuvant Therapy

Treatment of advanced HNSCC with surgery and radiotherapy alone is often associated with a suboptimal outcome in terms of locoregional recurrence, distant metastasis, and DFS. Two trials, EORTC 22931 and RTOG 9501, have compared high-risk disease (ECE and positive surgical margins) treated with CCRT versus radiotherapy alone and have shown positive outcomes with regard to locoregional control (LRC) and DFS, highlighting the role of cisplatin in the treatment of advanced HNSCC.[120,121] Cisplatin is associated with exacerbation of the acute toxicities mucositis and

Table 7-4 Primary definitive chemotherapy

Squamous cell cancers of the lip, oral cavity, oropharynx, hypopharynx, glottic larynx, supraglottic larynx, ethmoid sinus, maxillary sinus, occult primary	
Primary systemic therapy + concurrent RT	
High-dose cisplatin (preferred) (category 1) Carboplatin/infusional 5-FU (category 1) 5-FU/hydroxyurea (category 2B) Carboplatin/paclitaxel (category 2B) Cetuximab (category 2B) Cisplatin/infusional 5-FU (category 2B) Cisplatin/paclitaxel (category 2B) Weekly cisplatin 40 mg/m^2 (category 2B)	The preferred chemoradiotherapy approach for fit patients with locally advanced disease remains concurrent cisplatin and radiotherapy
Postoperative chemoradiation	
Cisplatin (category 1 for high-risk (+ ENE and + margins) nonoropharyngeal cancers)	
Induction/sequential chemotherapy	
Docetaxel/cisplatin/5-FU (category 1 if induction is chosen) Paclitaxel/cisplatin/infusional 5-FU Following induction, agents used with concurrent chemoradiotherapy typically include weekly carboplatin, weekly cisplatin (category 2B), or weekly cetuximab	Cisplatin-based induction chemotherapy can be used, followed by radiation-based locoregional treatment (i.e., sequential chemoradiotherapy). However, an improvement in overall survival with the incorporation of induction chemotherapy compared to proceeding directly to state-of-the-art concurrent chemoradiotherapy (cisplatin preferred) has not been established in randomized studies After induction chemotherapy, multiple options can be used for the radiation-based portion of therapy Radiotherapy alone vs. radiotherapy plus weekly carboplatin or cetuximab are among the options

dermatitis as well as significant systemic toxicities, and therefore is not tolerated by all patients with HNSCC. Cetuximab is again an alternative treatment that has shown favorable DFS and OS in this treatment group.[119]

Deintensification

Current treatment paradigms were developed prior to the discovery of the role of HPV in the pathogenesis of OPC. Recognizing that HPV-associated OPC has a better prognosis, independent of treatment modality, than HPV-negative HNSCC has led to the development of de-intensification strategies for treatment with the goal of minimizing late toxicities of therapy. Fakhry and colleagues published a landmark study that documented the favorable prognosis of HPV-positive OPSCC, ECOG 2399, wherein HPV-positive patients had higher response rates and improved OS.[122]

Induction Therapy

Induction therapy (ICT) has a role in inducing rapid tumor shrinkage, eliminating distant metastases, and preservation of organs, but does not necessarily improve OS compared to CCRT. Sequential therapy (ST) combines ICT with CCRT and was examined in the DeCIDE and PARADIGM trials, which compared ST with docetaxel to CCRT. Neither showed a difference in OS.[123,124]

Systemic Therapy for Recurrent or Metastatic Head and Neck Squamous Cell Carcinoma

See Table 7-5. The goals of therapy become palliative for patients who develop recurrent or metastatic disease that is not responsive to surgical salvage or reirradiation.

The EXTREME trial compared carboplatinum versus cisplatin and fluorouracil with or without cetuximab in patients with recurrent, metastatic HNSCC and demonstrated that adding cetuximab resulted in a benefit in OS and progression-free survival (PFS).[125] The addition of cetuximab to standard platinum-based chemotherapy has become the first-line standard of care for patients with recurrent, metastatic, platinum-sensitive HNSCC.

For patients with recurrent, metastatic HNSCC that are refractory to platinum-based regimens, the anti-PD1 monoclonal antibody nivolumab has been shown to significantly improve OS.[89] The safety and tolerability of pembrolizumab

Table 7-5 Chemotherapy for recurrent, unresectable, or metastatic, non-nasopharyngeal head and neck squamous cell carcinoma (with no surgery or radiotherapy option).

	Preferred Regimens	Other Recommended Regimens
First Line	Cisplatin/5-FU/cetuximab (category 1)*	*Combination therapy*
	Carboplatin/5-FU/cetuximab (category 1)*	Cisplatin/cetuximab
		Cisplatin or carboplatin/docetaxel or paclitaxel
	Immunotherapy	Cisplatin/5-FU
	Pembrolizumab/platinum (cisplatin or carboplatin)/5-FU*	Cisplatin or carboplatin/docetaxel/cetuximab
	Pembrolizumab (for PD-L1 positive tumors)	Cisplatin or carboplatin/paclitaxel/cetuximab
		Single agents
		Cisplatin
		Carboplatin
		Paclitaxel
		Docetaxel
		5-FU
		Methotrexate
		Cetuximab
		Capecitabine
Subsequent Line	*Immunotherapy*	*Combination therapy or single agents*
	Nivolumab if disease progression on or after platinum therapy (category 1)	See options listed for first-line therapy
	Pembrolizumab if disease progression on or after platinum therapy (category 1)	*Targeted therapy*
		Afatinib if disease progression on or after platinum therapy (category 2B)

*Data suggest an overall survival advantage for patients treated with pembrolizumab/platinum/5-FU when compared to cetuximab/platinum/5-FU for first-line treatment of recurrent metastatic squamous cell carcinoma.

Source: Adapted with permission from National Comprehensive Care Network (NCCN) Guidelines Version 3.2019, 9/16/2019, Principles of Systemic Therapy. https://www.nccn.org/professionals/physician_gls/pdf/head-and-neck.pdf

were demonstrated in the KEYNOTE-012 trial.[126] In 2016 the FDA approved nivolumab and pembrolizumab for second-line treatment of HNSCC.

Immunotherapy

Patients with HNSCC have a relatively poor prognosis despite major advancements in the standard of care therapies, surgery, and CCRT. Although the prognosis for HPV-positive HNSCC is better than for HPV-negative HNSCC, both have high relapse rates for locoregional and distant metastatic disease. Recurrent or metastatic HNSCC has limited treatment options and immunotherapy offers an intervention that may improve OS for these patients.

Checkpoint Inhibitors

Immune checkpoints are a system of receptor/ligand interactions between T cells and other cells in the body that distinguish self from non-self. A recognition of non-self triggers an immune response and tumor cells are able to express self-ligands to avoid such a response. Receptors in the immune checkpoint system include cytotoxic T-lymphocyte-associated protein 4 (CTLA-4), programmed cell death protein 1(PD-1), and programmed cell death receptor ligand 1 (PD-L1). Ipilimumab is anti-CTLA-4, is approved for metastatic melanoma, and is currently being tested for its efficacy in HNSCC. Nivolumab is anti-PD-1 and was investigated in the CheckMate 141 trial, showing improved survival compared with standard of care in recurrent/metastatic HNSCC patients with progression on platinum therapy.[127] Pembrolizumab showed encouraging results in the KEYNOTE-012 trial for recurrent or metastatic HNSCC.[126]

Immune System Agonists (Co-stimulatory Molecules)

Agonist antibodies to the co-stimulatory molecules OX-40 and 4-1BB can enhance T cell proliferation and function and thereby generate therapeutic antitumor responses. Anti-OX-40 and Anti-4-1BB are currently under investigation in the treatment of HNSCC.

Adoptive T Cell Therapy

Adoptive T cell therapy (ACT) is a process that starts with the harvesting of tumor-infiltrating T cells from autogenous tumor and expanding them with IL-2 to test for tumor specificity. They are then expanded for reinfusion in a lymphocyte-depleted patient. ACT has been used in the treatment of metastatic melanoma with promise and there have been successful reports of its use in HNSCC.[128]

Active Immunotherapy (Vaccines)

An optimal antitumor immune response is necessary to mediate the therapeutic effect of immunotherapies such as PD-1 inhibitors. Many types of vaccines are under investigation for their ability to promote an antitumor T cell response and thereby complement the effect of checkpoint inhibitors and immune system agonists. Examples are peptide and whole-protein vaccines, whole-cell vaccines, autophagosome-based vaccines, the HPV vaccine, and oncolytic virus vaccines.

PROGNOSIS

The most important factors influencing survival in patients with oral and oropharyngeal cancer are the presence of HPV and the stage of disease at diagnosis.[67] Unfortunately, the majority of oral cancers continue to be diagnosed at advanced stages, after becoming symptomatic. Cancers positive for HPV, particularly type 16, have a better prognosis compared to HPV-negative tumors.[94,122] This parameter is now critical to stratify the patient's risk; however, HPV testing must not be considered in isolation, as there are important interactions with other parameters, such as tobacco and alcohol exposure. Additional prognostic factors for oral cancer include DOI, perineural invasion, differentiation level, lymphocytic infiltrate at interface, status of surgical margins, and ENE of cervical metastases.[68]

There is rarely a second chance for a cure, as cure rates decline rapidly if the lesion is not successfully managed with initial therapy, and therefore the initial approach to therapy is critical. Locoregional causes of death from head and neck cancer may be due to erosion of major vessels, erosion of the cranial base, nutritional compromise, cachexia, and secondary infection of the respiratory tract. The fact that the OS in younger patients is better reflects that a more complex medical background and comorbidities in older patients expose them to additional systemic complications and poorer outcome.

PREVENTION

Primary prevention has focused on tobacco as a major cause of upper aerodigestive tract cancers, and attention has been paid to strategies of tobacco cessation. Diet has been studied, with evidence supporting a diet rich in fresh fruits and vegetables in developing countries, but with less support in the developed world. Vitamins or nutritional supplements have not been shown to be effective, including no definitive studies investigating antioxidant supplementation. Without vaccination, almost all adults who have been sexually active are exposed to HPV at some point in their lives, usually before age 26. Population-level intervention for preventing

associated oral/oropharyngeal cancer is aimed at elimination of HPV infection through vaccine.

Human Papillomavirus Vaccine

Human papillomavirus is known to have 19 different oncovirus strains. These are known to cause cervical, vaginal, vulvar, anal, penile, and head and neck cancers. Current vaccination is expected to prevent 90% of these cancers. The vaccine can be given to children (boys and girls) age 9 to adults age 45. Gardasil® 9 (Merck, West Point, PA, USA) can provide immunity to 9 of the 19 HPV strains known to cause cancer.

Vaccine recommendations have expanded to include both male and female adolescents. It has been estimated that effective sex-neutral sustained vaccination for HPV 16, 18, 6, and 11 of 80% of the population could result in elimination of these oncoviruses.[129] As there is no current treatment for HPV once a patient is infected, future therapies are aimed at enhancing the immune response to clear the virus once exposed. Pathways involve using therapeutic vaccines with live vector, protein, mRNA or DNA, or cell-based vaccines aimed at one or more oncoproteins (E6, E7) of the HPV virus.[130]

Early Diagnosis and Cancer Control

Head and neck and oral examinations have been shown in a large trial in India to result in earlier identification of OSCC and to translate into improved survival compared with a control group.[131] Furthermore, it is possible that this approach is cost-effective, as shown in this high-risk patient population.[132]

A position paper by the United States Preventive Services Task Force (USPSTF) noted that there is insufficient evidence to assess the balance of benefits and harms of screening for oral cancer in asymptomatic adults by nondental providers. This reflects the fact that OSCC is a rare disease and progress of disease once present is unpredictable. While the USPSTF's conclusion represents the available evidence in terms of cost-effective and risk–benefit analysis, it challenges guidance from a public health perspective and specifically excludes dental providers from the recommendations. It is thought that early detection based upon a visual and tactile examination performed in the dental care setting may be associated with improved survival with reduced costs. However, false-positive and false-negative findings and the potential for overtreatment are a concern in HNSCC, as they are in other malignancies such as breast and prostate cancer. Considering that oral cancer screening is an integral component of the overall routine comprehensive head and neck examination in the primary dental care setting (opportunistic screening), it is considered to be good practice.[82,133]

MALIGNANT TUMORS OF THE SALIVARY GLANDS

Salivary gland tumors represent approximately 6% of head and neck tumors and most commonly arise in the parotid glands, where the majority of tumors are benign adenomas; that is, pleomorphic adenoma, myoepithelioma, basal cell adenoma, Warthin's tumor, canalicular adenoma, duct papilloma, and cystadenoma. The parotids may be the site of transformation in a relatively small number of these cases (approximately 15–35% of salivary gland malignancies). Malignant tumors of the salivary glands develop most commonly in the submandibular, sublingual, and minor salivary glands (approximately 40%, 70–90%, and 45–80% of salivary gland malignancies, respectively). Major salivary gland carcinomas, unlike most head and neck carcinomas that are squamous in origin, are classified into over 20 histologic subtypes.[22] The most common of these are mucoepidermoid carcinoma, adenoid cystic carcinoma, and acinic cell carcinoma. The cause of salivary gland tumors remains obscure, but ionizing radiation has been identified as a risk factor. Many chromosomal events and oncogenes are postulated in the pathogenesis of salivary gland cancer.

Clinical Presentation and Diagnosis

Malignant salivary gland tumors most commonly present as a painless mass. When the mass is superficial or large, it may cause intraoral or extraoral asymmetry. When the mass is intraoral, it may be ulcerated. Neurologic involvement may lead to discomfort and numbness, and with parotid gland tumors involvement of the facial nerve may cause facial paralysis. In the floor of the mouth, salivary gland malignancies may cause ankyloglossia.[134] Most small malignant lesions are clinically indistinguishable from benign lesions. The most common site of minor salivary gland cancer is the posterior hard palate, but other sites in the oral cavity or upper respiratory tract may be involved. Most salivary gland tumors spread by local infiltration, by perineural or hematogenous spread, or less commonly via lymphatics.[78]

Biopsy of masses in the major glands may be accomplished by FNA or CNB, and diagnosis may be made without open biopsy; however, surgical biopsy may be necessary if FNA is not diagnostic. In masses involving minor glands, biopsy can be performed with routine techniques.[134]

Treatment and Prognosis

Studies assessing treatment and prognosis are complicated by the large variety of histologic subtypes, and the small numbers seen of each type of salivary gland cancer. Therefore, treatment trials provide limited guidance. Surgery is the principal treatment of the primary tumor. Despite the

anticipated low proliferative index of many salivary gland cancers, radiotherapy at a high dose is effective and may be employed in malignant salivary gland tumors. Postoperative radiation can contribute to cure and to improved local control, and is indicated for patients with residual disease following surgery, extensive perineural involvement, lymph node involvement, high-grade malignant disease, tumors with more than one local recurrence after surgery, inoperable tumors, malignant lymphoma, and for those who refuse surgery. Doses and fractionation similar to those used in the treatment of SCC are usually employed. Heavy-particle radiation sources (neutron beam and proton beam) have been shown to provide effective treatment for salivary gland tumors.[135,136]

Various single-agent chemotherapy protocols and combination protocols have been evaluated, but in general all with small studies, therefore limiting conclusions. Unlike with OSCC, chemotherapy does not seem to be effective for advanced or metastatic salivary gland disease. Perhaps the slow growth of salivary gland cancer could explain the overall poor results to date with chemotherapy protocols. In the future, advances in management may mirror those of breast cancer, where subtypes of salivary gland cancer may be assessed by evaluation of cell surface markers including HER2-neu, EGFR, and other markers, in order to guide chemotherapy and targeted therapies. Among the chemotherapeutics examined, limited benefit has been seen, while data on targeted agents is being evaluated alone or in combination with cytotoxic chemotherapy.[137]

The prognosis of salivary gland tumors is related to tumor type (histology and degree of differentiation) and stage of disease (tumor size, lymph node involvement, and extension of disease). Small tumors have a favorable prognosis and a high probability of cure with surgical management. Tumors with a poor prognosis include large tumors, adenocarcinoma, adenoid cystic carcinoma, high-grade mucoepidermoid carcinoma, poorly differentiated carcinoma, and SCC. Histologic findings that correlate with lymph node involvement include deep (>8 mm) and diffuse invasion of stromal tissue and invasion of lymphatics.[138,139]

ODONTOGENIC TUMORS

Odontogenic neoplasms form from epithelial and mesenchymal remnants of tooth germs. The WHO classifies tumors of odontogenic origin into malignant and benign odontogenic tumors. Of the malignancies, ameloblastic carcinoma, primary intraosseous carcinoma, sclerosing odontogenic carcinoma, clear cell odontogenic carcinoma, ghost cell odontogenic carcinoma, odontogenic carcinosarcoma, and odontogenic sarcomas are included.[22] These tumors are extremely rare and our knowledge of them is based on case reports and small case series, making standardized treatment recommendations difficult. Most of these tumors are aggressive and the primary treatment is radical excision.

MALIGNANT TUMORS OF THE JAW

Malignant lesions of the jaw may be of hematopoietic origin, such as lymphoma and multiple myeloma, or of bone origin, such as osteosarcoma, chondrosarcoma, and Ewing sarcoma. Metastases to the jaw should be considered during clinical evaluation of any cancer patient with a cancer history, particularly in breast, prostate, gastrointestinal, and renal carcinoma. This section focuses on osteosarcoma, which is the most common bone-originating jaw malignancy.

OSTEOSARCOMA

Osteosarcoma is a malignant tumor, characterized by the formation of bone or osteoid by tumor cells. Osteosarcomas of the jaws may develop in a broad range of ages, but are more common in the third and fourth decades.[140] Osteosarcoma occurs slightly more often in the mandible than in the maxilla. Most osteosarcomas of the jaws are centrally located in the bone. Juxtacortical or parosteal location, a location adjacent to the outer surface of the cortical bone, is unusual. Osteosarcomas may also develop in a patient affected by Paget's disease or in a patient who has been irradiated either for a benign bone lesion or for adjacent soft tissue disease. The latent time period may vary widely.

Clinical Presentation and Diagnosis

The most common presenting finding of osteosarcomas of the jaws is mass (85–95.5%). Pain accompanies the swelling in approximately half of cases, and trigeminal sensory disturbances occur in about a fifth of cases. Additional symptoms associated with intraosseous location are mobile teeth, toothache, and nasal obstruction.[141,142]

The radiographic appearance varies between radiopaque, radiolucent, and mixed. The border of the lesion is not well defined. The classic radiographic presentation is of a "sun-ray appearance," in which the radiograph may show an opaque lesion with bony trabeculae directed perpendicularly to the outer surface. This is observed in about 25% of cases. Over time, there is expansion and perforation of the cortical bone. The osteolytic type is far less characteristic and appears as an ill-defined radiolucency that causes expansion and destruction of the cortical bone. In the presence of teeth,

a widening of the periodontal ligament may be observed even before changes can be noticed elsewhere in the bone. Root resorption may create a spiked shape to the apical third of the root. Loss of follicular cortices of unerupted teeth is highly suggestive of malignancy. Widening of the mandibular canal is another ominous sign. Bone scintigraphy will show a positive uptake in tumor and indicate the extent of tumor, but is not diagnostic.

Histopathologic proliferation of atypical osteoblasts, irregular osteoid and bone formation, and anaplastic fibroblasts may be seen. Vascular clefts result in variants such as telangiectatic osteogenic sarcoma. Multinucleated giant cells may be scarce or abundant. Osteosarcomas of the jaws are, in general, better differentiated than similar tumors in the long bones. Even if the tumor largely consists of malignant-looking cartilage, the so-called chondroblastic type, it is still to be considered an osteosarcoma whenever osteoid and bone are present in the stroma. Low-grade osteosarcomas may be misdiagnosed as fibrous dysplasia or other benign fibro-osseous lesions. Osteosarcomas are usually graded according to histopathologic criteria from low-grade (grade I) to high-grade (grade III) malignancies.

Treatment and Prognosis

Treatment requires aggressive local surgery. Several authors report the use of (neo)adjuvant chemotherapy. Others report that the introduction of chemotherapy did not dramatically alter the prognosis of osteosarcoma of the jaw. Metastasis is usually via the bloodstream and often occurs within 1–2 years. Of the patients who die from osteosarcoma, most do so with uncontrolled local disease. The 5- and 10-year survival rates after treatment are approximately 60–70% and 50%, respectively. Large tumors, higher-grade secondary osteosarcomas, and recurrence are associated with decreased survival. Mandibular location and clear surgical margins are associated with improved survival.[143]

SARCOMAS OF THE SOFT TISSUES

Soft tissue sarcomas of the oral cavity are rare and account for approximately 1% of all oral malignancies. Subtypes include fibrosarcoma, malignant fibrous histiocytoma, liposarcoma, rhabdomyosarcoma, leiomyosarcoma, angiosarcoma, and alveolar soft part sarcoma. Soft tissue sarcoma usually presents as a slow or rapid-growing swelling of the mucosa involving any part of the oral cavity. Treatment usually consists of surgery with adjuvant radiotherapy for those with high-grade tumors and/or positive margins following surgery. The efficacy of adjuvant chemotherapy is poorly defined.[144,145]

METASTASES TO THE HEAD AND NECK

Metastatic tumors to the oral region are uncommon and may occur in the oral soft tissues or in the jawbones. The most common primary sites from which oral metastases arise are the lung, kidney, liver, and prostate for men, and breast, female genital organs, kidney, and colo-rectum for women. Prostate and breast metastases are mainly concentrated in the jaws rather than the soft oral tissues.[68,72]

The clinical presentation of metastasis to the jawbones includes swelling, pain, and paresthesia.[68] Metastases to the oral soft tissues may manifest as a submucosal mass or gingival mass.[72] Radiographic presentation is mainly radiolucent with a poorly defined border, although radio-opacities or mixed radiographic lesions may be seen in some cases.[68,146] A diagnosis of oral metastasis is a poor prognostic indicator and the literature suggests an average seven-month survival time, with treatment being mainly supportive.

NASOPHARYNGEAL CARCINOMA

Nasopharyngeal carcinoma (NPC) accounts for 0.7% of all cancers diagnosed in 2018 and is relatively uncommon worldwide. East and Southeast Asia account for 70% globally of all cases. The high rates of NPC in East and Southeast Asia are attributed to a combination of EBV, genetic morphology, and factors such as smoking, environmental toxins, consumption of preserved foods, and alcohol. EBV is a member of the herpesvirus family with a double-stranded, linear DNA viral genome. While an estimated 90% of the global population has been exposed to EBV, for most this was at an early age through saliva and they never experience symptoms or complications related to this infection. Some individuals, particularly with immunosuppression, experience latent infection in memory B cells and develop Hodgkin or Burkitt lymphomas. Malignant transformation of epithelial cells in the nasopharynx and oral cavity can lead to both nasopharyngeal and salivary gland carcinomas.[3]

Five-year survival is approximately 40% and 60%, for keratinizing and nonkeratinizing SCC, respectively. However, clinical stage at diagnosis is the most important prognostic factor for NPC survival. FNA can provide tissue diagnosis, and the sensitivity can be enhanced by DNA amplification (polymerase chain reaction) of the EBV genome, which is commonly associated with NPC but is rare in other head and neck cancers. Furthermore, rapid clearance of EBV DNA from plasma may be used as a marker for response to treatment.[147]

Treatment of early-stage disease without obvious neck metastasis is high-dose definitive radiotherapy to the nasopharynx (66–72 Gy) and often bilateral RT to the neck.

Obvious neck or distant metastasis is preferentially treated with a clinical trial or concurrent chemoradiotherapy, induction chemotherapy followed by chemoRT, or chemoRT followed by adjuvant radiotherapy. Chemotherapy for concurrent therapy includes cisplatin followed by cisplatin or carboplatin/5-FU, while induction chemotherapy begins with docetaxel/cisplatin/5-FU, cisplatin/5-FU, cisplatin/epirubicin/paclitaxel, or docetaxel/cisplatin, and agents typically include weekly cisplatin or carboplatin (Table 7-6).[90]

While standard of care is treatment with IMRT, oral complications are substantial and have great impact on the quality of life. Surgery may play a role in the treatment of recurrent or metastatic disease. Transoral robotic surgery is becoming more commonly used in early-stage NPC. Proton therapy can be considered when photon therapy is expected to damage critical structures, and has been demonstrated to decrease radiation dose to the oral cavity.[148] Some studies have reported an improvement in 5-year survival in patients treated with proton therapy versus photon therapy for paranasal sinus and nasal cavity malignant disease.[149]

NPC presents a number of concerns to dental providers, because patients may present with complaints that mimic temporomandibular disorders (TMDs). The common clinical presentation of NPC is otalgia and neck mass. Common TMD signs and symptoms include pain and limited jaw opening. Symptoms that aid in differentiation of TMD and NPC may occur late or concurrently and include dysphagia, nasal stuffiness, nose bleed, neck mass, or cranial involvement.[150] Cases of nonkeratinizing NPC for which EBV infection is a risk factor are endemic in Asia and, while uncommon, may be increasing in prevalence in the United States.[151]

Table 7-6 American Joint Committee on cancer staging for nasopharyngeal carcinoma 8th edition.

Primary Tumor (T)	
Tx	Primary tumor cannot be assessed
T0	No tumor identified, but EBV+ cervical node involvement
T1	Tumor confined to the nasopharynx, or extension to oropharynx and/or nasal cavity without parapharyngeal involvement
T2	Tumor with extension to parapharyngeal space, and/or adjacent soft tissue involvement (medial pterygoid, lateral pterygoid, prevertebral muscles)
T3	Tumor with infiltration of bony structures at skull base, cervical vertebra, pterygoid structures, and/or paranasal sinuses
T4	Tumor with intracranial extension, involvement of cranial nerves, hypopharynx, orbit, parotid gland, and/or extensive soft tissue infiltration beyond the lateral surface of the lateral pterygoid muscle
Regional Lymph Nodes (N)	
Nx	Regional lymph node cannot be assessed
N0	No regional lymph node metastasis
N1	Unilateral metastasis in cervical lymph node(s) and/or unilateral or bilateral metastasis in retropharyngeal lymph node(s), ≤6 cm, above the caudal border of cricoid cartilage
N2	Bilateral metastasis in cervical lymph node(s), ≤6 cm, above the caudal border of the cricoid cartilage
N3	Unilateral or bilateral metastasis in cervical lymph node(s), >6 cm, and/or extension below the caudal border of cricoid cartilage
Distant Metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis
Clinical Stage	
I	T1 N0 M0
II	T2 N0–1 M0, T0–1 N1 M0
III	T3 N0–2 M0, T0–2 N2 M0
IVA	T4 or N3 M0
IVB	Any T, any N, M1

MUCOSAL MELANOMA

Mucosal melanomas (MMs) are very rare and only comprise 1.3% of all melanomas (see also Chapter 5, "Pigmented Lesions of the Oral Mucosa"). The most common sites in the head and neck are the conjunctiva, nasal cavity, paranasal sinuses, and oral cavity. MM is more common in those over the age of 65 and has a slightly higher incidence in women. Risk factors may include cigarette smoking and exposure to formaldehyde. MM is an aggressive disease with a poor prognosis and, unlike cutaneous melanoma, the biology and pathogenesis of MM are poorly understood. Presenting signs of MM depend on the anatomic site involved. In the nasal cavity and paranasal sinuses, signs such as nasal obstruction and discharge, epistaxis, and facial pain can be misinterpreted as signs of sinonasal inflammatory disease. In the oral cavity, lesions of MM are easier recognized and typically present as hyperpigmented/melanotic nodules or macules, but can also be amelanotic.

The most commonly involved sites in the oral cavity are the hard palate and gingiva. For both oral cavity and sinonasal MM, satellite lesions may accompany the primary lesion. Oral MM is categorized by the presence of pigmentation and growth type (nodular, macular, or mixed). Regional nodal metastasis is typically more likely at diagnosis in oral cavity MM than sinonasal MM and more common in lesions with a DOI >5 mm. Nodal metastasis may be more common in lesions with a nodular growth pattern. Treatment follows the treatment guidelines for cutaneous melanoma and usually involves surgical resection, with possible postoperative radiation therapy. Medical treatments in the form of targeted therapies and immunotherapies have changed the way in which cutaneous and MMs are treated. Targeted therapies for melanoma with a BRAF V600 mutation include BRAF inhibitors dabrafenib and vemurafenib and the MEK inhibitor trametinib. For melanomas with a KIT gene mutation, the KIT inhibitors imatinib, dasatinib, and nilotinib are recommended. For patients with metastatic or unresectable MM, immunotherapy is recommended with ipilimumab (anti-CTLA-4), nivolumab (anti-PD-1), and pembrolizumab (anti-PD-L1).[152]

PARANEOPLASTIC SYNDROMES AND ORAL CANCER

Oral cancer is reported in the literature in association with several syndromes or chronic diseases. These disorders are considered paraneoplastic because they accompany the malignant tumor, but are not directly related to the cancerous mass, its invasion, or its metastasis. The diagnosis of oral cancer may precede, develop simultaneously, or develop following the diagnosis of the paraneoplastic syndrome.

Within the group of endocrine paraneoplastic syndromes, oral cancer may be associated with inappropriate secretion of antidiuretic hormone (SIADH), humoral hypercalcemia, hypercalcemia with leukocytosis, and autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED). Within the group of cutaneous paraneoplastic syndromes, oral cancer is associated with Bazex syndrome (acrokeratosis paraneoplastica), Sweet's syndrome (acute febrile neutrophilic dermatosis), and paraneoplastic pemphigus. Additional vascular, hematologic, rheumatoid, and ocular syndromes are associated with oral cancer.[153]

HEAD AND NECK MALIGNANT DISEASE IN HIV/AIDS

HIV infection that leads to immunosuppression increases the risk of the development of neoplastic disease. KS was the most common neoplastic disease of AIDS prior to antiretroviral therapies (ART). KS is a multicentric neoplastic proliferation of endothelial cells and was very common prior to ART, occurring in up to 55% of individuals with AIDS and often representing the first sign of progression to AIDS. KS is associated with the oncovirus human herpesvirus type 8 (HHV-8). KS can involve any oral site, but most frequently involves the attached mucosa of the palate and gingiva, or the dorsum of the tongue. Lesions begin as blue-purple or red-purple flat discolorations that can progress to tissue masses that may ulcerate (Figures 7-2 and 7-3). The lesions do not blanch with pressure. Initial lesions are asymptomatic, but can cause discomfort and interfere with speech, denture use, and eating if they progress. The differential diagnosis includes ecchymosis, vascular lesions, salivary gland tumors, and metastatic disease. Definitive diagnosis requires biopsy.

Intralesional chemotherapy for treatment of oral KS provides effective palliation.[154] Intralesional treatment with vinblastine and interferon has been reported. The lesions can be treated with the injection of vinblastine (0.2 mg/mL) under local anesthesia. The effect of treatment may continue for several weeks and may result in palliation for approximately four months. Repeat injection can be completed with similar efficacy. KS is radiosensitive, and radiation can be palliative for regional disease. Fractionated radiotherapy (for a total dose of 25–30 Gy over 1–2 weeks) may be provided for oral KS. If KS progresses at multiple sites, systemic chemotherapy is indicated. Additional approaches to management include drugs that reduce angiogenesis, antiviral agents for HHV-8 infection, and agents that block VEGF.

Certain lymphoma subtypes are more common in people with AIDS. Non-Hodgkin lymphoma (NHL) is considered an AIDS-defining entity, and this disease is currently the most common type of cancer in HIV-infected individuals in the United States and Europe. NHL, most commonly of B cell origin, may present with central nervous system involvement, but also may present with head, neck, or oral lesions. Hodgkin lymphoma is not considered an AIDS-defining malignancy; however, its incidence is increased in HIV-infected individuals. The lymphomas are aggressive and carry a poor prognosis. Treatment of lymphoma with chemotherapy for HIV patients on antiretroviral therapy may be challenging.

Oral and oropharyngeal SCC has been reported in patients with HIV disease. Despite the widespread use of ART, with HPV-related oral lesions being more prevalent, the prevalence of oral or oropharyngeal cancers in HIV patients is projected to increase.[155]

CONCLUSION

New understandings of head and neck cancers continue to emerge. These include information about the etiologic risk factors, current epidemiology, advances in treatment, recommendations for prevention, and importance of surveillance for possible cancer recurrence or new second cancers. The role of the dental professional extends from detection and diagnosis of head and neck cancers throughout the cancer continuum of treatment and survivorship, and requires close communication with the oncology team. With the emergence of new therapies and therefore new complications, an appropriate level of oral care requires a thorough understanding of these diseases and their treatments. Given advances in therapies and the subsequent increases in survivorship, the oral healthcare professional's involvement in the care of the cancer patient becomes crucial to helping these patients maintain an acceptable quality of life.

Oral Complications of Nonsurgical Cancer Therapies

Siri Beier Jensen, DDS, PhD
Douglas E. Peterson, DMD, PhD, FDS RCSEd

OVERVIEW

Oral complications from cancer therapies are commonly of significant morbidity to the patient and may cause disruption of cancer treatment compromising the prognosis and increase health care costs. A wide range of oral complications of cancer therapies often appear concurrently which may complicate diagnoses and management; for example, intense oral and pharyngeal pain induced by a combination of oral mucositis, oropharyngeal candidiasis, salivary gland hypofunction, and xerostomia frequently lead to dysphagia in cancer patients compromising nutritional intake.[1] Thus, oral complications of cancer therapies may severely affect quality of life during cancer treatment or when manifest as late oral complications months or years following treatment.

Oral complications induced by cancer therapies result from a complex interplay among multiple factors and the recognition of the underlying mechanisms causing oral complications continues to develop. However, there are no effective agents or protocols to collectively prevent adverse effects from cancer therapies. Thus, the current approach to

Burket's Oral Medicine, Thirteenth Edition. Edited by Michael Glick, Martin S. Greenberg, Peter B. Lockhart, and Stephen J. Challacombe.

minimize incidence and severity of oral complications of cancer therapies is the elimination of pre-existing dental, periodontal, and mucosal infections in coherence with regular oral assessment and implementation of basic oral care protocols and prompt diagnosis of emerging oral complications during and after cancer therapy with adequate alleviation and treatment.[2]

An interdisciplinary approach, including dental professionals, is required to work in close collaboration with the patient in order to regularly—and by validated outcome measures—evaluate, prevent, and treat oral complications of cancer therapies.

This chapter addresses oral complications of nonsurgical cancer therapies and evidence-based clinical practice guidelines for management.

Types of Cancer Therapies

Design of cancer treatment protocols is based on a number of key considerations, beginning with histopathologic confirmation of the type of malignancy. Additional components include staging (solid tumors), age and performance status of the patient, projected efficacy in relation to toxicity, and patient preferences.

Patients with hematologic malignancy

Patients with hematologic disease (Figure 8-1; Figure 8-2) may be treated by moderate or high-dose chemotherapy, with or without hematopoietic stem cell transplantation (HSCT). As with head and neck cancer patients, factors influencing incidence and severity of oral complications across patients with hematologic disease include extent of oral disease prior to cancer treatment, intensity of cancer therapy, genetically-governed susceptibility to oral mucosal injury, and patient compliance with health professional Recommendations regarding oral hygiene, diet, smoking cessation, and related variables.

HSCT-related oral toxicities are additionally influenced by the degree of genetic disparity between donor and patient. Acute and/or chronic graft-versus-host disease (GVHD) that results from immune-modulated injury to the patient's tissues can cause clinically significant salivary gland and/or oral mucosal disease.

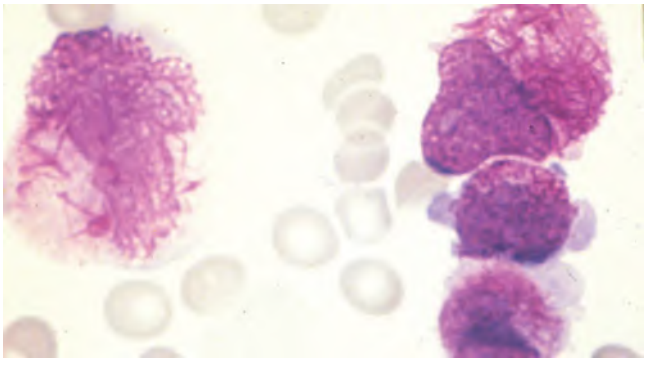

Figure 8-1 Peripheral blood smear from a patient with newly diagnosed acute myelogenous leukemia in blast crisis. The high-dose induction chemotherapy regimen that will be used to treat this patient is profoundly myelosuppressive, and typically causes severe ulcerative oral mucositis for at least two weeks duration. The interface of profound myelosuppression with disruption in integrity of the oral mucosal barrier can result in risk for life-threatening bacteremia and/or sepsis. *Source:* Quintessence 2019.[69]

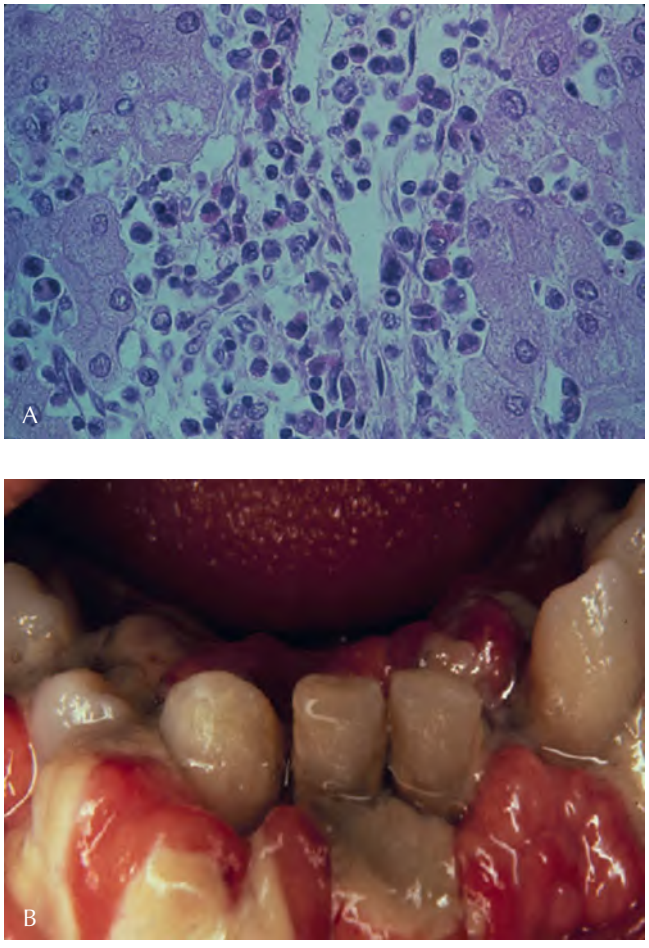

Figure 8-2 Acute leukemia can be considered "naturally metastatic" in that the neoplasm arises within the white blood cell progenitors produced in the bone marrow. Because of the inherent circulation of these cells the disease is widespread by time of diagnosis. (A) Histopathology based on hepatic biopsy, demonstrating widespread infiltrate of the blast leukemic cells. (B) Gingival leukemic infiltrate in newly diagnosed acute myelogenous leukemia patient. Note the evidence of extensive gingival engorgement caused by the infiltrating leukemic cells. The resulting ischemia can contribute to develop of tissue necrosis as well as opportunistic infection such as pseudomembranous candidiasis. *Source:* Quintessence 2019.[69]

Patients with Head and Neck Cancer

Depending upon these variables, cancer treatment for a patient with solid head and neck cancer (e.g., oral, oropharyngeal, or laryngeal tumor) can consist of:

- Surgical excision with resultant cure (early stage solid tumor).
- Head and neck radiation, administered in fractionated or hyperfractioned doses five times/week for 6–7 weeks for a total cumulative dose of approximately 60–70 Gy.
- Multimodality treatments that incorporate chemotherapy based on the following schema:

  Neoadjuvant chemotherapy:
  Administered prior to surgery, for purposes of debulking tumor.
  Adjuvant chemotherapy:
  Administered after surgery and prior to head and neck radiation.
  Concurrent/concomitant chemotherapy:
  Administered in combination with head and neck radiation, typically on a weekly basis throughout the duration of the 6–7 weeks of radiation.

Factors influencing incidence and severity of oral complications across patients with head and neck cancer include extent of oral disease prior to cancer treatment, dose and anatomic location of radiation therapy, genetically-governed susceptibility to oral mucosal injury, and patient compliance with health professional recommendations regarding oral hygiene, diet, smoking cessation, and related variables.

Patients Receiving Targeted Cancer Therapies

Use of targeted cancer therapies such as multitargeted tyrosine kinase inhibitors and mammalian target of rapamycin (mTOR) inhibitors has increased in recent years.[3,4] These biologics are directed to molecular pathways that are unique to tumor cells, versus normal cells. Despite their targeting, however, side effects such as oral mucosal and dermal lesions can occur.

Epidemiology of Oral Complications of Cancer Therapies

The types of oral complications vary in pattern, duration, and intensity for each individual patient and depending on the cancer therapy regimen and dose intensity: e.g. cancer chemotherapy, head and neck radiation therapy, targeted cancer therapies, and hematopoietic stem cell transplantation.[5–8] The Oral Care Study Group and the Mucositis Study Group of the Multinational Association of Supportive Care in Cancer and International Society of Oral Oncology (MASCC/ISOO) have performed systematic reviews of the most common oral complications of cancer therapies and provided prevalence of oral mucositis,[9–11] oral pain,[12] oral fungal infection,[13] oral viral infection,[14,15] salivary gland hypofunction and xerostomia,[16] dysgeusia,[17] trismus,[18] dental disease,[19,20] osteoradionecrosis,[21] and medication-related osteonecrosis of the jaw[22,23] in relation to various regimens of cancer therapy. The prevalence data presented in these systematic reviews highlight the multiple variables that translate into the degree to which a cancer patient experiences a given toxicity, including pre-existing oral status, type and intensity of cancer treatment, the patient's genetically governed response, and patient-reported outcomes.

ORAL CARE PROTOCOLS FOR PATIENTS RECEIVING CHEMOTHERAPY AND HEAD AND NECK RADIATION

Oral Care, Precancer Treatment

Elimination or stabilization of selected oral disease prior to initiation of chemotherapy or head and neck radiation can prevent or mitigate subsequent acute oral toxicities such as infection of dental, dental pulpal or, periodontal origin. Decision-making relative to this medically necessary oral care, precancer treatment is illustrated in Figure 8-3.

Implementation of Systematic Basic Oral Care Protocols for Oncology Patients

Oral care interventions are pertinent to all cancer patients in order to prevent and reduce the incidence and severity of oral complications and promote oral comfort during and following cancer therapies.

Development and implementation of oral care protocols should be interdisciplinary (nurse, physician, dentist, dental hygienist, dietician, pharmacist, and others as relevant) and include education of the patient, family, and health care professionals. The protocols should be focused on: Regularly scheduled oral assessment and decontamination to reduce the risk of infection, oral moisturization to reduce the risk of friction and trauma-induced oral mucosal injury, and pain management to promote oral comfort and avoid dose reduction and interruption of cancer treatment.

Evidence-based patient care fact sheets are available with a multidisciplinary approach on how to care for your mouth before, during and after radiation for head and neck cancer as well as during active chemotherapy (http://isoo.world/patient-education.html).[25] The fact sheets are multilingual and available in 21 languages.

Oral Decontamination

Toothbrushing two to three times a day with a soft nylon-bristled toothbrush (with regular replacement of the toothbrush) is recommended.[2,24,25] The bristles can be softened in

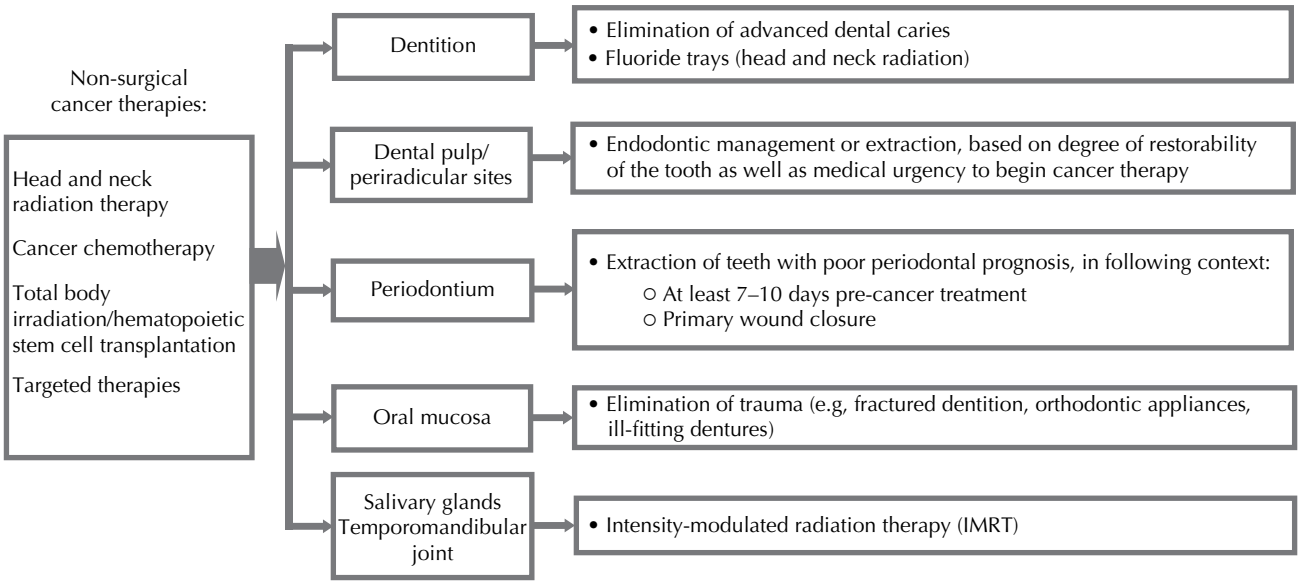

Figure 8-3 Oral care, precancer treatment.

warm water if oral hygiene procedures become discomforting, or can be modified to an ultrasoft toothbrush to ensure continued mechanical oral decontamination for as long as possible during cancer treatment. Toothbrushing should be supplemented by dental flossing once daily with instruction on atraumatic technique. Fluoridated toothpaste should be used, supplemented by high concentration prescription fluoride regimens if the patient's ability to perform oral care is compromised or if increased risk of dental caries due to salivary gland hypofunction (e.g., 5000 ppm fluoride toothpaste or 1% neutral sodium fluoride gel in a dental tray for 5 minutes before bedtime: the dental tray should overlap the gingival margins of the teeth and still avoid unnecessary contact with the gingiva). Toothpastes containing sodium dodecyl/laureth sulfate (surfactant) and mint flavor should be avoided if it causes soreness of the oral mucosa. Antiseptic mouthwashes such as 0.12% chlorhexidine gluconate may be administered as a supplement to toothbrushing depending on the manifestation of periodontal disease or if toothbrushing is no longer possible due to oral pain.[2,24,25] Professional mechanical bacterial plaque removal should be performed before the patient begins rinsing with chlorhexidine gluconate.[26]

Oral Hydration

Alleviation of xerostomia comprises gustatory, masticatory, or pharmacologic stimulation of residual salivary gland secretory capacity or regular and frequent sipping and topical application to the oral cavity of water, bland rinses, or saliva substitutes (e.g., mouthwash, spray, or gel).[25,27,28] Lubrication of lips should be incorporated to prevent crusting and ulceration of the prolabium.

The use of bland rinses, for example 0.9% saline rinse or sodium bicarbonate solution (1 teaspoon salt, 1 teaspoon baking soda in 1 liter of water) is recommended in cancer therapy populations for decontamination, moisturization, neutralization of pH, and for promoting oral comfort.[2,24,25] Saline and sodium bicarbonate rinses are considered harmless to the oral cavity, thus frequent rinsing without swallowing can be performed as needed.

Evidence-based clinical practice guidelines for management of salivary gland hypofunction and xerostomia are described in detail in Chapter 9 "Salivary Gland Diseases."

Integration of Tobacco Intervention in Oral Supportive Care in Cancer

Tobacco intervention is essential after the diagnosis of cancer to improve clinical outcomes and should be a multidisciplinary approach with screening carried out throughout the continuum of care with intervention services available at each point of care.[29,30]

ORAL TOXICITY MANIFEST IN PATIENTS BOTH DURING CHEMOTHERAPY AND HEAD AND NECK RADIATION

Cancer patients can be at high risk for oral complications secondary to their cancer treatment (Figure 8-4). Incidence and severity are governed by a number of cancer treatment variables, as described below.

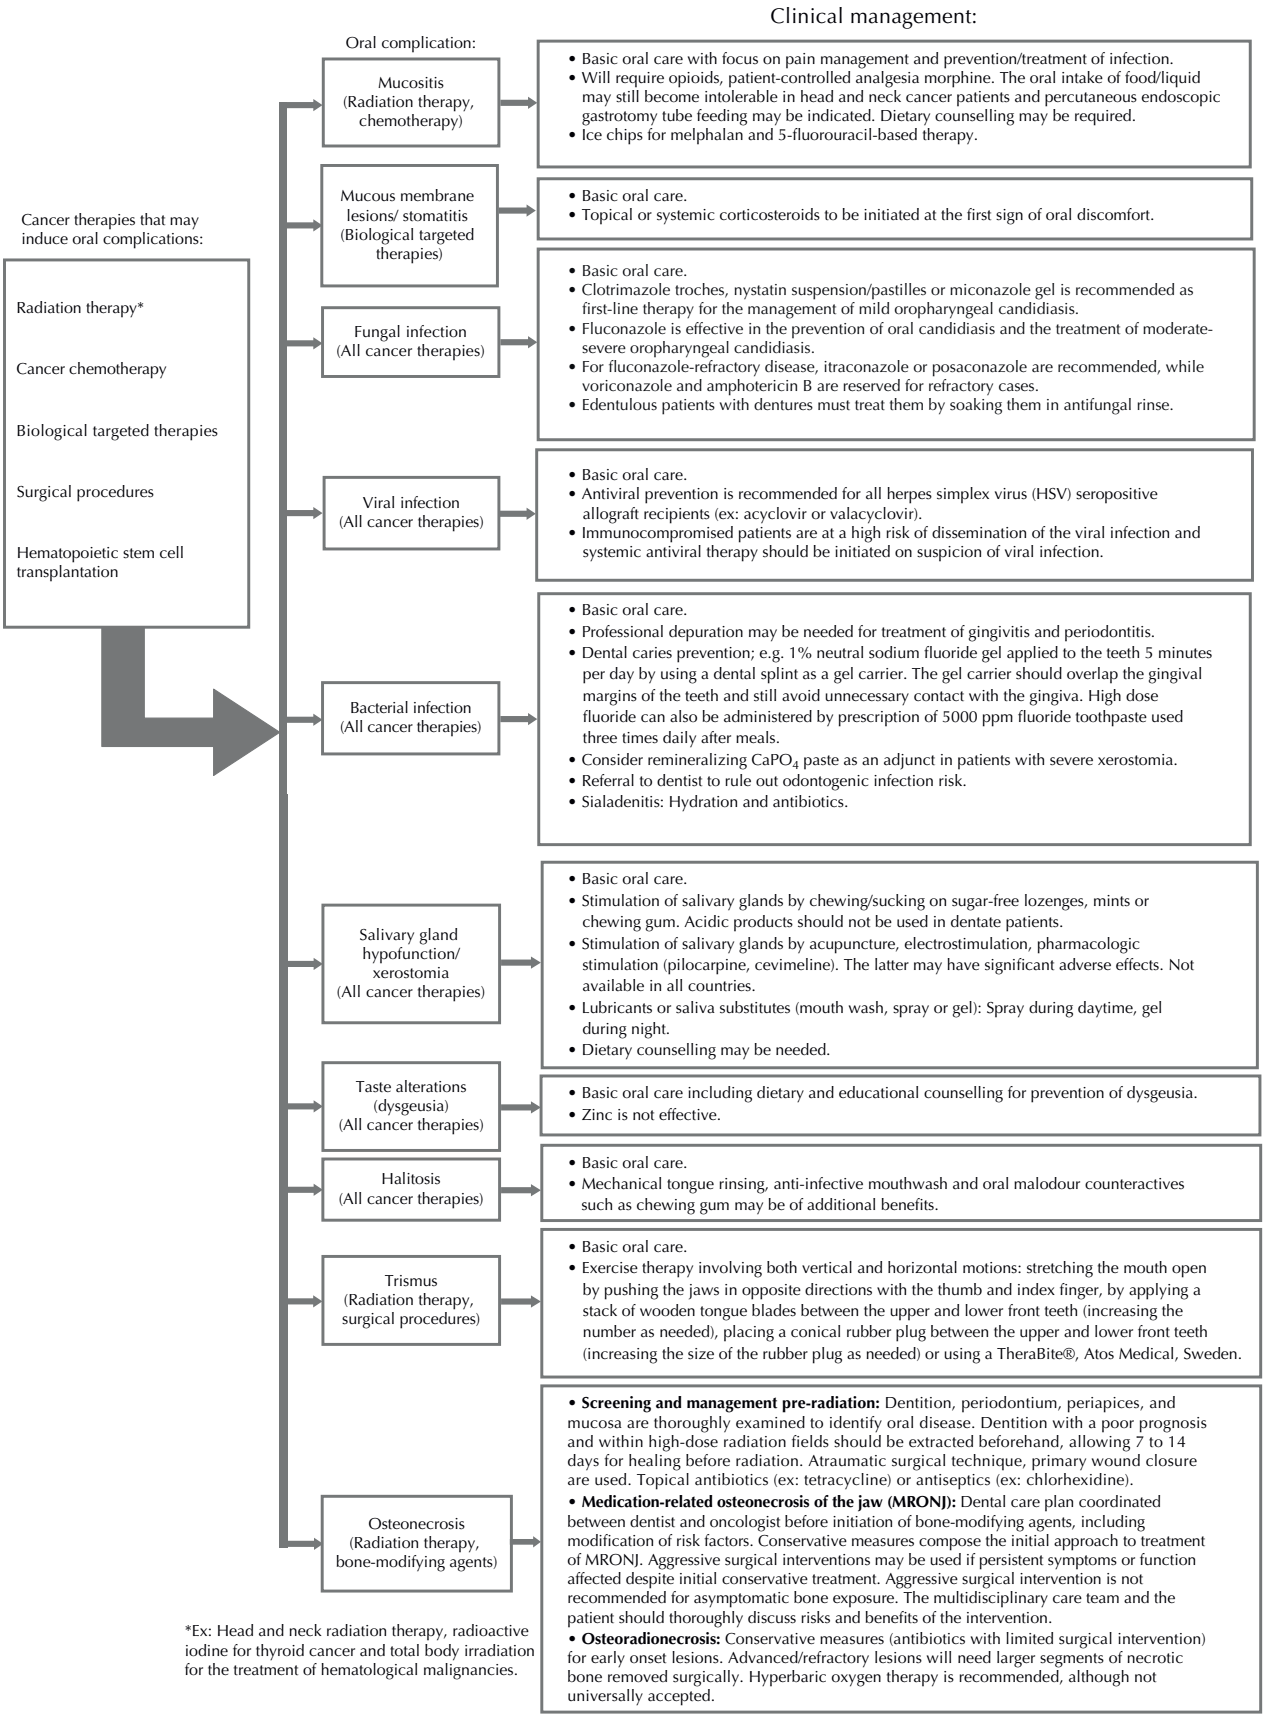

Figure 8-4 Clinical management of oral complications of nonsurgical cancer therapies.

Oral Mucositis

Oral mucositis can have significant clinical and economic consequence in oncology practice (Figure 8-5). The pain associated with the lesion can be sufficiently severe as to cause hospitalization in order to support nutritional intake and other daily functions. The pain can also cause dose reduction in future cycles of chemotherapy, thus compromising optimal delivery of the chemotherapy regimen.

Despite the prominence of oral pain in the clinical setting, however, there has been limited investigative research into the neuropathology component of the lesion. Mucosal injury in the neutropenic cancer patient can be source of systemic infection, with resultant morbidity and, in selected patients, mortality. Oral mucositis can thus cause clinically and economically adverse impact.

The current five phase pathobiologic model of oral mucositis is complex, and involves both epithelium as well as submucosa (Figure 8-6).[31–33] In addition, the potential role of the oral microbiome in relation to oral mucositis pathobiology has received increasing research attention as well. Incidence of moderate–severe oral mucositis in high-dose chemotherapy patients is approximately 40%.[34]

Evidence-based guidelines for management of oral mucositis are centered on supportive care.[9,11]

The evidence base for clinical practice guidelines for prevention and treatment of oral mucositis was reviewed in 2019 by the Mucositis Study Group, MASCC/ISOO. The results were incorporated into recommendations or suggestions at three levels: (i) *in favor* of interventions for oral mucositis; (ii) *against* interventions for oral mucositis; or (iii) no guideline possible due to insufficient or conflicting evidence.[10,11] Conclusions from these 2019 mucositis guidelines include:

Figure 8-5 Oral mucositis in breast cancer patient receiving high-dose chemotherapy. The extensive pseudomembranous lesions can signficiantly impair normal oral function, and represent a portal of entry for severe systemic infection. *Source:* Quintessence 2019.[69]

1) Of the *growth factors and cytokines* studied for the management of oral mucositis, the evidence supports a recommendation *in favor* of intravenous keratinocyte growth factor (KGF)-1 for prevention of oral mucositis in patients with hematological cancer undergoing autologous HSCT with high-dose chemotherapy and total body irradiation and a suggestion *against* granulocyte-macrophage colony-stimulating factor (GM-CSF) in certain clinical settings.[35]
2) Numerous *natural products and herbal remedies* have been studied for the management of oral mucositis. Of the agents reviewed in the systematic review, a guideline *in favor* was made for honey (combined topical and systemic), while a guideline *against* was made for chewing gum.[36]
3) Of the agents studied for the management of oral mucositis-associated *pain*, the evidence supports a suggestion *in favor* of topical morphine 0.2% mouthwash in patients with head and neck cancer receiving radiation therapy and chemotherapy.[37] Additional guidance has been provided in a 2019 review by Epstein and Miaskowski, as cited in section Oral Pain.[38]
   The evidence supports recommendations for the use of *oral cryotherapy* for the prevention of oral mucositis for either (i) patients undergoing autologous hematopoietic stem cell transplantation with high-dose melphalan conditioning protocols or (ii) patients receiving bolus 5-fluorouracil chemotherapy.[39]
4) Regarding *basic oral care*, the evidence supports implementation of multiagent combination oral care protocols for prevention of oral mucositis (in chemotherapy, head and neck radiation therapy, and hematopoietic stem cell transplantation) defined as interventions carried out by the patients, lay caregivers, and/or nondental care professionals. The rationale for their implementation is to increase awareness of both patients and staff of the importance of good oral hygiene, which may indirectly lead to less frequent and less severe oral complications.
5) Typically, the protocols included in the systematic review involved a multifaceted approach to oral hygiene, including recommendations with regard to timing, frequency, and products such as combination of varying types of bland mouth rinses, toothbrushes, and flossing procedures.[2]
6) Chlorhexidine was suggested *not to be used* in basic oral care protocols to prevent oral mucositis in patients with head and neck cancer undergoing radiation therapy. However, it was emphasized by the systematic review panel that this recommendation is specific to the prevention of oral mucositis and this recommendation does not apply to other conditions where chlorhexidine is indicated; for example, oral infections.[2]

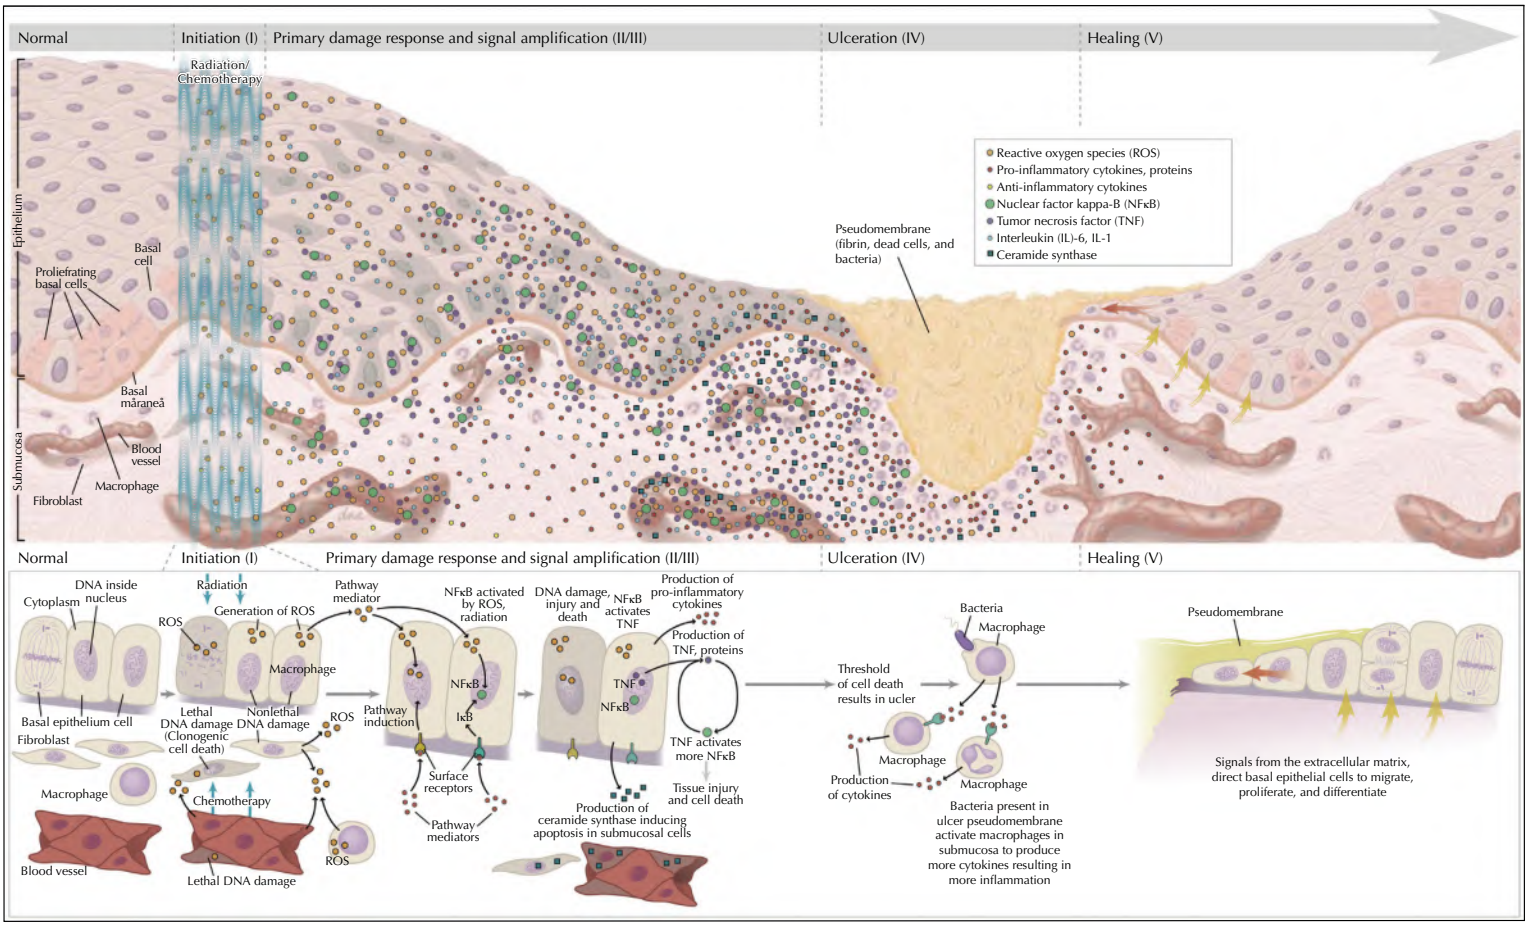

Figure 8-6 The conceptual framework for oral mucositis pathobiology consists of five stages, ranging from initial injury with hours of exposure to high-dose cancer therapy to eventual healing approximately 2–4 weeks after cessation of that treatment. Although the illustration depicts an orderly and sequential mechanistic process, the likely course of molecular and cellular events is more likely dysregulated and biologically confounded. *Source:* Sonis 2007.[31]

7) For other empiric basic oral care measures, only limited data were available. Thus, expert opinion supplements the basic oral care guidelines in support of the use of professional oral care for oral mucositis prevention; that is, dental evaluation and treatment as indicated prior to cancer therapy to reduce the patient's risk for local and systemic infections from odontogenic sources. It was also the panel's opinion that educating patients over the benefits of basic oral care strategies may improve the patient's self-management and adherence to the recommended oral care protocol during cancer treatment.
8) Despite the limited data available for oral bland rinses, the panel recommends saline and sodium bicarbonate mouth rinses that increase oral clearance which may be helpful for maintaining oral hygiene and improving patient comfort.[2]
9) Of the *anti-inflammatory agents* studied for oral mucositis, the evidence supports use of benzydamine mouthwash for prevention of oral mucositis in patients with head and neck cancer receiving radiation therapy and chemotherapy.[40]
10) Of the *vitamins*, *minerals*, *and nutritional supplements* studied for the management of oral mucositis, the evidence supports a recommendation *against* parenteral glutamine in patients receiving HSCT and a suggestion *in favor* of oral glutamine for management of oral mucositis in patients with head and neck cancer.[41]
11) The evidence supports the use of specific settings of *photobiomodulation* therapy for the prevention of oral mucositis in specific patient populations. Under these circumstances, photobiomodulation is recommended for the prevention of oral mucositis. The guidelines are subject to continuous update based on new published data.[42]
12) There is only one US Food & Drug Administration-approved biologic for prevention of oral mucositis (see the section Patients undergoing hematopoietic stem cell transplantation [HSCT]). Additional interventions, including pharmacologic and photobiomodulation, are also being studied.[42,43]

Oral Pain

Oral pain in cancer patients is likely due to both nociceptive and neuropathic pathways; treatment of both of these mechanistic processes is thus needed to achieve effective management.[38] The level of oral pain should be scored on a systematic basis, utilizing a validated pain ladder.

Pain management by patient-controlled analgesia with morphine in hematopoietic stem cell transplantation, topical 0.2% morphine mouthwash in head and neck radiation therapy, or 0.5% doxepin mouthwash (patient population not specified) have been recommended or suggested depending on the level of evidence as interventions to treat pain due to oral mucositis.[37] Management of pain from oral mucositis during head and neck radiation begins with nonsteroidal anti-inflammatory drugs (NSAIDs) since generally there is not an increased risk of hemorrhage and this can be combined with opioids as the severity of oral mucositis and pain increases.[44]

Depending on the severity of mucositis, topical anesthetic rinses can be used to allow for continuity of oral care and food intake with the precaution that the patient is carefully informed to avoid mechanical trauma and burns in the anesthetized mucosal areas.

Oral Hemorrhage

Compromised basic oral care increases the risk of oral infection (gingivitis, periodontitis, oral candidiasis) which increases the risk of oral hemorrhage. Hemorrhage may also be caused by cancer treatment-induced thrombocytopenia in patients receiving high-dose chemotherapy or undergoing hematopoietic stem cell transplantation.

Hemorrhage can be controlled with basic oral care and adequate periodontal and antifungal treatment. However, if prolonged hemorrhage occurs (> 2 min), periodontal treatment should be discontinued and the oncologist/hematologist consulted. Further management of oral hemorrhage includes the use of vasoconstrictors, clot-forming agents, and tissue protectants.[45]

PATIENTS RECEIVING HIGH-DOSE CHEMOTHERAPY

Chemotherapy can be used in a variety of primary or adjunctive oncology settings (Table 8-1). In addition to oral mucositis, oral infection can occur in association with chemotherapy-

Table 8-1 Single and multimodality cancer treatments for oral cancer.

Neoadjuvant: (debulk)	Sole use prior to surgery (e.g., 5 days 5-fluorouracil: mucositis)
Adjuvant: (curative)	Use after surgery/before radiation therapy (e.g., 5 days 5-fluorouracil: mucositis)
Concurrent/ Concomitant: (synergistic)	Combination with radiation therapy (e.g., head and neck radiation therapy + weekly cisplatin)

Source: Reprinted with permission from Peterson DE. Quintessence 2014.[68]

induced myelosuppression (Table 8-2). Unlike the head and neck radiation patient, however, long-term effects of high-dose chemotherapy on the oral tissues are rare.

Patients may develop pseudomembranous oral candidiasis during periods of bone marrow suppression (Table 8-3). Contributing factors may also include difficulties with oral hygiene during periods of oral mucositis as well as salivary gland hypofunction induced by medications used to support the care of the patient (e.g., antiemetics). Clinical diagnosis can often be established based on history and examination, although the assessment may be confounded by the concurrent presentation of chemotherapy-induced oral mucositis as noted above. Topical oral antifungal therapy with nystatin rinses or clotrimazole troches can be considered for management (Table 8-4). Resolution of the lesion typically occurs in the setting of bone marrow recovery and re-establishment of optimal oral care.

The periodontium may infrequently be a site of acute infectious flare during profound myelosuppression (Figure 8-7). These lesions are rarely encountered in oncology practice. When they do occur, however, the infection may not be readily detectable due to the impaired inflammatory response in the setting of profound neutropenia. Treatment usually consists of topical oral antimicrobial rinses and gentle mechanical plaque removal. Supervision of this intervention by a health professional with experience in dental management is highly recommended. Broad-spectrum antimicrobial therapy should be considered if the clinical presentation so indicates.

Table 8-2 High risk oral lesions in the myelosuppressed cancer patient.

Advanced and/or symptomatic dental caries

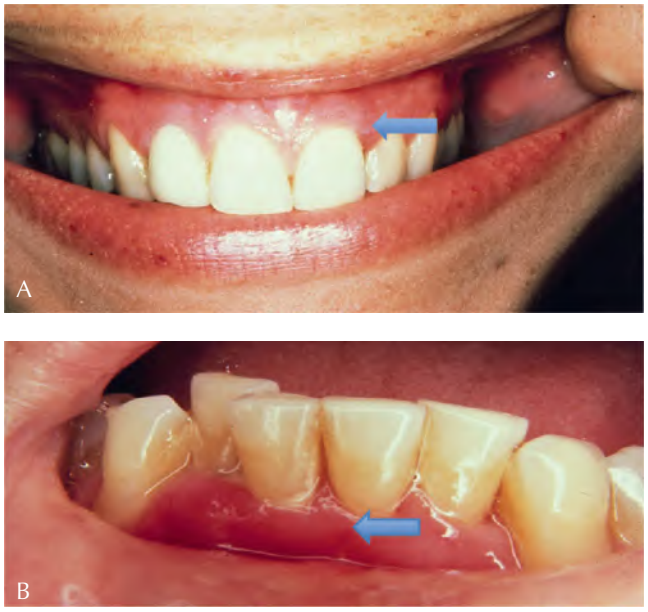

Figure 8-7 (A) Acute periodontal infection in a neutropenic cancer patient with < 500/mm^3. Classic inflammatory signs including erythema and purulence are not clinically prominent due to suppression of neutrophil number and function. (B) Acute periodontal infection in a chemotherapy cancer patient with < 1000 neutrophils/mm^3. Classic inflammatory signs are more evident due to a more robust neutrophil response. *Source:* Quintessence 2019.[69]

Patients Undergoing Hematopoietic Stem Cell Transplantation (HSCT)

Patients undergoing HSCT are at risk for development of a wide range of oral toxicities (Table 8-5).[24,46] Incidence and severity are directly influenced by a number of key variables. For example, the patient undergoing HSCT will typically receive a conditioning regimen containing chemotherapy at a high dose or reduced intensity level. As with chemotherapeutic regimens in the non-HSCT setting, risk for infection increases as the depth and duration of myelosuppression increases. An additional key factor is the degree of genetic homology between donor and recipient. Chapter 20, "Transplantation Medicine", provides further detail regarding these risk factors. Infections in patients undergoing HSCT can be of viral, bacterial, and/or fungal origin.

Oral Mucositis

Oral mucositis is a common toxicity in patients undergoing HSCT, with moderate–severe oral mucositis developing in patients undergoing high-dose conditioning regimens. Selected chemotherapeutic agents (e.g., melphalan) are also typically mucotoxic.

Table 8-5 Oral complications of hematopoietic stem cell transplantation.

Transplant phase	Oral complication
Phase I: Preconditioning	Oral infections: dental caries, endodontic infections, periodontal disease (gingivitis, periodontitis), mucosal infections (i.e., viral, fungal, bacterial)
	Gingival leukemic infiltrates
	Metastatic cancer
	Oral bleeding
	Oral ulceration: aphthous ulcers, erythema multiforme
	Temporomandibular dysfunction
Phase II: Conditioning, neutropenic phase	Oropharyngeal mucositis
	Oral infections: mucosal infections (i.e., viral, fungal, bacterial), periodontal infections
	Hemorrhage
	Salivary gland hypofunction/xerostomia
	Taste dysfunction
	Neurotoxicity: dental pain, muscle tremor (e.g., jaws, tongue)
	Temporomandibular dysfunction: jaw pain, headache, joint pain
Phase III: Engraftment, hematopoietic recovery	Oral infections: mucosal infections (i.e., viral, fungal, bacterial)
	Acute GVHD
	Salivary gland hypofunction/xerostomia
	Hemorrhage
	Neurotoxicity: dental pain, muscle tremor (e.g., jaws, tongue)
	Temporomandibular dysfunction: jaw pain, headache, joint pain
	Granulomas/papillomas
Phase IV: Immune reconstitution, late posttransplant	Oral infections: mucosal infections (i.e., viral, fungal, bacterial)
	Chronic GVHD
	Dental/skeletal growth and development alterations (pediatric patients)
	Salivary gland hypofunction/xerostomia
	Relapse-related oral lesions
	Second malignancies
Phase V: Long-term survival	Relapse or second malignancies
	Dental/skeletal growth and development alterations

GVHD = graft-versus-host disease.
Source: Reprinted from National Cancer Institute Physicion Data Query (NCI PDQ) website:Oral Complications of Chemotherapy and Head/Neck Radiation.[44]

The pathobiologic model and clinical trajectory appears to be similar to that of patients receiving high-dose chemotherapy without HSCT. An additional consideration, however, is the possibility of acute GVHD involving the oral mucosa. Acute GVHD can mimic oral mucositis clinically and can confound diagnosis and management of the concurrent toxicities.

In 2004, the US Food and Drug Administration approved the first-in-kind molecularly targeted drug for oral mucositis. This product, palifermin (KGF-1), was approved for the treatment of oral mucositis in patients with hematologic malignancies and who are receiving intensive chemotherapy and radiotherapy followed by a blood or bone marrow stem cell transplant.

See Oral Mucositis at the beginning of this section (Oral toxicity manifest in patients both during chemotherapy and head and neck radiation) for additional detail regarding assessment and treatment.

Oral Viral Infection

Oral viral infection caused by reactivation of herpes simplex virus (HSV) does not commonly occur in contemporary oncology practice, since prevention by thymidine kinase inhibitors such as acyclovir, valacyclovir, and their derivatives is highly effective. Pretransplant serologic testing for carrier status of HSV is important in identifying who patients may benefit from the viral prophylactic regimen. HSV titers greater than or equal to 1:16 are often used clinically as the indicator for initiation of the prophylactic regimen.

The infection (Figure 8-8), when it does occur, can co-develop in the setting of oral mucositis and/or acute GVHD.[47] This in turn not only confounds the diagnostic process but also intensifies the severity of the mucosal injury.

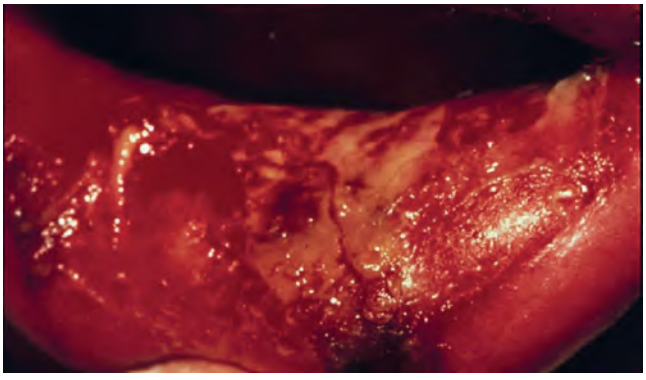

Figure 8-8 Reactivated herpex simplex virus in an immunocompromised hematopoietic stem cell transplant patient can be extensive and fatal. The compromised mucosal and circulating immune defenses result in a rapidly progressing, painful and sometimes fatal systemic viral infection. Fortunately, antiviral prophylaxis or treatment with thymidine kinase inhibitors such as acyclovir or its derivatives is highly efficacious. Drug-resistant herpes simplex is an infrequent occurrence. *Source:* Photo courtesy of M. M. Schubert: Quintessence 2019.[69]

As with all infections in this population, early diagnosis is essential in order to initiate prompt, directed treatment. Viral culturing remains the gold standard. Other types of testing, such as direct immunofluorescence, immunoassay, and shell vial testing, may be useful in context of producing more rapid results.

Oral Candidiasis

Pseudomembranous oral candidiasis, as with high-dose chemotherapy patients who did not undergo stem cell rescue, can occur in settings of compromised mucosal and salivary defenses (Figure 8-9). Other types of fungal infection can also occur including lesions caused by *Aspergillus*, *Mucormycosis*, and *Rhizopus* spp. Culturing and/or biopsy of these latter lesions are essential for diagnosis in that the lesions may mimic clinical appearance of nonyeast toxicities in patients receiving HSCT.

The reader is also referred to Chapter 20 "Transplantation Medicine" for more detailed discussion of these lesions as well as prevention and management of oral toxicity unique to the HSCT patient population.

TARGETED CANCER THERAPIES

Oral Ulcerations/Stomatitis Induced by Targeted Cancer Therapies

Targeted cancer therapies include monoclonal antibodies and small molecule drugs interfering with specific extra- and intracellular pathways required for tumor progression (Table 8-6). Such pathways include inhibition of growth factor receptors involved in cancer cell proliferation and angiogenesis, by intracellular delivery of small molecules toxic to cancer cells, by inducing apoptosis of cancer cells, or by triggering an immune response resulting in destruction specifically of cancer cells. They continue to be used to treat a broad range of cancers; for example, renal cell carcinoma, nonsmall cell lung cancer, breast cancer, colorectal cancer, squamous cell carcinoma of the head and neck, non-Hodgkin's lymphoma, and leukemia. Oral mucosal toxicity is a relatively frequent adverse effect of selected molecularly targeted cancer therapies, including multitargeted tyrosine kinase inhibitors, mammalian target of rapamycin (mTOR) inhibitors, and PD-1 inhibitors.[3,4,7,48,49]

The clinical manifestation of mTOR inhibitor-induced oral toxicity resembles aphthous stomatitis and is distinct from conventional oral mucositis (Figure 8-10). Depending upon severity of pain, the lesion may result in the need for dose reductions of cancer treatment or delay of treatment. The lesions typically appear within a few days after

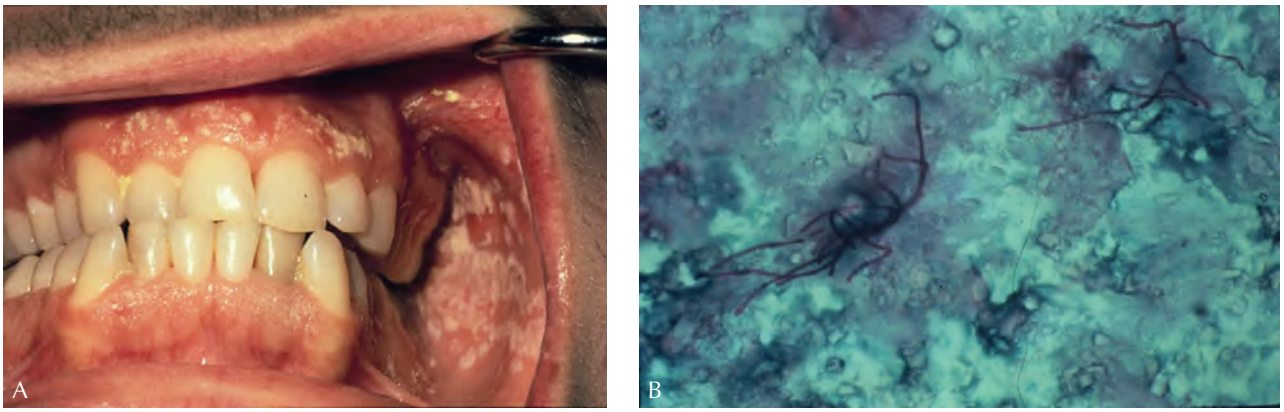

Figure 8-9 Pseudomembranous oral candidiasis can occur in oncology patients secondary to myelosuppression and/or compromised salivary defense mechanisms. (A) A Clinically documented pseudomembranous oral candidiasis in an allogeneic hematopoietic stem cell transplant patient with chronic graft-versus-host disease (GVHD) involving the major salivary glands. The resultant compromised salivary flow rate and composition (e.g., lactoferrin, salivary IgA, transferrin and mucins) can lead to this and opportunistic infections. (B) Cytologic smear demonstrating the dimorphic candidal organism and hyphae. Quintessence 2019.[69]

Table 8-6 Examples of targeted cancer therapies potentially causing oral ulceration/stomatitis.

Drug class	Active drug	Treatment indication
Mammalian target of rapamycin (mTOR) inhibitor	Temsirolimus	Kidney cancer
Epidermal growth factor receptor inhibitor (tyrosine kinase inhibitor)	Erlotinib	Pancreatic and nonsmall cell lung cancer
Multitargeted tyrosine kinase receptor inhibitor	Sunitinib	Kidney cancer, gastrointestinal stromal tumor
Vascular endothelial growth factor inhibitor	Bevacizumab	Colorectal, lung, breast, glioblastoma, kidney, and ovarian cancer
Protein kinase inhibitor	Sorafenib	Kidney, liver, and thyroid cancer

Source: Adapted from Elting et al.[70] and Martins et al. [71]

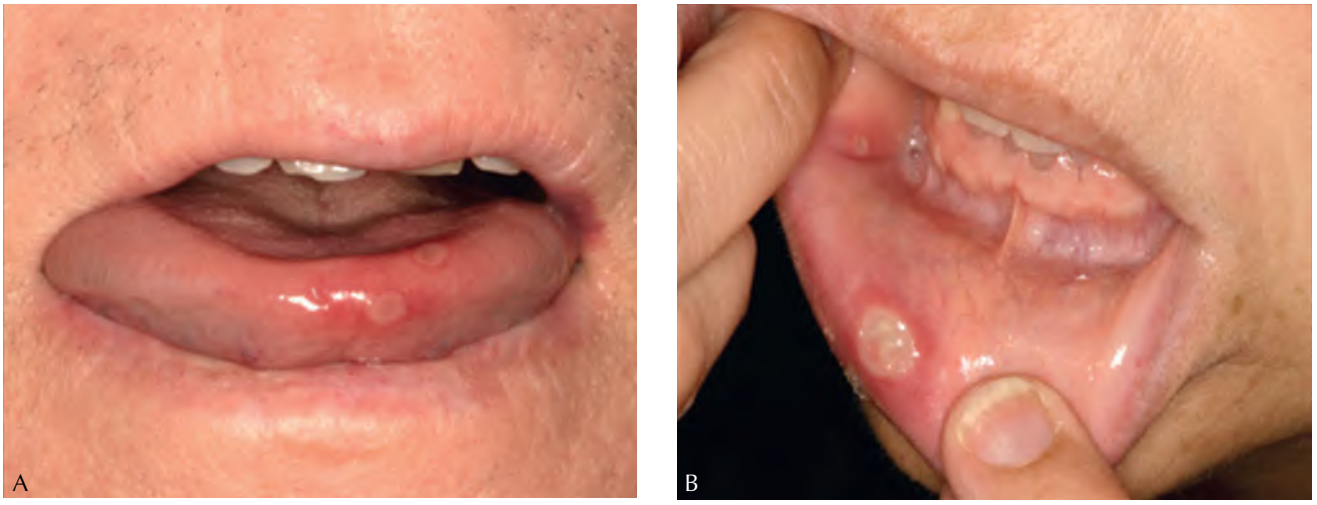

Figure 8-10 Selected mammalian target of rapamycin (mTOR) inihibitors used for treatment of cancer have caused oral mucosal lesions that clinically are uniquely distinct from oral mucositis caused by conventional cancer therapies such as chemotherapy and head and neck radiation. The oral lesions caused by targeted therapies resemble recurrent aphthous ulceration clinically and often respond to topical, intralesional or systemic corticosteroid management. This clinical phenotype is thus quite different from the traditional model of oral mucositis. Further research regarding pathobiology and optimal clinical management including prevention is needed. (A) Tongue, after patient received three 21-day cycles (63 days) of ridaforolimus. (B) Inner lips, in patient who developed mTOR inhibitor-associated stomatitis within 10 days of initiating treatment with everolimus (10 mg once daily) in combination with figitumumab. *Source:* Pilotte 2011.[72]

administration of the first cycle of the drug (a mean of 10 days has been reported (range of 4–25 days) and resolve in approximately 1 week.[4,50] It is a characteristic that the prevalence and severity are less pronounced during following cycles of targeted cancer therapy. The lesions are characterized by painful, distinct, ovoid, superficial, well-demarcated ulcerations with a central grey area surrounded by an erythematous halo and localized on the movable oral/oropharyngeal mucosa while not manifest on the keratinized mucosa of the hard palate, gingiva, or dorsum of the tongue. The pathogenesis is presumed but has not been definitively proven to be similar to recurrent aphthous stomatitis.[4,51]

Patients who develop oral mucosal ulcerations from molecularly targeted cancer therapies may be more prone to develop acneiform dermatitis and nonspecific cutaneous rashes.[4,7]

Among mucosal adverse effects, diarrhea was the most frequently reported in a meta-analysis of selected targeted cancer therapies (i.e., vascular endothelial growth factor inhibitor bevacizumab, epidermal growth factor (EGF) tyrosine kinase inhibitors gefitinib and erlotinib, the dual tyrosine kinase inhibitor lapatinib (interferes with HER2/neu and EGF receptors), multitargeted receptor tyrosine kinase inhibitor sorafenib and sunitinib, and trastuzumab which interferes with HER2/neu receptors).[52]

The clinical management strategy of mTOR inhibitor-associated stomatitis is empirically based on drugs that have been used for the prevention and treatment of aphthous stomatitis and includes topical, intralesional, or systemic corticosteroid therapy depending on severity of the oral lesions.[4]

PATIENTS UNDERGOING HEAD AND NECK RADIATION

Acute Oral Complications

Oral Mucositis

Oral mucositis induced by radiation therapy is the consequence of a complex cascade of biological events involving the epithelium and the submucosa.[6] The extent of oral mucosal damage is strongly related to the radiation dose, volume of irradiated mucosa, and fractionation regimen and is characterized by mucosal atrophy and erythema followed by ulceration and subsequently healing after completing cancer therapy. Oral mucositis is primarily affecting the buccal mucosa, lateral margins and ventral surface of the tongue, soft palate, floor of the mouth, and lips. The ulcerations are commonly colonized with bacteria contributing to the mucositis development. The first clinical signs of oral mucositis in radiation therapy are erythema, epithelial sloughing, and oral discomfort presenting by the end of the first week (days 7 to 14) of a conventional 2 Gy/day, five times a week radiation regimen. Ulceration will typically become clinical evident during the second week of radiation and increase in severity in the subsequent weeks of radiation therapy. The lesions will then usually resolve during the 4 weeks following cessation of the cancer treatment. Oral mucositis results in severe pain and the patient often requires systemic narcotics for pain relief. Oral mucositis also negatively affects nutrition, oral hygiene, and quality of life. In general, the oral lesions will heal within 2 to 4 weeks after radiation; however, some patients will develop late radiation effects of the oral mucosa characterized by epithelial atrophy, telangiectasia, loss of deeper capillary vessels, and fibrosis of the submucosa leaving the oral mucosa permanently prone to infection, in particular oral candidiasis and mechanical trauma (Figure 8-11).

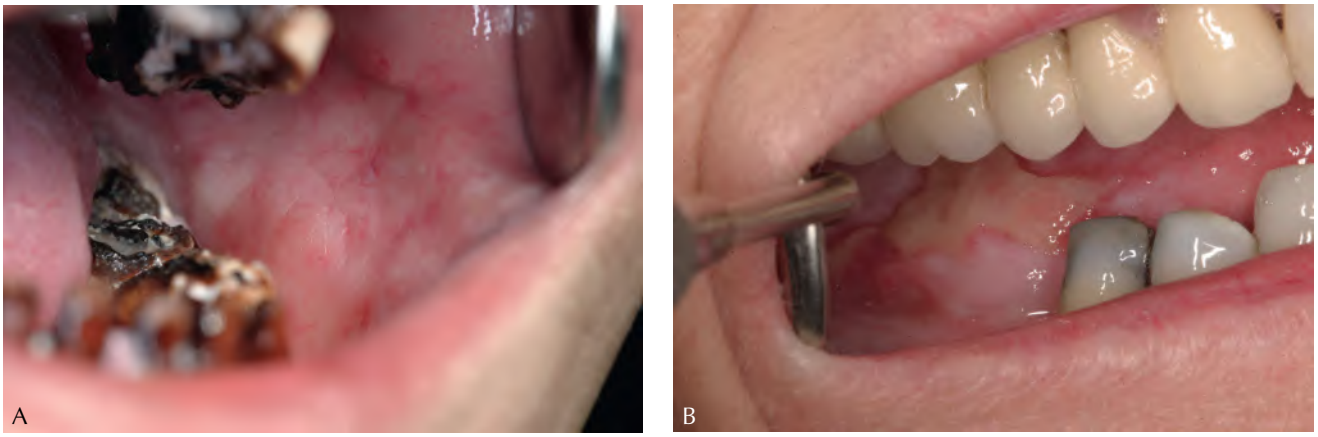

Figure 8-11 Late oral mucosal radiation sequelae. (A) Dryness, telangiectasia, and fibrosis of the left buccal mucosa with pronounced soreness. Conventional radiation therapy 1 year previously for oral cancer. The unstimulated whole saliva flow rate is 0.04 mL/min and the stimulated whole saliva flow rate is 0.16 mL/min. The patient also has rampant caries due to hyposalivation and impaired oral hygiene (complicated by oral pain and trismus). (B) Chronic ulceration of the right margin of the tongue as late radiation sequelae. Intensity-modulated radiation therapy 2 years previously for tonsil cancer on the right side. The patient's mandibular denture had to be adjusted to reduce mechanical friction in the area.

Management of oral mucositis includes oral pain control, basic oral care, prevention and treatment of infection, and nutritional support, see details of basic oral care in the previous section in this chapter Implementation of Systematic Basic Oral Care Protocols for Oncology Patients.[2] See section High-dose Chemotherapy Patients: Oral Mucositis for additional detail regarding management.

Acute and Late Oral Complications

Salivary Gland Hypofunction and Xerostomia

Radiation therapy may induce salivary gland hypofunction (decreased saliva secretion) and xerostomia (a subjective feeling of oral dryness); that is, radiation therapy in head and neck cancer involving the salivary glands within the radiation field, total body irradiation in hematopoietic stem cell transplantation, and radioactive iodine in thyroid cancer.[28] Irradiation of salivary glands in head and neck cancer patients results in a substantial decline in saliva secretion within the first week of radiation therapy with a continuous reduction that may reach scarcely measurable saliva secretion by the sixth week of treatment. A further decline may be noted up to 3 months after completion of radiation therapy (Figure 8-12). However, salivary glands may hold a potential to gradually recover within 1 to 2 years if gland-sparing radiation regimens have been applied, such as intensity-modulated radiation therapy, and if it has been achievable to keep the radiation dose to the gland tissue below thresholds of ~26 Gy to the parotid gland and ~39 Gy to the submandibular gland.[28]

Xerostomia is the most common late adverse effect of radiation therapy in head and neck cancer patients with an immense negative impact on quality of life affecting general comfort and oral functions of speech, taste, and chewing/swallowing, which may further result in inadequate food intake and difficulties with social interaction. Thus, to increase coping mechanisms, it is of great importance to the patient to be informed of the expected acute and late salivary gland physiologic changes and the timeline of late radiation sequelae, in particular to prepare the patient for the further deterioration of salivary gland function initially after the end of cancer therapy.

Management of salivary gland hypofunction and xerostomia is symptomatic by stimulation of a residual salivary gland secretory capacity or by use of water, bland rinses, or saliva substitutes, see the section on "Oral Hydration".[25,27,28] For evidence-based clinical practice guidelines for management of salivary gland hypofunction and xerostomia, see Chapter 9, "Salivary Gland Diseases". Furthermore, salivary gland hypofunction implies a high risk of dental caries, attrition, abrasion, and erosion (Figure 8-13), oral candidiasis (Figure 8-14), and increased mucosal sensitivity and risk for mucosa/mucosal trauma (Figure 8-11).

Oropharyngeal Candidiasis

Oral and oropharyngeal candidiasis are common in patients undergoing head and neck radiation with a prevalence of oral candidiasis of 37% during treatment.[13] The most common cause of oral candidiasis is *Candida albicans* with clinical presentations as: (1) erythematous candidiasis manifest as red inflamed areas of the mucosa; (2) pseudomembranous candidiasis (thrush) manifest as removable white curd-like pseudomembranes; (3) chronic hyperplastic candidiasis manifest as hyperkeratotic white patches, which cannot be removed; and (4) angular cheilitis manifest as erythema, fissuring, and ulceration of the labial commissures (Figure 8-14). Oral candidiasis is often associated with a burning mucosal sensation

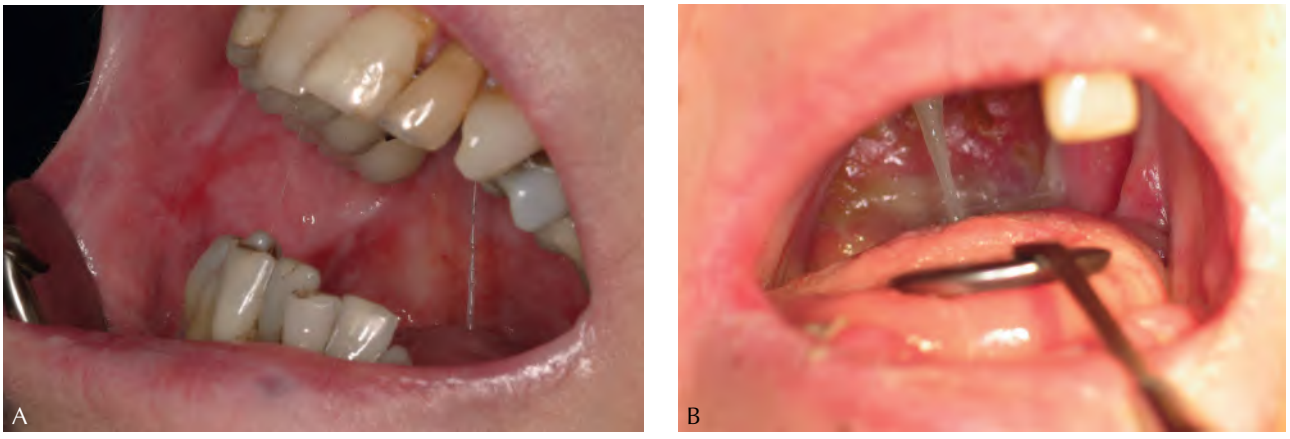

Figure 8-12 Hyposalivation and viscous saliva following radiation therapy. (A) Unilaterally irradiated for tonsil cancer 2 years previously, unstimulated whole saliva flow rate 0.01 mL/min, stimulated whole saliva flow rate 0.23 mL/min, the saliva is thick and sticky which is a hallmark of salivary gland dysfunction during and after radiation therapy. (B) Intensity-modulated radiation therapy for cancer of the left maxillary sinus, unstimulated whole saliva flow rate 0 mL/min, stimulated whole saliva flow rate 0.20 mL/min. The saliva is extremely thick and sticky and crusts of dried saliva constituents are seen at the back of the oropharynx causing immense discomfort to the patient.

Figure 8-13 Characteristic clinical manifestations of dental caries, attrition, abrasion, and erosion in patients with radiation-induced hyposalivation. (A and B) Dental caries along the cervical area of the incisors and canines. This type of lesion often spreads circumferentially in the cervical area of the tooth and may result in amputation of the tooth crown if profound carious lesions develop. (C and D) Generalized demineralization (less translucent and whitish color of the teeth) with rapid and pronounced attrition/abrasion/erosion of the incisal, occlusal, and palatinal surfaces of the teeth. (E) Complete loss of enamel and extensive demineralization of the dentine with heavy brown discoloration of the teeth. Notice the caries localization to the lower anterior teeth which are normally least prone to dental caries. (F) Complete carious destruction of the tooth crowns. The roots have been treated endodontically and left in the jaw to avoid surgical intervention and prevent osteoradionecrosis. Also note the dry lips.

Figure 8-14 Oral candidiasis following radiation therapy. For all the patients shown periodic acid-Schiff (PAS) stained smear tests were positive for Candida blastospores and hyphae. Furthermore, all the patients have radiation-induced hyposalivation and xerostomia. (A) Erythematous oral candidiasis. The dorsum of the tongue is depapillated, fissured, and with slight central erythema. The patient describes a stinging sensation from the tongue. (B) Erythematous oral candidiasis and angular cheilitis caused by *Candida albicans*. The dorsum of the tongue is depapillated, fissured, and erythematous and the corners of the mouth are erythematous, fissured, and ulcerated. The patient describes a burning sensation from the tongue. (C) Recurrent pseudomembraneous oropharyngeal candidiasis 2 years after radiation therapy for tonsil cancer. The oral mucosa is erythematous and covered with white plaques that can be scraped off. The patient suffered from dysphagia which resolved when prophylactic antifungal treatment was established.

and taste changes (e.g., metallic taste). During radiation therapy, manifestations of erythematous and pseudeomembranous candidiasis are each common. They should be considered within the differential diagnosis of oral mucositis or as a comorbidity contributing to the symptom profile of oral mucosal injury.[37,53]

In general, topical agents are considered preferable to systemic agents due to lower risk of side effects and drug interactions; however, compliance can be compromised with administration of topical agents several times a day during active cancer treatment compared to once a day administration of systemic agents. Also, studies present an inconsistent picture of the efficacy of topical agents in patients receiving cancer therapy.[13] Additional considerations of antifungal treatment decision-making in the radiation head and neck cancer population are salivary gland dysfunction and oral mucositis/chronic mucosal radiation sequelae, since administration of antifungal treatment as troches/pastilles requires saliva to dissolve and can be traumatic to a vulnerable oral mucosa. Systemic agents may be limited by their side effects and drug interactions while the emergence of resistant species is also an important concern, in particular for antifungal prophylaxis.[13,54] For further details on oral candidiasis and management guidelines, see Chapter 4 "Red and White Lesions of the Oral Mucosa."

Oral Bacterial Infections

Patients irradiated for head and neck cancer are prone to oral mucosal infection/gingivitis due to salivary gland hypofunction, trismus, oral mucositis/chronic mucosal radiation sequelae, oral pain, and compromised oral hygiene. Additionally, dental caries is a disease of infectious character and head and neck cancer patients are at high risk of rampant caries.[20] Bacterial infections involving the bone, such as periodontal infection and periapical infection, increase the risk of osteoradionecrosis (see section Osteoradionecrosis).[55]

Thus, prevention of oral bacterial infection is directed towards reducing the microflora, and dental caries should be managed by supplemental administration of high-dose fluoride; see the section Oral Decontamination. In patients irradiated for head and neck cancer and suffering from salivary gland hypofunction, the major salivary glands may become acutely infected (bacterial sialadenitis) due to retrograde bacterial colonization through the gland ducts.[56]

Oral and Perioral Viral Infections

The risk of oral and perioral reactivation or *de novo* viral infections is low in patients undergoing radiation therapy for head and neck cancer. Herpes simplex virus infection is the most common viral infection followed by other Herpes viridae; for example, varicella zoster virus, Epstein-Barr virus, and cytomegalovirus.[14,15] There is a significant increase in prevalence if treated with combined chemotherapy and radiation therapy.[14,15]

For further details on viral infections and management guidelines, see Chapter 3 "Ulcerative, Vesicular and Bullous Lesions" and Chapter 21 "Infectious Diseases."

Dysgeusia (Taste Alterations)

Dysgeusia often occur with head and neck radiation therapy and chemotherapy and can appear as hypogeusia (decreased taste sensation), dysgeusia (distorted taste sensation; e.g., bitter, metallic, sour, salty, or unpleasant) or hypergeusia (increased taste sensation).[17] Dysgeusia may onset within the first week of head and neck radiation due to a direct toxic effect on taste cells further aggravated by salivary gland hypofunction, oral infections, compromised oral hygiene, drug intake, zinc deficiency, gastrointestinal reflux, or as sequelae from cancer surgery and may not resolve until months after cancer treatment.[57,58] Some patients may experience permanent dysgeusia.[59]

Halitosis

Halitosis (oral malodor) may be due to compromised oral hygiene during cancer therapy. Further aggravating oral factors can be accumulation of food debris, oral mucositis, oral candidiasis, periodontal infection, salivary gland hypofunction, or tumor growth/tissue necrosis. Systemic causes of halitosis can be gastrointestinal disease, hepatic disease, renal disease, or upper airway/lung infections. Halitosis can be reduced by comprehensive basic oral care procedures with an emphasis on mechanical tongue rinsing, supplemented by antiseptic mouthwashes and oral malodor interventions.[60]

Late Oral Complications

Trismus

Trismus (restricted mouth opening) is frequent in patients irradiated for head and neck cancer and may severely impact food intake, speech, and compromise oral hygiene. Radiation therapy can induce fibrosis of the temporomandibular joint and oral soft tissues depending on the inclusion in the radiation field and this can be further aggravated by tumor growth into the temporomandibular joint/masticatory muscles and surgical procedures. Radiation-induced trismus can onset from the end of radiation therapy or any time (e.g., years) following cancer therapy. The appearance and severity is rather unpredictable and thus it is recommended that an attempt is made to prevent trismus with daily exercise therapy, although the evidence base for this is inconclusive.[18,61,62]

Osteoradionecrosis

Osteoradionecrosis (ORN) is defined as bone death secondary to radiotherapy and is characterized by a nonhealing area of exposed bone.[63] Patients who have received high-dose radiation therapy to the head and neck are at lifelong risk for the lesion, the risk being directly related to the radiation

dose to the bone, with an overall risk of approximately 15% (Figure 8-15). ORN most frequently involves the mandible compared with the maxilla. Clinical manifestations include pain, sensory disturbances, infection, and fistulae.

Figure 8-15 Osteoradionecrosis of the left mandible. (A) Root tips were present several months after completion of high-dose external beam radiation to the left mandible. (B) Facial skin lesion exhibiting purulent drainage. (C) Panoramic radiograph demonstrating findings consistent with extensive left mandibular bone destruction. *Source:* Photos courtesy of L. Assael.

Management of ORN is based on prevention that begins with comprehensive oral and dental care before radiation therapy and close follow-up postradiation. If smaller lesions form, management is conservative with limited surgical intervention and antibiotics, while advanced or treatment refractory lesions will need large segments of necrotic bone removed. The cure rate associated with minimally extensive ORN by conservative therapy is approximately 50%, while the cure rate of surgical approaches when conservative therapy has failed is approximately 40%.[63]

Hyperbaric oxygen therapy has been historically recommended to prevent or treat ORN, but clinical efficacy is inconclusive. Hyperbaric oxygen therapy is thus not currently routinely used at many centers.[64]

THE ONCOLOGY PATIENT RECEIVING BONE-MODIFYING AGENTS

Patients with skeletal metastatic disease (e.g., multiple myeloma) may benefit from use of a bone-modifying agent (Figure 8-16; Figure 8-17).[23,65] There are three different classes of these agents, all designed to reduce of skeletal bone fracture:

Figure 8-16 Medication-related osteonecrosis of the jaw (MRONJ). *Source:* Courtesy of Dr. Eduardo Fregnani.

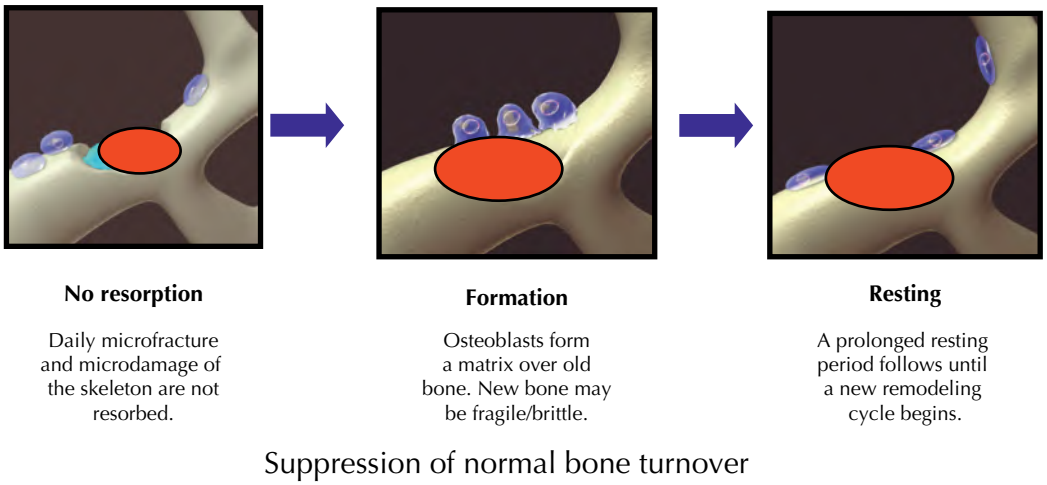

Figure 8-17 Inhibition of bone remodeling by bisphosphonates. *Source:* Photo courtesy of C. Migliorati.

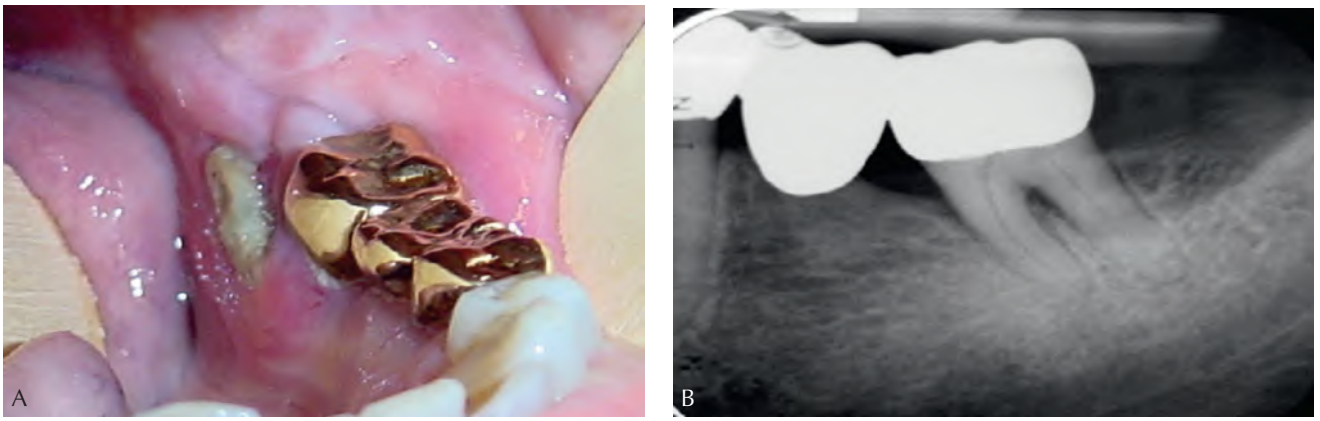

Figure 8-18 Osteonecrosis of the jaw in cancer patient receiving a bone-modifying agent. (A) Exposed bone on lingual aspect of posterior left mandible. (B) Periapical radiograph demonstrating evidence of diffuse osseous destruction. *Source:* Photos courtesy of C. Migliorati.

- bisphosphonates
- denosumab
- antiangiogenics.

Medication-related osteonecrosis of the jaw (MRONJ) can develop in a small subset of these patients (Figure 8-18; Table 8-7). Despite differences in mechanism of action across these three classes, risk for development of MRONJ is comparable (approx. 1–2%) in the oncology population. Documentation of the MRONJ lesion in a patient is established when all three of the following criteria are met:[23]

- current or previous treatment with a bone-modifying agent or angiogenic inhibitor;
- exposed bone or bone that can be probed through an intraoral or extraoral fistula in the maxillofacial region and that has persisted for longer than eight weeks; and
- no history of radiation therapy to the jaws or metastatic disease to the jaws.

It is important to note, however, that clinically exposed oral bone may not be evident in the early stage of MRONJ.

Although actual incidence in the clinical setting is low, resolution of the lesion can be protracted and associated with considerable oral morbidity in some patients. Patients about to be placed on a long-term protocol of one of these agents should undergo oral evaluation and dental treatment of lesions that may in the future contribute to risk for development of MRONJ.[66] Examples of such pre-existing oral lesions include advanced dental caries, moderate–severe periodontal disease, and periradicular lesions. These lesions should ideally be eliminated prior to initiation of the bone-modifying regimen.

Treatment for MRONJ depends upon staging of the lesion (Table 8-8).[23,65,67] Current literature suggests that conservative, nonaggressive therapy may be most beneficial in management of early stage MRONJ. As with any dental intervention, it is essential that thorough discussion and informed consent documentation be performed with the patient prior to initiating MRONJ management (Table 8-9).

Table 8-7 Key differences between bisphosphonates and denosumab as utilized in oncology practice.

Medications	Action	Medical Use
Bisphosphonates Alendronate Risedronate Pamidronate Zoledronic Acid	Osteoclast inhibitor via mevalonate pathway	Osteoporosis Bone metastasis Multiple myeloma Antitumor
Denosumab	Receptor activator of nuclear factor kappa-beta ligand (RANK-RANKL) pathway inhibitor	Osteoporosis Bone metastasis
Antiangiogenics Bevacizumab Sunitinib Sorafenib	Vascular Endothelial Growth Factor (VEGF) inhibitors	Advanced tumors

Source: C. Migliorati.

Table 8-8 American association of oral and maxillofacial surgeons staging criteria for osteonecrosis of the jaw.

Category	Criteria
At risk	Clinically normal, asymptomatic patients who have received antiresorptive therapy
Stage 0	No clinical evidence of exposed bone, but presence of non-specific symptoms or clinical and/or radiographic abnormalities
Stage 1	Exposed and necrotic bone in patients who are asymptomatic and have no evidence of infection
Stage 2	Exposed and necrotic bone associated with pain and/or signs of infection in the region of bone exposure with or without purulent drainage
Stage 3	Exposed and necrotic bone in patients with pain, infection, and at least one of the following: • exposure and necrosis extending beyond the local alveolar tissues; • radiographic evidence of osteolysis extending to the inferior mandibular • border or the maxillary sinus floor; • pathologic fracture; • oro-antral, oro-nasal or oro-cutaneous communication

Source: Ruggiero et al.[67].

Table 8-9 Treatment of medication-related osteonecrosis of the jaw (MRONJ).

• Patients with MRONJ should be managed by professionals with experience in managing such lesions.
• Use of systemic antibiotics is recommended for patients with active infection and or clinical paresthesia.
• Home oral hygiene maintenance is essential; utilize oral rinses with chlorhexidine as needed.
• Conservative protocol, with periodic clinical evaluation of the progress of disease in MRONJ stages 1 and 2
• Pain management as needed
• Surgical intervention in advanced cases (stage 3, American Association of Oral and Maxillofacial Surgeons Staging Criteria) and in non-responding lesions

Salivary Gland Diseases

Leah M. Bowers, DMD
Arjan Vissink, DDS, MD, PhD
Michael T. Brennan, DDS, MHS, FDS, RCSEd

INTRODUCTION

The most common presenting complaints of a patient with salivary gland disease are oral dryness (xerostomia) or a glandular swelling or mass. This chapter discusses how to evaluate a patient with these and other signs and symptoms suggestive of salivary gland disease, including clinical examination techniques and imaging. Diseases, disorders, and some neoplasms affecting the salivary glands are introduced as well as management of xerostomia, hyposalivation, and sialorrhea.

Optimal function of the salivary glands results in the production of adequate amounts of saliva: a complex and unique biologic fluid with myriad functions. The importance of saliva in maintaining oral, dental, and general health cannot be understated. It provides lubrication to the oral and oropharyngeal mucosae, protects dental and mucosal surfaces, facilitates speech, mastication, and swallowing, and is involved in taste and digestion, among other functions. Hyposalivation, or even the perception of a lack of saliva, can have a significant impact on quality of life. Quantified salivary hypofunction or a significant change in the composition of saliva can increase the risk of oral diseases such as dental caries, dental erosion, and fungal infections.

SALIVARY GLAND ANATOMY AND PHYSIOLOGY

Saliva is produced by three paired major salivary glands (the parotid, submandibular, and sublingual glands), and numerous minor salivary glands (Figure 9-1). The parotid glands, the largest of the major salivary glands, are located on the lateral aspects of the face overlying the posterior surface of the

Burket's Oral Medicine, Thirteenth Edition. Edited by Michael Glick, Martin S. Greenberg, Peter B. Lockhart, and Stephen J. Challacombe.

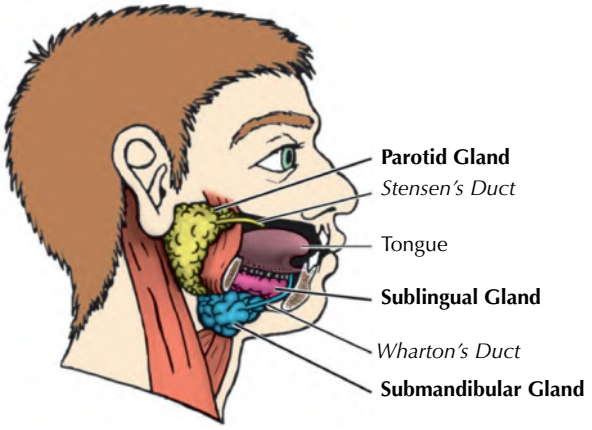

Figure 9-1 Diagrammatic representation of the major salivary glands and associated ducts.

mandible, anteroinferiorly to the auricle. The parotid gland is often described as being divided into superficial and deep lobes by the intraparotid facial nerve and its branches. Encapsulation of lymphoid tissue during embryogenesis results in the presence of intraglandular lymphoid tissue; a feature not seen in the other major salivary glands and one that results in a predilection for development of parotid gland lymphomas, most notably in patients with Sjögren's syndrome.

The submandibular glands are a pair of organs shaped like flattened hooks that reside in the submandibular triangle. Although they are often described as being a pair of glands, the two parts are contiguous forming a "U" shape enveloping the posterior border of the mylohyoid muscle.

Each of the paired sublingual glands is composed of a major sublingual gland and approximately 8 to 30 minor sublingual glands. The glands lie on opposite sides of the lingual frenulum, superior to the mylohyoid muscle. Bimanual palpation, using one hand intraorally on the floor of the mouth and the other hand extraorally below the mandible, is necessary to evaluate these glands adequately.

There are an estimated 450 to 1000 minor salivary glands distributed primarily in the oral cavity and oropharynx, but they may be found anywhere along the aerodigestive tract as well as in the sinonasal cavity and middle ear. The minor salivary glands are named for the sites they occupy (e.g., labial, buccal, lingual, palatal, retromolar) and contribute approximately 8% to 10% of the total volume of saliva.[1]

There are also three sets of minor salivary glands of the oral tongue: the glands of Weber, found along the lateral borders of the tongue; the glands of von Ebner, surrounding the circumvallate papillae; and the glands of Blandin and Nuhn (also known as the anterior lingual glands), found in the musculature of the anterior ventral tongue. Distinctive mucoceles may arise in the glands of Blandin and Nuhn, highlighting their unique anatomic location.

Salivary glands can be classified based on the dominant saliva-producing acinar cell type: serous, mucous, or a mix of serous and mucous cells. Serous cells produce a watery, enzyme-rich saliva, while mucous cells secrete a more viscous fluid with plentiful salivary glycoproteins known as mucins. Salivary mucins expressed from the submandibular and minor salivary glands act as lubricants and help to form a selectively permeable barrier of mucosal membranes. Their presence helps maintain tissue hydration and an overall sense of comfort.

The parotid gland is composed primarily of serous cells; the submandibular gland is a mix of mucous and serous types, and the sublingual and minor salivary glands are of the mucous type. The glands of Weber are mucus-secreting, the glands of von Ebner are purely serous, and the glands of Blandin and Nuhn are of mixed type.

Parotid gland saliva is secreted through Stensen's ducts which emerge from the glands, traverse the buccal fat pad superficial to the masseter muscles, and pierce the buccinator muscles to open at papillae in the vicinity of the maxillary first or second molars (Figure 9-2). Stensen's duct is, on average, between 4 and 6 cm in length and has a diameter between 2.0 and 2.5 mm with the narrowest portions typically appearing at the papilla and where it pierces the buccinator.[2] The masseteric bend, where the duct curves around the anterior border of the masseter, may present a navigational challenge; for example, during an endoscopic procedure.

Saliva from each submandibular gland is secreted through a submandibular (Wharton's) duct. Each Wharton's duct is approximately 5 cm in length and between 1 and 3 mm in diameter. Along its course, two bends are encountered; a typically obtuse angle is formed as the duct curves around the mylohyoid muscle, resulting in a propensity for stone formation and obstructive kinks.[3] A second bend occurs adjacent to the duct punctum just before the duct opens into the oral cavity at the sublingual caruncles on either side of the lingual frenulum (Figure 9-3). As Wharton's duct

Figure 9-2 Arrow indicating opening of Stensen's duct on the left buccal mucosa.

Figure 9-3 Arrows indicating openings of Wharton's ducts on the floor of mouth.

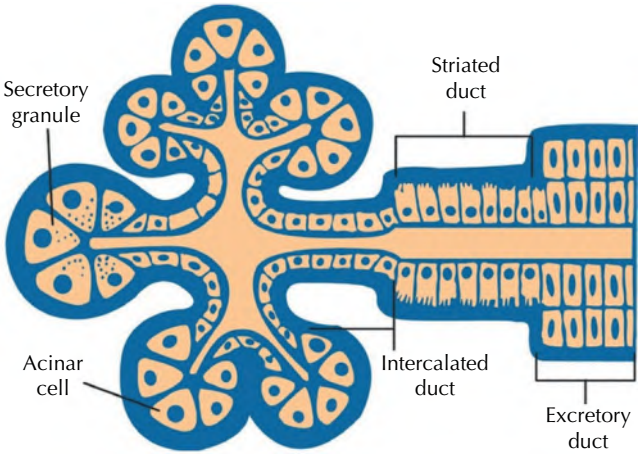

Figure 9-4 Diagrammatic representation of salivary gland acini and ducts.

traverses the glandular parenchyma, it demonstrates an abrupt transition in diameter, in contrast to that of the parotid gland which shows a more gradual decrease.

Saliva from the anterior, major portion of each sublingual gland drains through the sublingual (Bartholin's) duct into the submandibular (Wharton's) duct, while saliva from the smaller, posterior portion of the sublingual glands drains directly onto the floor of the mouth via multiple smaller ducts of Rivinus. The minor salivary glands secrete their mucinous product onto the mucosa through short ducts. A minor salivary gland may share an excretory duct with an adjacent minor salivary gland or may have a duct of its own.

Histologically, the major salivary glands are composed of acinar (secretory cells) and ductal cells arranged like a cluster of grapes on a stem. The clustered acinar cells (the "grapes") make up the secretory end pieces, while the ductal cells (the "stems") form an extensively branching system that modifies and transports the saliva from the acini into the oral cavity. There are three types of ductal cells: intercalated, striated, and interlobular (Figure 9-4).

Production of saliva involves water transport from the serum into the terminal portion of the acinar cell followed by selective reabsorption of sodium and chloride and the secretion of potassium and bicarbonate to produce a hypotonic solution. Upon stimulation of salivary flow, sodium, chloride, and bicarbonate concentrations increase while potassium decreases via ion exchange in the ductal system. Salivary proteins are contributed mostly from the acinar cells.[4]

Whole saliva (WS; the mixed fluid contents of the oral cavity) is composed of more than 99% water and less than 1% proteins and salts. It is hypotonic relative to blood plasma and contains secretions from the major and minor salivary glands along with variable amounts of gingival crevicular fluid, microorganisms, food debris, exfoliated mucosal cells, and mucous. Salivary proteins are numerous and serve a variety of functions including digestion (e.g., α-amylase, lipase, proteinases, DNase and RNase), and protection (e.g., immunoglobulins, lysozyme, lactoferrin, lactoperoxidase, and mucins).

Normal daily production of WS ranges from 0.5 to 1.5 L. The composition of WS follows a circadian rhythm: at night and in the resting state, the submandibular and sublingual glands are the main contributors with some saliva being produced by the minor salivary glands.[5] At stimulation, the parotid and submandibular glands are responsible for the majority of saliva production with minor gland secretions accounting for less than 10% of the volume. Stimulation of salivation typically occurs between 10% and 20% of the day, influenced by olfactory, gustatory, and mechanical stimuli.

The secretion of salivary fluid and salivary proteins is controlled by both the sympathetic and parasympathetic subsystems of the autonomic nervous system. Stimulus for fluid secretion is transmitted via muscarinic-cholinergic receptors, which release acetylcholine, inducing the secretion of saliva by acinar cells. The stimulus for salivary protein secretion is transmitted via sympathetic β-adrenergic receptors that release noradrenaline.[6]

Electrolyte concentrations and volume of saliva may be influenced by a number of factors including circadian rhythm, various stimuli, and number of functional secretory units. Factors that may increase salivary flow include taste and olfactory stimuli, mechanical stimulation (chewing), pain, hormonal changes, aggression, and sympathomimetic and parasympathomimetic drugs. Menopause-related hormonal changes, stress, antiadrenergic and anticholinergic drugs will decrease salivary flow rate.[7] A loss of acini, seen in a number of clinical conditions, particularly in Sjögren's syndrome, also results in decreased saliva production.

Whether salivary flow diminishes with normal aging has been the subject of much debate. Many studies suggest age-related changes in either volume or salivary constituents, while others have found no related changes. Postmortem histologic studies show that with aging, parenchymal tissue of the salivary glands undergo replacement with fat, connective tissue, and oncocytes. Acinar atrophy, ductal dilatation, and inflammatory infiltration have also been observed with aging in normal subjects.[8]

In reports that assert that in healthy, unmedicated adults, salivary production remains stable with age despite the loss of acinar cells, it is hypothesized that a secretory reserve capacity exists and that disease, surgery, radiotherapy, and chemotherapy, for example, tax this reserve resulting in compromised function.[9,10] A gradual, age-related loss of this reserve capacity may explain the greater magnitude of effect from conditions adversely affecting saliva production in older individuals compared to their younger counterparts.

DIAGNOSIS OF THE PATIENT WITH SALIVARY GLAND DISEASE

The most common complaint associated with salivary gland disease is xerostomia, denoting subjective mouth dryness. Hyposalivation refers to a quantified reduction in salivary flow rate which may or may not be accompanied by xerostomia. Similarly, xerostomia may or may not be associated with hyposalivation and can be the result of a change in salivary composition. The term "salivary gland dysfunction" is commonly used to indicate decreased salivary flow (hyposalivation) or other quantifiable alteration in salivary performance. Hypersalivation (sialorrhea or ptyalism) refers to an increase in production of saliva and/or a decrease in oral clearance of saliva.

Since the causes of xerostomia and salivary gland dysfunction are numerous, a systematic approach to establish a diagnosis is necessary. Salivary gland dysfunction may be the result of a systemic disorder and therefore early recognition and accurate diagnosis may be of great benefit to an individual's general health and well-being.

Where salivary gland dysfunction is suspected, a thorough examination to identify the cause of the condition is warranted. Patients should be queried regarding the severity and duration of their complaint, inciting events, whether the condition is progressive or intermittent, known relieving and exacerbating factors, possible circadian associations, and effect on quality of life. Patients should also be asked about dryness affecting other areas, especially the eyes, nose, and other mucosal surfaces.

An initial evaluation should also include a detailed inquiry into associated symptoms, medical and dental history, medications, and dietary habits. A head/neck/oral examination and an assessment of salivary function involving quantification of unstimulated and stimulated salivary flow should be performed (see section: Sialometry). Additional techniques that may be indicated are analysis of salivary constituents, imaging, biopsy, and clinical laboratory assessment, some of which are described below in greater detail.

Some causes of salivary gland hypofunction include xerogenic medications (including many antidepressants, anticholinergics, antispasmodics, antihistamines, antihypertensives, sedatives, diuretics, and bronchodilators) and other xerogenic agents (e.g., caffeine, alcohol, cigarette smoking), head and neck radiation (i.e., external and internal beam radiation therapy), systemic disease (e.g., diabetes mellitus), salivary gland masses, psychological conditions (e.g., depression, anxiety), malnutrition (e.g., bulimia, dehydration), and autoimmune disease (e.g., Sjögren's syndrome).[11] A list of some differential diagnoses for salivary gland dysfunction is outlined in Table 9-1.

Table 9-1 Partial list of differential diagnoses for salivary gland dysfunction.

Autoimmune
Chronic graft-versus-host disease
Sjögren's syndrome
Developmental
Salivary gland aplasia and hypoplasia
Iatrogenic
Botulinum toxin injection
External beam radiation
Internal radiation (e.g., Radioactive iodine [^{131}I])
Postsurgical (e.g., adenectomy, ductal ligation)
IgG4-related disease (i.e., Küttner tumor; Mikulicz's disease)
Infectious
Bacterial: *Staphylococcus aureus,* MRSA, *Haemophilus influenzae*
Viral: CMV, HIV, hepatitis C, paramyxovirus
Inflammatory
Granulomatous: Tuberculosis, sarcoidosis
Medication-associated
Neoplastic
Benign and malignant salivary gland tumors
Non-neoplastic
Sialolithiasis
Systemic
Anorexia nervosa, chronic alcoholism, diabetes mellitus,

Abbreviations: MRSA, methicillin-resistant *Staphylococcus aureus*; CMV, cytomegalovirus; HIV, human immunodeficiency virus

Symptoms of Salivary Gland Dysfunction

Symptoms of salivary gland hypofunction are related to decreased fluid in the oral cavity affecting mucosal hydration and oral functions. Patients may complain of dryness of all the oral mucosal surfaces, including the lips and throat, and difficulty chewing, swallowing, and speaking due to dryness. Other associated complaints may include oral pain, an oral burning sensation, chronic sore throat, and pain on swallowing (odynophagia). The mucosa may be sensitive to spicy or coarse foods limiting the patient's enjoyment of meals, which may compromise nutrition.[12]

Patients experiencing chronic salivary gland dysfunction may carry water with them at all times and drink frequently in an attempt to relieve oral dryness. However, as wettability of the oral mucosa and enamel by water is poor, relief of xerostomia is usually very temporary.[13] Patients may describe drinking copious amounts of water throughout the day which may effectively wash away saliva as well as disrupt sleep due to nocturia.

A complaint of oral dryness (xerostomia) does not always correlate with a quantified decrease in salivary function, although related specific symptoms may.[14] For example, complaints of oral dryness while eating, the need to sip liquids in order to swallow food, or difficulties in swallowing dry foods (i.e., activities that rely on stimulated salivary function), have all been highly correlated with measurable decreases in secretory capacity. In contrast, complaints of oral dryness at night or upon awakening have not been consistently found to be associated with reduced salivary function. Furthermore, xerostomia, particularly in the elderly, may be due to an impaired or altered perception of oral moisture or change in the composition of saliva rather than due to true hyposalivation.

Medical History

A thorough review of the patient's medical history may reveal medical conditions, both past and present, medications, or procedures associated with salivary gland dysfunction leading to a direct diagnosis (e.g., a patient who received radiotherapy for a head and neck malignancy or an individual taking a tricyclic antidepressant). Medications can have a number of adverse effects on salivary gland function (see section: Medication-Induced Salivary Dysfunction). The most well-known of these are hyposalivation and xerostomia but medications may also produce objective or subjective sialorrhea. More than 400 drugs with xerogenic potential have been identified including antidepressants, anticholinergics, antispasmodics, antihistamines, antihypertensives, sedatives, and bronchodilators, and attempts have been made to compile a comprehensive list of medications with documented effects on salivary gland function.[15]

A thorough review of all the patient's medications (including over-the-counter medications, supplements, and herbal preparations) must be performed. Often, upon further inquiry, a temporal association of symptom onset with a culpable agent may be made. Some side effects, however, including xerostomia and hyposalivation, may not appear until years after initiation of treatment, upon increase in dose, or other change in medication regimen. Furthermore, it is possible that certain drugs taken individually do not exert a xerogenic effect, but xerostomia arises as a result of a drug–drug interaction.[16] When history alone does not offer an obvious diagnosis, further exploration of the symptomatic complaint should be undertaken. For example, a report of eye, throat, nasal, skin, or vaginal dryness, in addition to xerostomia and fatigue, may be an indication of the presence of a systemic condition, such as Sjögren's syndrome.

Clinical Examination

Signs of salivary gland hypofunction may affect several areas of the oral cavity and mouth. The lips are often dry with cracking, peeling, and atrophy; the buccal mucosa may be pale and corrugated; and the dorsal tongue may appear smooth, erythematous, and depapillated, or fissured.

In the absence of the buffering capacity usually afforded by saliva, there is often an increase in dental caries and erosive lesions. These lesions often affect root surfaces and cusp tips of teeth: areas usually resistant to decay. The decay may be progressive, even where good oral hygiene is maintained, and recurrent decay is common. An increased accumulation of food debris and plaque may occur in interproximal areas due to a lack of cleansing salivary flow. Patients with hyposalivation, therefore, may have increased plaque indices and bleeding on probing scores.[17]

Two additional indicators of oral dryness are the "lipstick" and "tongue blade" signs. The former denotes the presence of lipstick or shed epithelial cells on the labial surfaces of the anterior maxillary teeth. A positive "tongue blade" sign results when a tongue blade, pressed gently and then lifted away from the buccal mucosa, adheres to the tissue. Both signs suggest that the mucosa is not sufficiently moisturized by saliva.

Oral candidiasis is often associated with salivary gland hypofunction and may be due to the effect of hyposalivation on the oral microbiome. The erythematous form of candidiasis (red patches of mucosa) is more prevalent in the presence of hyposalivation than the more familiar white, curd-like pseudomembranous (thrush) form (Figure 9-5). Angular cheilitis (persistent cracking or fissuring of the oral commissures) may also be present. Clinical examination should include noting the presence of the stigmata of an oral colonization and may include taking a smear or buccal swab for diagnosis.

Figure 9-5 Erythematous candidiasis of the hard palate in a patient with salivary gland hypofunction.

Salivary gland dysfunction can present as enlargement of the salivary glands due to inflammatory, infectious, neoplastic, or other conditions. Inspection and palpation of the normal salivary gland should be painless and without detection of masses. The consistency of the glands should be slightly rubbery but not hard. Enlarged glands that are painful on palpation are indicative of infection, acute inflammation, or tumor. Neoplasms of the salivary glands, either benign or malignant, usually present as painless masses but may present with dull pain suggestive of an inflammatory-based process.

The major salivary glands should also be massaged to express saliva from the main excretory ducts. Normally, saliva can be easily expressed from each major gland orifice by gently compressing the glands and drawing pressure toward the orifice. The expressed saliva should be colorless, transparent, and of sufficient volume. In health, saliva should be seen to pool on the floor of the mouth during examination. Viscous or scant secretions suggest chronically reduced function. Saliva that appears frothy, ropy, or stringy also indicates hyposalivation. A cloudy exudate may be a sign of infection, although some patients with very low salivary function will have hazy, flocculated secretions that are sterile. In these cases, mucoid accretions and clumped epithelial cells result in a cloudy appearance. The exudate should be cultured if it does not appear clinically normal, particularly in the case of an enlarged gland.

Sialometry

Sialometry refers to the measurement of salivary flow. Sialometric techniques and specialized devices can be used to ascertain the production rate of whole saliva, saliva from individual major salivary glands, and in the stimulated and unstimulated state. Although no single sialometric technique is perfect, these methods allow for objective assessment of salivary flow where salivary gland dysfunction is suspected.

Since the resting, unstimulated state of the salivary glands is predominant, it has a greater influence on perceived oral comfort and health of the tissues. Normal subjects typically report mouth dryness when unstimulated whole salivary flow is reduced by approximately 50% or more.[18] Examination of stimulated salivary flow allows for assessment of the relative functional capacity of the salivary glands and can determine whether sialogogues are likely to be of benefit. It is therefore important to assess both unstimulated and stimulated salivary flow when investigating a complaint of xerostomia.

To prepare for sialometry, the patient is instructed to refrain from eating, drinking, smoking, chewing gum, and oral hygiene practices or any other oral stimulation for at least 90 minutes prior to the assay. Excessive movement and talking is discouraged during the testing period. At least 10 minutes before the test begins, the patient should rinse the mouth gently with water to remove debris.

The main methods of whole saliva collection are the passive and active drainage methods, suction, and absorption methods. In the passive drainage method, saliva is allowed to passively flow from the oral cavity into a pre-weighed graduated container (Figure 9-6). This method is reproducible and reliable, but is vulnerable to inaccuracy if there is significant evaporation of saliva. The active drainage method requires the patient to allow saliva to accumulate in the mouth and expectorate into a pre-weighed tube, usually every 60 seconds for 5–15 minutes. This method is also reproducible and reliable but is susceptible to inaccuracy due to saliva evaporation and stimulation of salivary flow by the act of spitting.

In sialometric methods employing suction, saliva pooling at the floor of the mouth is suctioned into a pre-weighed graduated container. The advantage of this technique is that it does not rely on patient collaboration. The vacuuming of saliva during the assay, however, may act as a stimulus for salivary flow.

Absorption sialometric methods involve placing a pre-weighed absorbent swab or roll into the patient's mouth for a set period of time after which it is re-weighed. This technique is potentially portable to outpatient clinics and does not require specialized equipment. It is not considered as reliable as the aforementioned methods, however. The absorbent material may act as a stimulus for salivary flow and this method cannot be used to determine the constituents of saliva as the concentration of some salivary components may be altered due to the interaction of saliva with the absorbent material.[19]

Figure 9-6 Patient demonstrating the active drainage method of whole saliva collection by spitting into a pre-weighed graduated container.

With respect to assessing stimulated salivary flow, the type of stimulus will influence how the glands are affected. Mechanical stimulation (chewing) results in a marked response of the parotid glands while a gustatory stimulus activates all three pairs of major salivary glands.[19] Mechanical stimulation may be elicited by instructing the patient to chew a piece of paraffin wax, silicone, or unflavored gum base at a controlled rate (usually 60 times per minute, paced using a metronome). Gustatory stimulation may be provoked by application of a 2% citric acid solution to the lateral borders of the tongue at timed intervals. This stimulation technique, often used in a research setting, should not be used where analysis of whole saliva is required but can be used when assessing parotid gland saliva via the use of Lashley cups, for example (see below).

Using specific apparatuses, it is possible to collect saliva from the right or left parotid or submandibular/sublingual glands. Isolation of saliva from either the submandibular or sublingual glands is not possible as they share a common duct. Quantitative and qualitative analyses may reveal changes such as selective hyposecretion or changes in electrolyte and protein (enzyme) levels, such as observed in Sjögren's syndrome. Collection of saliva from the parotid glands can be achieved using Carlson–Crittenden collectors

Figure 9-7 Patient with Carlson–Crittenden collectors in place undergoing collection of parotid gland saliva.

or Lashley cups placed over Stensen's duct orifices and held in place with gentle suction (Figure 9-7). Collection of saliva from the submandibular/sublingual glands may be accomplished using a Wolff collector or Schneyer apparatus placed over the opening of Wharton's duct or by using an alginate-held collector called a segregator.[20]

Flow rates are determined gravimetrically in milliliters per minute, assuming that the specific gravity of saliva is 1 (i.e., 1 mL of saliva is equivalent to 1 g). Samples to be retained for compositional analysis should be collected on ice and frozen until tested. Flow rates may be affected by many factors such as patient position, hormonal status, hydration status, diurnal and seasonal variation, and time since stimulation. Regardless of the technique chosen, it is important to use a well-defined, standardized, and clearly documented procedure which allows for meaningful comparisons between individuals and for repeat measurement in an individual over time.

It is difficult to define absolute "normal" values for salivary output due to great interindividual variability and, consequently, a large range of normal values exists. About 0.3–0.4 mL/min for unstimulated flow and 1.5–2.0 mL/min for stimulated flow are considered normal. Unstimulated whole saliva flow rates of < 0.1 mL/min and stimulated whole saliva flow rates of < 0.7 mL/min are abnormally low and indicative of marked salivary gland hypofunction.[21] Higher levels of output do not guarantee that function is normal, however, as they may represent marked hypofunction for some individuals. Therefore, these stated values represent a lower limit of normal and should serve only as a guide for the clinician.

Sialochemistry

Normal saliva is a colorless, transparent fluid with a pH between 6 and 7. It is composed of approximately 99% water

with inorganic ions of, amongst others, sodium, chloride, calcium, potassium, bicarbonate (HCO_3^-), phosphate (i.e., dihydrogen phosphate, $H_2PO_4^-$), fluorine (i.e., fluoride, F^-), iodine (i.e., iodide, I^-), magnesium, and thiocyanate (SCN^-). Bicarbonate ions buffer saliva, while calcium and phosphate ions neutralize acids detrimental to tooth structure and contribute to remineralization of the tooth surface.

The organic components of saliva include urea, ammonia, uric acid, glucose, cholesterol, fatty acids, lipids, amino acids, steroid hormones, and proteins. Many of the constituent proteins such as mucins, amylases, agglutinins, lactoferrin, and secretory IgA play a role in protection of the oral tissues.[22] The proline-rich proteins (PRPs), another group of protective proteins, are amongst the most prevalent group of proteins in saliva accounting for 70% of all salivary proteins in humans.[23] PRPs are antimicrobial and contribute to lubrication of oral surfaces, formation of the salivary pellicle, and tooth mineralization.[24]

When investigating a complaint of xerostomia, it is important to recognize that changes in salivary composition may be as important as a reduction in salivary output. That is, demonstration of apparently adequate salivary flow alone is not a guarantee of normal salivary gland function. While changes in saliva chemistries have been associated with a variety of salivary gland disorders as well as the sequela of radiation therapy, most alterations are changes in electrolytes related to reduced gland function as a result of damaged parenchyma, reduced salivary secretion, or a combination of both, rather than a specific disorder. Therefore, most salivary constituent changes are nonspecific diagnostically and have minimal utility in determining the cause of the salivary gland dysfunction.

An example of how systemic disease may affect sialochemistry is in patients with renal failure. These patients often develop high levels of salivary urea because of reduced renal clearance. Salivary urea is converted into ammonia and CO_2 by plaque bacteria resulting in an increase in plaque pH which can cause supersaturation and precipitation of the calcium phosphate species hydroxyapatite, dicalcium phosphate dihydrate (brushite), β-tricalcium phosphate (whitlockite), and octacalcium phosphate. Consequently, these patients have a tendency to develop greater amounts of calculus. Similarly, in patients who are exclusively tube fed, with no oral consumption of fermentable carbohydrates, plaque pH tends to remain high, favoring supersaturation of the aforementioned calcium phosphates leading to a greater propensity for calculus formation.[25]

Salivary Diagnostics

Saliva is an important medium in disease detection and can provide information about both local and systemic health. The use of saliva in diagnostics has many advantages over blood, for example, including relative ease of collection with no requirements for special equipment or training, noninvasiveness, and cost-effectiveness for screening large populations.[22]

Salivary diagnostics can allow for monitoring of hormone levels and other endocrine functions through the use of dynamics tests (e.g., dexamethasone suppression tests), determining the concentration and metabolism of hormones used as drugs (e.g., hormone replacement therapy), and in determining the free fraction of many hormones. Saliva can be used to help in diagnosis and monitoring of a number of systemic conditions, including Sjögren's syndrome, for screening for drugs of abuse such as alcohol, cocaine, and MDMA (3,4-methylenedioxy-methamphetamine), and for the presence of viral infection (e.g., HIV, hepatitis C, and human papilloma virus).

Established tests for the detection of antibodies to HIV-1 and HIV-2 in saliva, such as the Food and Drug Administration [FDA]-approved OraQuick ADVANCE Rapid HIV-1/2 Antibody Test (OraSure Technologies, Bethlehem, PA), provide for rapid, convenient, and relatively inexpensive screening. Other saliva-based assays can detect and quantify specific periodontal pathogens and high-risk human papilloma viruses (e.g., MyPerioPath® and OraRisk HPV®, OralDNA Labs, Eden Prairie, MN).

Saliva can serve as a source of biomaterial for DNA extraction and screening for the presence of biomarkers (objectively measurable markers indicating presence of a disease, condition, or susceptibility) which may be used in diagnosis, staging, prognosis, and to indicate response to treatment. Using saliva for detection of disease biomarkers presents many advantages. Apart from being readily available and easy to collect, some disease-discriminating biomarkers are present only in saliva or are found at a greater concentration in saliva compared to other biofluids.[26]

At present, various salivary biomarkers have been proposed and few have shown promise. MMP-8 (matrix metalloproteinase-8), for example, has been proposed as a salivary biomarker for diagnosis and prediction for progression of periodontal disease. Given the complex nature of disease, however, it is unlikely that any single biomarker will be both sufficiently sensitive and specific. In future, biomarkers will likely be used in combination with other data as in the "precision medicine" model where genetic, genomic, environmental, and clinical information is used to identify the most effective patient care. Prior to this, however, large-scale multicenter research is needed to establish normative biomarker values.

Saliva-based assays for early detection and diagnosis of cancer and Sjögren's syndrome are in development. Research

into the presence of tumor markers in saliva for oral cancers and precancers and variation in the salivary microbiome associated with other cancers shows promise.[27] A "liquid biopsy" refers to the use of a biofluid (such as saliva, serum, or urine) to detect circulating tumor cells and fragments of tumor DNA shed from tumor cells into the circulatory system. Circulating tumor DNA (ctDNA) can be distinguished from normal cell-free DNA by the presence of mutations, thereby potentially allowing for early, noninvasive detection. Since the mutations and amplifications caused by ctDNA are closely related to the occurrence and development of tumors, it is hoped that they may also be used to monitor therapeutic effect.[28]

Salivaomics

Salivaomics refers to the study of diagnostic components such as the salivary genome, proteome, transcriptome, metabolome, and microbiome. The salivary genome, composed of approximately 70% host and 30% oral microbiota DNA, allows access to the host genome via saliva collection.[29] This feature has been exploited by companies (e.g., 23andMe®, AncestryDNA®) who provide direct-to-consumer genetic testing kits that can determine the presence of genomic variants (e.g., single nucleotide polymorphisms), gene mutations (e.g., in *BRCA1* and *BRCA2*), and provide information regarding ancestry.[26]

The salivary proteome, composed of the entire set of proteins produced or modified by an organism, allows comparison of proteins produced in health versus disease. The human salivary proteome has been characterized for several diseases including oral squamous cell carcinoma, chronic graft-versus-host disease, and Sjögren's syndrome.[30]

The salivary microbiome refers to the nonpathogenic, commensal bacteria present in healthy salivary glands as distinct from the oral microbiome of the oral cavity. The Salivaomics Knowledge Base (SKB) is a data repository management system and web resource dedicated to salivaomic studies.[31] It is likely that information gleaned from the SKB will be used to develop saliva-based diagnostic point-of-care technologies for the detection of salivary biomarkers for human diseases.

Salivary Gland Imaging

Imaging in patients with suspected salivary gland disease can help confirm the salivary gland(s) as the origin of pathosis and can distinguish inflammatory from neoplastic processes. Some imaging modalities may also provide information on gland function, anatomic alterations, and space-occupying lesions. The following describes the application of plain film radiography, ultrasonography (US), computed tomography (CT), including cone beam computed tomography (CBCT), magnetic resonance imaging (MRI), positron emission tomography (PET) fused with CT or MRI (i.e., PET/CT, PET/MRI), sialography, salivary gland scintigraphy, and sialendoscopy as they relate to the diagnosis of salivary gland disorders. A summary of indications, advantages and disadvantages of each modality is presented in Table 9-2.

Advances in imaging have resulted in a shift from reliance on plain films and sialograms to nearly sole use of US, CT, MRI, and sialendoscopy. When selecting the best imaging modality or modalities, consideration should be made for relative accuracy, reliability, cost, radiation exposure, and patient desires, among other factors.

Plain Film Radiography

Plain film radiography may be the initial imaging modality employed in investigating a chief complaint involving the major salivary glands due to its availability; however, its clinical value may be limited. Use of conventional radiography has diminished with time in favor of cross-sectional imaging.

Signs and symptoms suggestive of salivary gland obstruction (e.g., painful, acute swelling of a gland, clinical detection of a sialolith) (Figure 9-8) warrant plain film radiography to help confirm or refute the presence of calcified blockages. Plain film may also depict bony destruction associated with malignant neoplasms and can provide a background for interpretation of a sialogram.

While plain film radiography is particularly useful for visualization of radiopaque sialoliths, phleboliths, hemangiomas with calcifications, and calcified lymph nodes may mimic sialoliths while smaller or poorly calcified sialoliths may not be visible.[32] If a stone is not evident on plain film but clinical evaluation and history are suggestive of salivary gland obstruction, additional imaging, such as CBCT, may be necessary.

Since the salivary glands are located relatively superficially, radiographic images may be obtained using standard dental radiographic techniques. Panoramic or lateral oblique projections can be used to image the parotid glands; however, overlap of anatomic structures, particularly in panoramic views, may obscure the appearance of a stone. A standard occlusal film placed intraorally adjacent to the parotid duct can help visualize a stone close to the gland orifice but may not capture the entire gland. The submandibular gland can be imaged in anterior posterior (AP) and ipsilateral oblique projections with the chin extended, mouth open, and the tongue pressed down to the floor of the mouth.[32] Sialoliths obstructing the submandibular gland

Table 9-2 Salivary gland imaging modalities: indications, advantages, and disadvantages.

Imaging Modality	Indications	Advantages	Disadvantages
Plain film	Sialolithiasis	Readily available; Inexpensive	Prone to anatomic overlap; Radiolucent sialoliths not visualized
Ultrasonography	Mass detection; Biopsy guidance; Helpful in assessment of Sjögren's syndrome	Noninvasive; Cost-effective	No visualization of deep parotid; No quantification of function; Observer variability
Computed Tomography	Inflammatory conditions; Calcified structures; Bony erosion	Differentiates osseous structures from soft tissue	No quantification; Requires contrast injection; Radiation exposure
Cone Beam Computed Tomography	Sialolithiasis	Can be combined with sialography; Reduced image degradation from metallic artefacts	Some radiation exposure
Magnetic Resonance Imaging	Neoplastic processes	Superior soft tissue resolution; No radiation exposure	Contraindicated with ferromagnetic materials and some pacemakers; High cost
Positron Emission Tomography fused with CT (PET/CT)	Staging and re-staging of malignant salivary gland tumors	Combines functional data with anatomic imaging	Radiation exposure; Cannot reliably distinguish malignant from benign tumors
Positron Emission Tomography fused with MRI (PET/MRI)	Salivary gland tumors	High sensitivity for detecting perineural spread; Reduced radiation exposure compared to PET/CT	Not widely available
Sialography	Sialolithiasis; Abnormalities of ductal system	Visualizes ductal anatomy/blockages; Superior spatial resolution	Invasive; No quantification; Contraindicated in active infection
Salivary Gland Scintigraphy	Assessment of salivary gland function after surgery, radiation therapy and in Sjögren's syndrome	Relatively easy to perform	Lengthy procedure; High cost; Radiation exposure; No morphologic data; Invasive
Sialendoscopy	Sialolithiasis; Ductal strictures and stenosis; Treatment of mucus plugs in Sjögren's syndrome	May allow for simultaneous visualization and treatment	Invasive; Cannot be used in acute sialadenitis

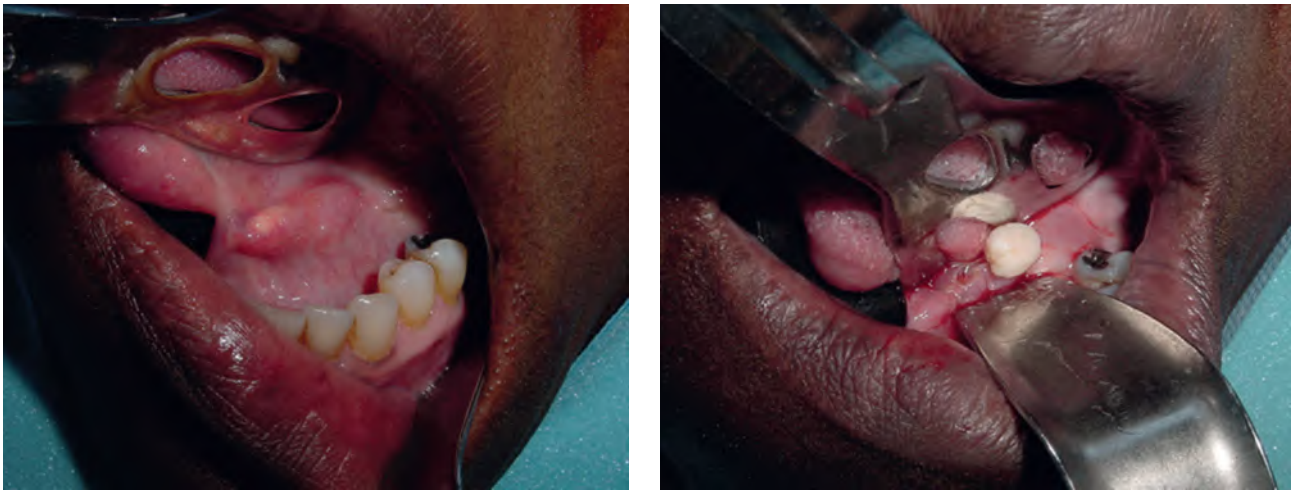

Figure 9-8 Left: Sialolith within the left submandibular gland duct. Right: Surgical exploration of a sialolith within the left submandibular duct. *Source:* Courtesy of Dr. Michael D. Turner, New York University.

may also be visualized in panoramic, occlusal, or lateral oblique views.

Ultrasonography

Using sound waves, ultrasound (US) generates a two-dimensional picture based upon the relative echogenicity of tissue; that is, the tissue's capacity to reflect or transmit ultrasound waves. US is often used during an initial evaluation, particularly where there is suspicion of sialolithiasis, acute sialadenitis or parotitis, and salivary gland abscesses. It is relatively inexpensive, widely available, safe and patient-friendly, even for children and pregnant women, and can delineate superficial salivary gland lesions as precisely as CT and MRI. High-frequency US also provides excellent resolution and characterization of tissue without exposure to radiation.[33]

US can also help distinguish focal from diffuse disease, assess adjacent vascular structures, distinguish solid from cystic lesions, guide fine-needle aspiration biopsy (FNAB), and evaluate lymph nodes for nodal staging.[34] It can also correctly differentiate malignant from benign lesions in 90% of cases and distinguish glandular from extraglandular masses with an accuracy of 98%.[35] Initial use of US, therefore, may guide the clinician in determining whether further imaging is required.

Due to their peripheral locations, the superficial portion of the parotid gland and the submandibular glands are easily visualized by US (Figure 9-9); the overlying mandibular ramus impedes evaluation of the deep portion of the parotid. Although US cannot directly visualize the facial nerve, it can suggest its position by accurate identification of intraglandular vessels within the parotid. Superficial lesions of the parotid and the submandibular glands may be amenable to core biopsy or fine-needle aspiration cytology (FNAC) under US guidance. US can also be used to guide procedures such as ductal stricture dilation and injection of botulinum toxin into a salivary gland as treatment for sialorrhea.

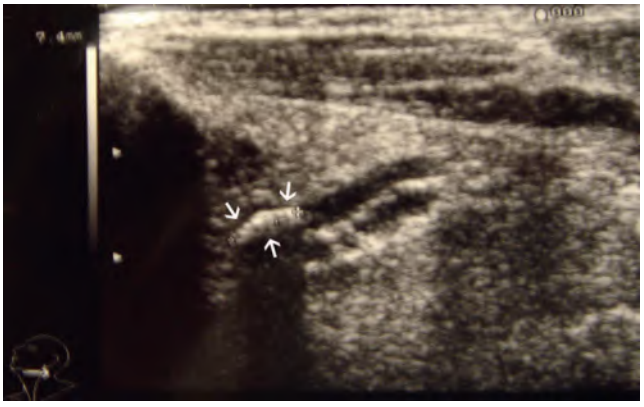

Figure 9-9 Ultrasound image with arrows indicating a sialolith within the left submandibular gland.

Salivary gland US can be a very helpful adjunct in the diagnosis and monitoring of Sjögren's syndrome. When compared to other diagnostic modalities, including scintigraphy, sialography, and salivary gland biopsy, salivary gland US consistently demonstrates high specificity and diagnostic accuracy. It provides a means to evaluate all the major salivary glands in one procedure, can highlight intraglandular calcifications and abnormal lymph nodes, and has been shown to be effective in identifying changes indicative of lymphoma development.[36] Further clinical testing, however, is needed with large cohorts to determine its overall diagnostic value in Sjögren's syndrome.

In order to be visible during US, the salivary ductal system must be filled. Filling may have occurred secondary to an obstructive pathology, or may be induced by oral administration of ascorbic acid. Retrograde administration of a contrast agent, similar to the procedure described for sialography (see below), can further aid in the visualization of the ductal system.

Sialoliths of less than 2 mm or those that are semicalcified may not be detected by US. Since it lacks the sensitivity required to fully visualize the internal ductal architecture, mucus plugs will also not be detected. In addition, US may not always allow for discrimination of phleboliths, arterial calcifications, and calcified lymph nodes from salivary gland calculi.

Ultrasound elastography, an imaging technique which evaluates the relative elasticity or stiffness of tissues, has been proposed to help differentiate between benign and malignant salivary gland tumors since malignant tumors are usually harder than benign ones. Current research suggests that real-time elastography could be used as an adjunct to conventional US for evaluation of salivary gland masses. Ultrasound elastography has already proven to be able to distinguish salivary glands affected by Sjögren's syndrome from normal glands.[37]

Conventional Computed Tomography

Conventional computed tomography (CT) is often the preferred initial imaging modality for evaluation of suspected calcifications and inflammatory conditions of the salivary glands owing to its high sensitivity and spatial resolution.[38] It is especially useful in the evaluation of malignant processes since it is able to depict mandibular cortical bone erosion and destruction, and cutaneous changes. Since CT can help define cystic walls and highlight the characteristic enhancing wall seen in abscesses, it is possible to distinguish fluid-filled masses (i.e., cysts) from abscesses. Landmark structures such as the retromandibular vein, carotid artery, and deep lymph nodes can also be identified on CT.

Imaging the major salivary glands can be optimally achieved using a standard neck CT protocol, which includes the skull base, nasopharynx, and oral cavity extending to include potentially enlarged lymph nodes in the neck, using continuous fine cuts through the gland(s) of interest. Both pre- and postcontrast studies must be performed in order to detect calcifications (precontrast) and enhancement patterns (postcontrast), and to allow distinction from normal anatomy. The initial precontrast scans are also reviewed for the presence of sialoliths (Figure 9-10), masses, glandular enlargement or asymmetry, nodal involvement, and loss of tissue planes.

Since glandular damage from chronic disease often alters the density of the salivary glands making identification of masses more difficult, contrast-enhanced images are often indicated as they will accentuate pathology. With contrast, tumors, abscesses, and inflamed lymph nodes may show abnormal enhancement when compared to normal structures. Enhanced CT can therefore help in staging malignant disease of the salivary glands by assessing lymphadenopathy of the pharynx and neck. Coronal and sagittal reconstructions are particularly useful in the evaluation of perineural spread, which, when present, implies a poor prognosis.[39]

CT maintains several advantages over MRI: it is less costly, more readily available, and it can be used in patients for whom MRI is contraindicated (e.g., individuals with certain implanted medical devices). CT may also be an alternative for patients who are unable to lie still long enough for an MRI (e.g., pediatric or geriatric patients or patients with mental or physical disabilities), and for whom MRI is otherwise contraindicated.

Dental restorations, maxillofacial fixation hardware, or other metallic hardware residing in the area imaged may produce streak artifact which may necessitate additional CT scans acquired with a different head position or gantry tilt angle and application of metal artifact reduction techniques. Additional disadvantages of CT include radiation exposure and the administration of iodine-containing contrast media for enhancement. Significantly impaired renal function and prior allergic reaction to a contrast agent may be contraindications for contrast-enhanced CT.

Cone Beam CT (CBCT)

Using a cone-shaped x-ray beam and two-dimensional detectors, a CBCT scanner collects volume data by means of a single rotation around the patient taking 9–40 seconds. It provides reduced superimposition and distortion of anatomic structures and higher sensitivity over two-dimensional radiography.

When compared with conventional CT, CBCT provides higher spatial resolution of osseous structures at a lower radiation dose, requires a shorter scan time, demonstrates reduced image degradation from metallic artifacts, and is less costly and more likely to be available in outpatient clinics and dental offices.[33,40] After plain film radiography, CBCT may be employed in patients with signs and symptoms consistent with sialolithiasis (see section: Sialolithiasis).[41]

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) employs strong, dynamic magnetic fields and radio waves to produce diagnostic images. It has proven value in assessment of major salivary gland diseases, especially neoplastic processes (Figure 9-11). It is the imaging modality of choice for preoperative evaluation of salivary gland tumors, especially where there is a strong suspicion for malignancy, because of its ability to differentiate soft tissues and availability of multiplanar imaging.[42] When comparing US, CT, MRI, PET/CT, and real-time elastography, MRI has demonstrated the greatest potential to discriminate malignant from benign neoplasms (see section: Imaging in the differentiation of benign and malignant salivary gland tumors).

MRI provides a higher degree of accuracy in assessing malignant perineural invasion, intracranial spread, deep tissue extension, and marrow infiltration/edema over CT.[34,43] It is also optimal for detection of extracapsular spread in regional lymph nodes.[44] For these reasons, MRI is indicated to assess complete tumor extent, local invasion, and perineural spread in deep tissues for staging and treatment planning purposes. MRI can also highlight postoperative recurrences.[34]

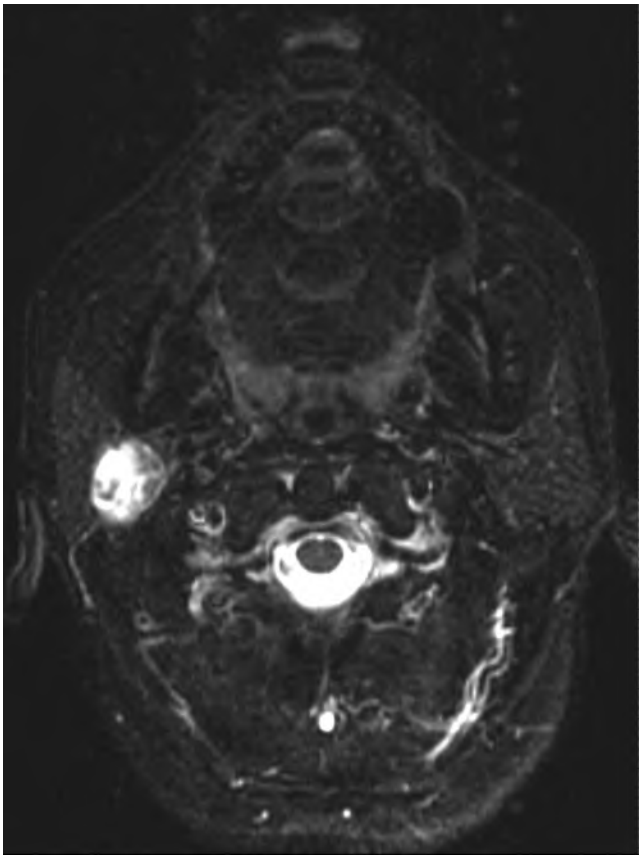

Figure 9-11 Axial MRI demonstrating a pleomorphic adenoma of the right parotid gland.

MRI may also be useful in the discrimination of disorders that mimic parotid gland swelling such as hypertrophy of the muscles of mastication and for detection of parotid gland changes associated with undiagnosed Sjögren's syndrome.[33,45] Such changes on MRI that can be associated with Sjögren's syndrome are an inhomogeneous internal pattern in both T1- and T2-weighted images giving a "salt-and-pepper" or "honeycomb-like" appearance.[46] A head and neck MRI can also help detect central nervous system and cranial nerve involvement in Sjögren's syndrome and can highlight changes associated with the development of malignant B-cell lymphomas, in particular mucosa associated lymphoid tissue (MALT) lymphomas; a true advantage as lymphomas arise in approximately 5–10% of Sjögren's syndrome patients.

The superior soft tissue contrast that MRI affords allows excellent discrimination of the salivary gland parenchyma and ductal structures. The utility of MRI is further enhanced by combining it with sialography allowing for a much finer evaluation of ductal alterations and filling defects (see section: MR Sialography). With respect to causes of ductal obstruction, however, MRI does not allow for differentiation between calcified sialoliths, fibrin, and mucus plugs and it may overestimate the size of calcified sialoliths from 10% to 30%.[47]

Additional advantages of MRI are that it does not expose patients to radiation, intravenous contrast media is not routinely required, and it is less susceptible to artifact from dental restorations than CT. MRI is contraindicated in patients with some cardiac pacemakers, automatic cardioverter defibrillators, or ferromagnetic metallic implants. Patients who cannot maintain a still position for the required scan time or those with claustrophobia may have difficulty tolerating the MRI procedure. Open bore or wide bore scanners are becoming more available to address these issues; however, the image quality is inferior to that of closed bore scanners.

PET/CT and PET/MRI

PET/CT is a whole-body imaging technique which combines the functional imaging provided by positron emission tomography (PET) with anatomic data from the CT scan. PET typically employs the radioactive tracer 2-deoxy-2-(^{18}F) fluoro-D-glucose (FDG); a glucose analogue taken up by cells with high glucose demand such as in the brain and kidneys, and cancer cells. A low level of physiologic uptake also occurs in normal tissues such as in the parotid and submandibular glands and tonsils. Uptake is increased at sites of active inflammation and infection and in benign, non-neoplastic processes, such as sarcoidosis and radiation-induced sialadenitis.[38]

PET/CT has an established role in staging head and neck cancer, searching for an unknown primary, assessing response to treatment, and differentiating relapse or recurrence from treatment effects.[48] It is considered a useful complementary technique to conventional imaging for staging malignant salivary gland tumors and for follow-up and restaging of treated tumors. In discriminating benign from malignant salivary gland processes, however, the PET/CT suffers from unacceptably high rates of false-positive and false-negative results.[38]

PET/CT has also demonstrated utility in assessing patients with primary Sjögren's syndrome. It can depict systemic manifestations such as lymphadenopathy and pulmonary and salivary gland involvement in these patients. In the parotid glands, a maximum standardized uptake value (SUVmax), a measure of FDG uptake, of ≥4.7 and/or the presence of focal lung lesions has been associated with the diagnosis of lymphoma in primary Sjögren's syndrome patients.[49]

The use of fused PET/MRI has recently been explored. Studies using retrospective fusion of MRI and PET datasets demonstrated that the fused PET/MRI images offered higher sensitivity and specificity with respect to the presence of

head and neck malignancy than with the unfused MRI and PET images. When compared with PET/CT, PET/MRI offers two additional advantages: the relative high sensitivity of MRI for detecting perineural spread, a route of metastasis favored by many salivary gland tumors, and reduced radiation dose.[50]

Sialography

Sialography achieves radiographic visualization of parotid and submandibular gland ducts, ductules, and parenchyma following retrograde instillation of soluble contrast material into Stensen's or Wharton's ducts, respectively. Since cannulation of multiple smaller ducts can be technically challenging, it is not typically used to image the sublingual glands. The most common sialographic findings include calcified sialoliths, noncalcified obstructive lesions (e.g., fibrin or mucus plugs), granulomatous collections on ductal walls, stenoses, strictures, and ductal kinks.

Because of its superior spatial resolution over CT, MRI, and scintigraphy, sialography allows for examination of the microanatomy of salivary duct systems.[51] It is used for evaluating intrinsic and acquired abnormalities (e.g., ductal stricture, obstruction, dilatation, and ruptures), and for identifying and localizing sialoliths, because it provides the clearest images of branching ducts and acinar end pieces.

In a patient who presents with a history of rapid-onset, painful swelling of a single gland (typically brought on by eating), sialography may be of value to detect the presence of calculi, ductal stricture, or obstruction due to mucus plugging. Sialoliths usually appear as voids (Figure 9-12) while focal collections of contrast medium within the gland usually indicate sialectasis (abnormal salivary ductal dilation) such as seen in sialadenitis and Sjögren's syndrome.

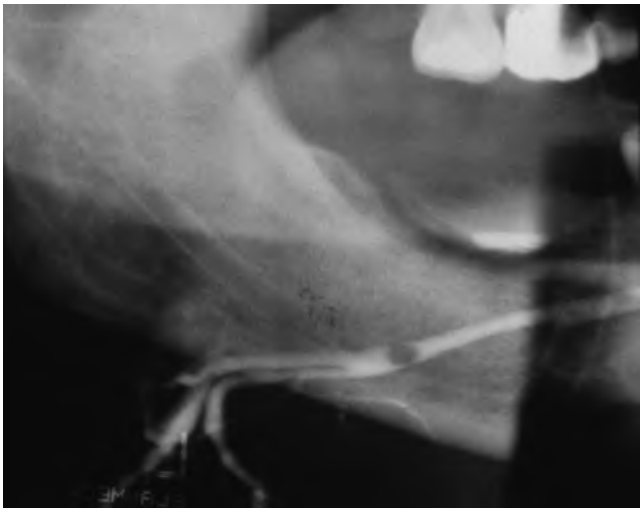

Figure 9-12 Sialogram showing an uncalcified sialolith in Wharton's duct visualized where the submandibular duct overlies the inferior alveolar canal. *Source:* Courtesy of Dr. Elisa Mozaffari, University of Pennsylvania.

Sialography may also be a valuable tool in presurgical planning for removal of salivary gland masses or to estimate ductal diameter prior to sialendoscopy. One of the chief advantages of sialography is that salivary stones can be localized to the salivary gland duct or gland parenchyma, which may influence the choice of treatment.[52] The ability to manipulate patient head position during examination may also provide enhanced visualization.

There are three main types of sialography: conventional sialography (with or without digital subtraction), CT sialography (including CBCT sialography), and MR sialography. In conventional sialography, the papilla of Stensen's or Wharton's duct is identified and, if required to facilitate access, the ductal orifice is dilated using incremental sizes of lacrimal probes. Once maximum ductal dilation is achieved, a sialographic catheter is introduced. Prior to infusion of a water- or fat-soluble sialographic contrast agent, an image is obtained to aid in distinguishing structures enhanced by the contrast agent or as a precontrast image for digital subtraction sialography (see below). Ductal filling is achieved by application of gentle, constant pressure on the syringe plunger until complete opacification of the ductal system is observed.

During sialography of a normal salivary gland, contrast medium will be seen initially in the peripheral portions of the duct extending towards the gland, filling and infiltrating into the intraglandular ductal branches (ductal phase). The image will resemble tree branches, initially leafless, gradually bursting into bloom, which represents introduction of the contrast material into the salivary gland parenchyma (parenchymal phase).[52] Radiographic views employed in conventional sialography include panoramic, lateral oblique, AP, and "puffed-cheek" AP views.

Following the sialographic procedure, the patient is instructed to massage the gland and/or to suck on lemon drops to promote the flow of saliva and contrast material out of the gland. Postprocedure imaging is performed to ensure that all contrast material elutes or is fully resorbed. Incomplete clearing can be due to obstruction of salivary outflow, extraductal or extravasated contrast medium, collection of contrast material in abscess cavities, or impaired secretory function.

Digital subtraction radiography refers to an image analysis technique which allows for detection of small radiographic changes between successive radiographs by "subtracting" distracting static anatomic structures. In digital subtraction sialography (DSS), precontrast images are subtracted from postcontrast images to provide high-resolution imaging of the extraglandular and intraglandular salivary ductal system, permitting detection of even small

sialoliths.[53] A distinct advantage DSS has over conventional sialography is that the former allows images to be captured during the initial filling of the main duct thereby preventing obscuration of mucus plugs by contrast medium.[54] Functional information can also be obtained after sialogogue administration.

Clinical indications for DSS are an acute swelling or palpable mass in the submandibular or parotid regions or gradual or chronic enlargement of a salivary gland where sialolithiasis or sialadenitis is suspected.[55] The principle weaknesses of DSS are that it is invasive (since it requires ductal cannulation), it requires the use of contrast and ionizing radiation, and that it has a high incidence of technical failure.[33]

Potential complications of sialography include ductal rupture, activation of clinically dormant infection, and adverse reaction to contrast agents.[32] Sialography is contraindicated in the presence of active infection (acute sialadenitis) and in a patient with a history of allergy to contrast agents. Performing sialography during an active infection may cause further glandular irritation and potential ductal rupture. Injection of contrast material may also force bacteria throughout the ductal structures, thereby spreading infection.

CT Sialography

CT sialography employs sialographic contrast to delineate the salivary ducts and enable the evaluation of the salivary gland parenchyma in fine detail. It is performed in the same manner as conventional sialography except that the patient is positioned in a CT scanner in a neutral supine position. Although CT sialography has a number of potential advantages over conventional sialography, it is not routinely performed for the following reasons: conventional CT without sialography typically provides adequate visualization of the main duct while the inability to dynamically visualize filling of the ducts in real time may lead to overfilling and subsequent rupture.

CBCT Sialography

Combining CBCT with sialography represents a relatively new approach that is showing promise as a supplementary noninvasive diagnostic method for visualizing the intraglandular ductal system. Using 3D and multiplanar reconstruction (i.e., converting data acquired in a one plane into another plane or planes), accurate mapping of salivary ducts can be achieved.[56]

CBCT sialography may be especially useful where US or sialendoscopy have failed to demonstrate pathology in patients with suspected salivary gland disease. It may serve as an advanced imaging modality since, following injection of contrast agent, visualization up to the sixth division of the ductal system is possible. While CBCT sialography is not a substitute for sialendoscopy (see section: Sialendoscopy), its selective use may eliminate the need for sialendoscopy if the causative pathology is identified in the intraglandular duct system or in the area around the hilum as these areas are not accessible to sialendoscopy.[57]

CBCT sialography provides several advantages over conventional sialography with respect to imaging the intraglandular ductal system including three-dimensional reconstruction, greater image manipulation, and generation of various cross-sectional slices. These advantages are particularly valuable in cases of complex anatomy.[39] By selecting appropriate parameters, the effective radiation dose from CBCT sialography can be equivalent to that of conventional sialography and it is less costly and more widely available than CT or MRI.

MR Sialography

Magnetic resonance sialography represents a fairly sensitive and reliable method for evaluating the salivary glands and may be used as the diagnostic method of choice in patients with suspected sialolithiasis where unenhanced CT has failed to demonstrate pathology. It provides several advantages over other imaging modalities: it can be employed in the diagnosis of parenchymal and ductal lesions with simultaneous visualization of all major salivary glands, it does not employ radiation, and, since it does not always require ductal cannulation and injection of contrast medium, it can be noninvasive and used in cases of acute sialadenitis.[58]

MR sialography is considered as accurate as conventional sialography in detecting obstructions, stenosis, and strictures of the main salivary gland ducts.[51] Advances in 3-D volumetric techniques and the ability to reformat images allow for the generation of virtual endoscopic views.[59] Disadvantages of MR sialography include a more limited availability and higher cost. It is also considered to have a lower sensitivity with respect to ductal pathologies, since its resolution does not extend beyond secondary divisions.[51]

Salivary Gland Scintigraphy

Scintigraphy using technetium (Tc) 99m pertechnetate is a dynamic and minimally invasive diagnostic assay employed to assess salivary gland function.[60] Technetium 99m pertechnetate is a pure gamma ray-emitting radiopharmaceutical, which, following intravenous injection, is taken up and transported by the salivary glands and secreted into the oral cavity generating quantitative information on the glands' function (Figure 9-13).[61] Salivary gland scintigraphy (SGS) can provide information on both the parenchyma and function of the parotid and submandibular glands after a single intravenous

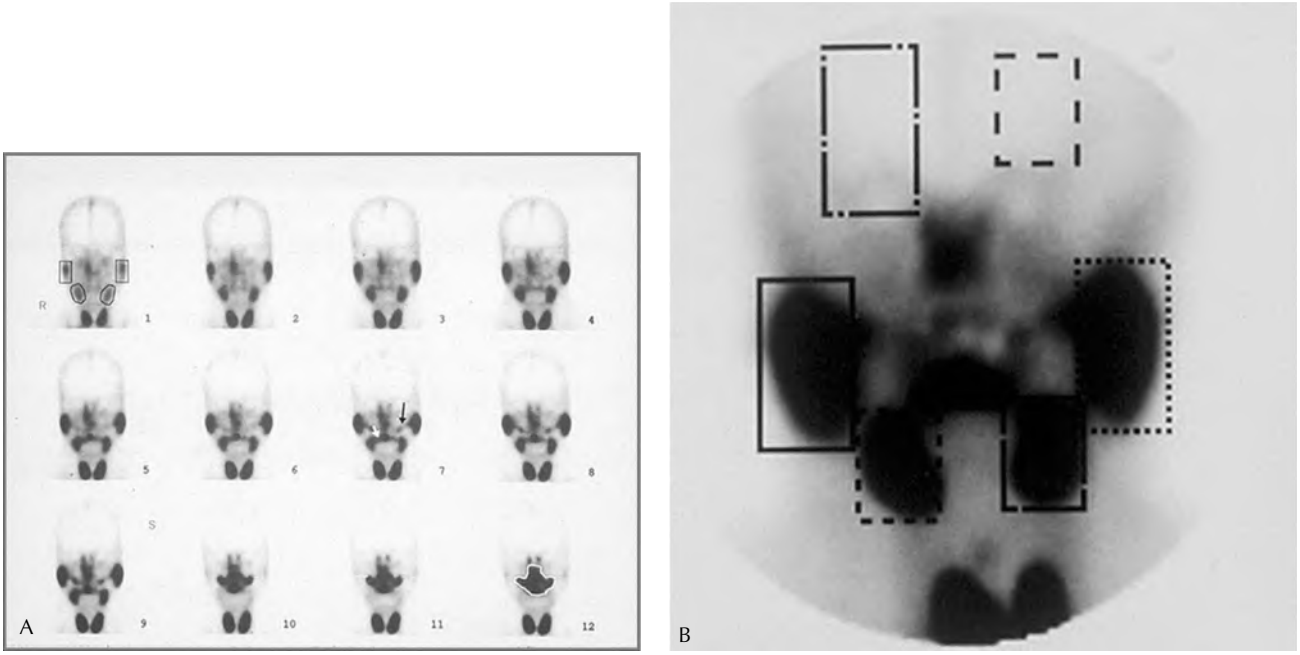

Figure 9-13 (A, left) Technetium 99m pertechnetate radionuclide image (scintigram) of the parotid and submandibular glands. This sequential salivary scintigram is an anterior Water's projection of an individual with normal salivary gland function. The four glands are outlined in frame 1 as regions of interest for further analyses. In frame 7, the dark arrow denotes Stensen's duct and the white arrow indicates Wharton's duct. A secretagogue, usually citric acid, is placed in the oral cavity between frames 9 and 10, inducing a rapid emptying of the glands. In frame 12, 10 minutes following the secretagogue, tracer is absent in the salivary glands and concentrated in the outlined oral cavity. (Courtesy of Dr. Frederick Vivino, University of Pennsylvania.) (B, right) A single frame of a salivary scintigram demonstrating significant uptake in both parotid and submandibular glands (four lower windows) with excretion into the oral cavity. The two upper windows represent background activity from blood flow, which is subtracted from the four regions of interest to determine specific salivary activity. *Source:* Courtesy of Dr. Frederick Vivino, University of Pennsylvania.

injection: a clear advantage over other imaging techniques.[62] Both uptake, which indicates the presence of functional epithelial tissue, and secretory phases can be recognized. SGS is indicated for the evaluation of patients when sialography is contraindicated or cannot be performed (i.e., in cases of acute sialadenitis or iodine allergy), or when the major duct cannot be cannulated successfully.

SGS can also estimate the severity of salivary gland involvement and functional change—even that which is not accurately reflected by morphologic damage.[63] As such, it has been used to assess salivary gland function following surgery, radiation, and radioiodine therapy. It has also been used to aid in the diagnosis of ductal obstruction, sialolithiasis, gland aplasia, and Sjögren's syndrome.[32] SGS has been proposed as a valid alternative to other forms of functional evaluation of the salivary glands in patients with Sjögren's syndrome. An abnormal SGS result is accepted as part of the 2002 American–European consensus group classification criteria for Sjögren's syndrome, but is not included in the 2012 ACR or 2016 ACR/EULAR criteria.[64–66]

A normal scintigraphic time–activity curve may be separated into three phases: flow, concentration, and washout. The flow phase is about 15–20 seconds and represents the time immediately following radionuclide injection when the isotope is equilibrating in the blood and accumulating in the salivary gland at a submaximal rate. The concentration (uptake) phase represents the accumulation of Tc 99m pertechnetate in the gland via active transport. With normal salivary gland function, the radionuclide will be secreted and tracer activity should be apparent in the oral cavity after 10–15 minutes. Approximately 15 minutes after administration, tracer concentration begins to increase in the oral cavity and decrease in the salivary glands. A normal image will demonstrate symmetric uptake of Tc 99m by both the parotid and submandibular glands.

In the excretory or washout phase, the patient is given a lemon drop, or citric acid is applied to the tongue, to stimulate secretion. Normal clearing of Tc 99m should be prompt, uniform, and symmetric. Activity remaining in the salivary glands after stimulation is suggestive of obstruction, certain tumors, or inflammation. With some exceptions, neoplasms arising within the salivary glands do not concentrate Tc 99m and will appear as voids or areas of decreased activity on the scintigram. The notable exceptions are Warthin's tumor and oncocytomas which will retain Tc 99m because they do not communicate with the ductal system and hence will appear as areas of increased activity on static images.[67]

Several rating scales have been used for the evaluation of salivary scintigrams; however, no standard method exists. Current approaches to functional assessment include visual interpretation, time–activity curve analysis, and numeric indices. Semiquantitative methods are also used in which Tc 99m uptake and secretion are calculated by computer analysis of user-defined regions of interest.

Although salivary gland scintigraphy is considered the gold standard for assessing salivary function and it is relatively easy to perform and reproducible, its use has fallen out of favor to noninvasive methods that do not subject the patient to radiation, such as US and MR imaging, including MR sialography.[68]

Sialendoscopy

Sialendoscopy has emerged as a valuable diagnostic and therapeutic technique for many salivary gland disorders affecting the submandibular and parotid glands. Using a small camera, it allows visualization of intraductal anatomy and strictures or other pathoses within the ducts. Insertion of surgical instruments or lasers through the endoscope may permit simultaneous fragmentation and removal of calcified material, biopsy, or stricture dilation. Typically, US, conventional sialography, contrast-enhanced CT, or MR sialography is employed prior to the sialendoscopic procedure to assess the ductal system. In many cases, the use of sialendoscopy may obviate the need for additional procedures or adenectomy.[47]

Sialendoscopy has also been used to flush out mucus plugs and irrigate the ductal system with saline or corticosteroids to enhance salivary flow and diminish xerostomia in patients with Sjögren's syndrome.[69] Following the sialendoscopic procedure, a stent may be placed to allow for healing of the duct and maintenance of salivary flow.

One limitation of sialendoscopy is that it can only be used for extraglandular duct pathologies or those close to the hilum.[57] The deepest portions of the gland (i.e., the proximal ductules) may not always be accessible, especially where stenosis is present. Very small stones, the presence of multiple smaller stones within different ductal branches, very large (> 9 mm) or immobile stones may also present a challenge.[41] Sialendoscopy is contraindicated in the presence of acute sialadenitis due to the increased risk of duct perforation.[70]

Imaging in the Differentiation of Benign and Malignant Salivary Gland Tumors

The ideal imaging modality would allow definitive discrimination between benign and malignant salivary gland tumors. In comparing US, CT, MRI, PET/CT, and real-time elastography (RTE), there is no statistically significant difference and no consensus on the use of one single modality or combination of modalities for this task. Of these, however, MRI shows the greatest potential.[43]

Histopathologic analysis remains the gold standard in evaluating the malignant potential of a neoplasm and imaging characteristics alone may never allow for definitive distinction between benign and malignant processes. One reason for this is because on imaging, lesions can demonstrate overlapping features; for example, a low-grade malignancy may appear well-defined with smooth borders.

Salivary Gland Biopsy

Definitive diagnosis of salivary gland pathology often requires histologic examination. The labial minor salivary glands are the most commonly biopsied, especially where Sjögren's syndrome is suspected, since they are the most accessible. Biopsy of the minor glands can also be used to diagnose amyloidosis, sarcoidosis, and chronic graft-versus-host disease (cGVHD), among other pathoses.

Minor Salivary Gland Biopsy

The minor salivary gland biopsy (MSGB) is a minimally invasive procedure that can be performed with limited morbidity using appropriate techniques.[71] An incision is made on the inner aspect of the lower lip, to one side of the midline, through normal-appearing mucosa, avoiding areas of trauma or inflammation that could influence the appearance of the underlying tissue. Six to ten minor gland lobules from just below the mucosal surface are removed and submitted for histopathologic examination. Clinicians should ensure an adequate specimen is obtained when Sjögren's syndrome is suspected, as generation of a focus score (see below) requires at least 8 mm^2 of evaluable salivary gland tissue.

The MSGB performed as part of a work-up for Sjögren's syndrome is considered the most accurate sole criterion for diagnosis of the salivary component of this disorder.[72] Histologically, the presence of focal lymphocytic sialadenitis is supportive of the diagnosis. The pathologic grading system results in a Focus Score (FS) which relates to the number of aggregates of ≥ 50 lymphocytes per 4 mm^2 of salivary gland tissue. A FS ≥ 1 is considered positive for Sjögren's syndrome.

Recent use of corticosteroids, smoking, and radiation exposure to the area of biopsy may adversely affect results. Complications associated with MSGB include long-term lower lip numbness (reported at 0–10%) and mucocele formation.[71]

Major Salivary Gland Biopsy

The parotid gland biopsy has been shown to be superior to the MSGB with respect to diagnosis of several conditions including sarcoidosis and lymphomas.[73] Where salivary

gland lymphoma is suspected, histopathologic analysis is often combined with techniques such as flow cytometry, and fluorescence *in situ* hybridization for definitive diagnosis and characterization. Here, the parotid gland as a biopsy site offers important advantages over the MSGB. The larger gland size offers multiple sites and opportunities for sampling and, since mucosa-associated lymphoid tissue (MALT) and non-Hodgkin lymphomas (NHL) are rarely observed in labial salivary glands, there is the opportunity to make a diagnosis even prior to clinical manifestation.[74] In addition, histopathologic results from the parotid gland can be directly compared with imaging or assays involving the same gland (e.g., scintigraphy, US, sialometry).[71]

With respect to Sjögren's syndrome, while the sensitivity and specificity of the parotid and minor salivary gland biopsies are comparable, the former may offer unique value in assessing disease activity, progression, and response to treatment. Risks that have been associated with biopsy of the parotid gland include sialocele and salivary fistula formation, injury to the facial nerve, and visible external incision, but these have not occurred where an appropriate technique has been applied. There are no reports of permanent morbidity associated with the parotid gland biopsy in contrast to the relatively higher hazard of permanent damage to the sensory nerves of the lower lip with the MSGB.[71]

Fine-Needle Aspiration Biopsy

Fine-needle aspiration biopsy (FNAB) is a simple technique that aids in the diagnosis of lesions using a fine-gauge needle to obtain a biopsy specimen for histopathologic analysis. Its use may prevent a significant number of patients from undergoing an open surgical procedure. The diagnostic sensitivity and specificity of FNAB for salivary gland lesions has been reported as above 80% and 95%, respectively. Limitations include difficulty in obtaining an adequate specimen, inability to determine tumor grade (i.e., discerning between high and low grade), reduced accuracy for non-neoplastic processes, and lack of information with respect to tissue architecture, capsular invasion, and lymphovascular involvement.[75]

Core Needle Biopsy

A core needle biopsy (CNB), in which a large bore needle is used to remove cylinders of tissue, may be used in the preoperative evaluation of salivary gland lesions. CNB has the advantages of having a lower rate of complications (bruising being the most commonly reported problem), and reduced risk of tumor seeding over FNAB.[75] CNB also provides increased material over the FNAB, allows preservation of histologic architecture, and can allow for assessment of extracapsular tumor invasion. Immunohistochemical stains are also more likely to be reliable with core biopsy specimens. Disadvantages of CNB include the requirement for local anesthesia and possibly increased pain and morbidity.

Ultrasound-Guided Core Needle Aspiration

US-guided core needle aspiration is indicated for distinct salivary gland masses of the major salivary glands and can also be used to investigate cervical lymphadenopathy.[76] Employing US significantly improves the safety, accuracy, and diagnostic rate over non-US guided biopsies.[77] A cytopathologist familiar with salivary gland cytology should inspect the aspirated specimen and offer a diagnosis or differential diagnoses based upon the cellular characteristics observed. Even if a definitive diagnosis is not rendered, it may be possible to determine whether a lesion is benign or malignant, which is helpful as awareness of the biologic aggressiveness of the tumor prior to definitive surgery aids in treatment planning.

Frozen Section Analysis

Frozen section analysis is a procedure in which specimens are rapidly processed and analyzed during a surgical procedure. It can help confirm or refine a presurgical diagnosis, including establishing whether a neoplasm is benign or malignant, and is used to evaluate margins for tumor involvement, and determine if there is neural or lymph node involvement. Frozen section analysis in parotid gland surgery has important implications. For example, discovery of involvement of the facial nerve by a malignancy will require sacrifice of one or more of its branches; lymph node involvement may necessitate neck dissection or radiation therapy. Frozen section analysis is estimated to have a 90% sensitivity and 99% specificity for salivary gland lesions.[78]

Serologic Evaluation

In addition to a review of medical history and clinical examination, serologic analyses can be helpful in the evaluation of a patient with dry mouth especially where an autoimmune process such as Sjögren's syndrome is suspected. Indeed, detection of serum autoantibodies has a central role in the diagnosis and classification of Sjögren's syndrome. The most extensively studied of these autoantibodies are the antinuclear antibodies (namely subtypes anti-SSA/Ro and anti-SSB/La), and rheumatoid factor (RF): 59–85% of patients with primary Sjögren's syndrome will display antinuclear antibodies and, of these, 50–70% will show anti-Ro/SSA and anti-La/SSB antibodies.[79] Although the anti-SSA/Ro

autoantibody is considered the most specific marker for Sjögren's syndrome, it may be found in a small percentage of patients with systemic lupus erythematous or other autoimmune connective tissue disorders and even in some normal individuals.

Serologic evaluation can also help to distinguish between Sjögren's syndrome and IgG4-related disease (IgG4-RD) since they may present similarly (i.e., salivary gland enlargement, sicca symptoms, arthralgias). In both, patients may have circulating antinuclear antibodies; however, anti-SSA/Ro and anti-SSB/La reactivity is not frequently found in patients with IgG4-RD. Similarly, in suspected cases of Sjögren's syndrome/sicca syndrome triggered by the cancer immunotherapy drugs known as immune checkpoint inhibitors, the serologic profile can be helpful as anti-SSA/Ro and anti-SSB/La antibody screening is usually, but not always, negative. However, as this phenomenon has a distinct phenotype with respect to histopathology and other features, additional assays including a minor salivary gland biopsy may be required to distinguish it from idiopathic Sjögren's syndrome (see section: Sjögren's Syndrome/Sicca Syndrome Triggered by Cancer Immunotherapies).[80]

SPECIFIC DISEASES AND DISORDERS OF THE SALIVARY GLANDS

Developmental Abnormalities

Salivary Gland Aplasia and Hypoplasia

Patients with salivary gland aplasia (incomplete development or absence) experience hyposalivation, xerostomia, and increased dental caries; in fact, rampant dental caries in children without other significant risk factors has led to the diagnosis of congenitally missing salivary glands. Although rare, salivary gland aplasia may occur with other developmental defects, especially malformations of the first and second branchial arches seen as various craniofacial anomalies. Enamel hypoplasia, congenital absence of teeth, and extensive occlusal wear are other oral manifestations associated with salivary gland aplasia.[81] There is often a hereditary pattern but some patients have no relevant familial history.

Parotid gland aplasia has been reported alone and in conjunction with congenital conditions, including hemifacial microsomia, mandibulofacial dysostosis (Treacher Collins syndrome), cleft palate, lacrimo-auriculodento-digital syndrome, and anophthalmia.[82] It has also been observed in patients with ectodermal dysplasia. Hypoplasia of the parotid gland has been associated with Melkersson–Rosenthal syndrome.

The Stafne Bone Defect

The Stafne bone defect (SBD; also known as the Stafne bone cyst) is an asymptomatic depression of the lingual surface of the mandible often associated with ectopic salivary gland tissue. It is, however, not a true cyst as there is no epithelial lining. The most common location of the SBD is inferior to the mandibular canal between the angle of the mandible and the mandibular first molar. There is also an anterior variant of the SBD occurring in the premolar, canine, or incisor regions of the mandible.[83]

SBDs are often diagnosed on plain film where they typically appear as a round, unilocular, well-circumscribed radiolucency. The characteristic location and radiographic appearance make the SBD easily recognizable. They can appear radiographically akin to a residual cyst and therefore may require further investigation including advanced imaging. Surgical intervention is reserved for atypical situations in which the diagnosis is unclear or a neoplasm or other pathology is suspected. Where indicated, fine-needle aspiration biopsy can be an accurate, cost-effective diagnostic tool for these lesions.[84]

The definitive etiology of the SBD has not been established. One theory suggests they result from pressure exerted by adjacent glandular tissue. The finding of salivary gland tissue upon surgical exploration of these defects is evidence to support this theory; however, other case reports have described finding muscle, lymphatic, or vascular tissues within the cavity.[83]

Ectopic Salivary Gland Tissue

Ectopic salivary gland tissue may occur as accessory tissue, associated with branchial cleft anomalies, or as heterotopic tissue (described below). Ectopic salivary glands have been reported in a variety of locations, including the middle and external ear, neck, mandible, pituitary gland, thyroglossal duct, thyroid and parathyroid gland capsules, lymph nodes, and cerebellopontine angle.[85]

The parotid gland is the most common major salivary gland associated with accessory tissue.[86] An accessory parotid gland is present in about 21% of the population and is considered a normal anatomic variant.[85] The most frequent location of the accessory gland is superior and anterior to the normal location of Stensen's duct. Ectopic salivary gland tissue associated with branchial cleft anomalies, such as the rare Huschke foramen (also known as foramen tympanicum), have been reported as presenting with fistula formation between the parotid gland and the external auditory meatus.[87] True heterotopic salivary gland tissue consists of mature salivary gland tissue found in a nonphysiological site usually in coexistence with original tissue in its usual anatomical location. The tissue has an independent ductal system and will clinically present as a saliva-draining skin fistula or an asymptomatic nodule.[88]

The histological features of the ectopic tissue are usually identical to those of the original major gland, but the ectopic tissue is more susceptible to neoplasms. Heterotopic salivary gland tissue is typically treated with excision for definitive diagnosis and serves to prevent neoplastic transformation.[89]

Diverticula

A diverticulum is a pouch or sac protruding from the wall of a duct. Diverticula in the ducts of the major salivary glands can be visualized by sialography. They often lead to local pooling of saliva and recurrent sialadenitis. Patients with diverticula are encouraged to regularly milk the involved salivary gland to promote salivary flow through the duct.[90]

Sialolithiasis (Salivary Stones)

Etiology and Pathogenesis

Sialoliths (salivary calculi or salivary stones) are calcified organic masses that form within the secretory system of the salivary glands. Although the exact mechanism of sialolith formation has not been established, it has been proposed that microcalculi are frequently formed in salivary ducts during periods of secretory inactivity. Migration of food debris and bacteria from the oral cavity into the main ducts and along into the smaller intraglandular ducts at the site of the impacted microcalculi eventually result in a focal obstructive atrophy. Since the nidus is protected from flushing, the antimicrobial effects of saliva, and the systemic immunity, bacteria may proliferate resulting in local inflammation and further atrophy. The inflammatory process may then spread to involve adjacent lobules resulting in swelling and fibrosis of the large intraglandular ducts. The resulting partial obstruction leads to ductal dilatation and stagnation of calcium-rich secretory material resulting in further lamellar calcification.[91]

The etiologic factors favoring sialolith formation may be classified into two groups: factors favoring decreased saliva production or stasis (i.e., dehydration, use of anticholinergics or diuretics, irregularities in the duct system, local inflammation), and changes in saliva composition (i.e., calcium saturation, deficit of crystallization inhibitors such as phytate). Bacterial infection also promotes sialolith formation due to an associated increase in salivary pH favoring calcium phosphate supersaturation.[92]

Sialoliths may be composed of a variety of organic and inorganic substances including calcium carbonates and phosphates, cellular debris, glycoproteins, and mucopolysaccharides.[93] They contain cores that vary from purely organic to heavily calcified material, surrounded by less-calcified or purely organic lamellae.[91] Hydroxyapatite is the most common mineral found in sialoliths, but other minerals such as β-tricalcium phosphate (whitlockite), dicalcium phosphate dihydrate (brushite), and octacalcium phosphate, are variably present depending on the mineral microenvironment.[94] Trace amounts of magnesium, potassium chloride, and ammonium salts are often also present.

Epidemiology

The true prevalence of sialolithiasis is difficult to definitively establish since many cases are asymptomatic or involve sialomicroliths which can only be detected microscopically. Sialolithiasis is more common in males and can occur in a wide age range of patients including children. The average age of patients with sialolithiasis in the submandibular gland is 40.5 years, it is 47.8 years for the parotid gland, and 50 years for the minor salivary glands. Since the underlying cause is frequently unidentified and uncorrected, the recurrence rate is estimated at around 20%.[95]

Sialoliths occur most commonly in the submandibular glands (80–90%), followed by the parotid (5–15%) and sublingual (2–5%) glands, and only very rarely occur in the minor salivary glands. Spontaneous secretion in the minor and sublingual salivary glands may provide continuous salivary flow, thereby preventing stasis.[90]

The higher rate of sialolith formation in the submandibular glands is due to: (1) the torturous course of Wharton's duct; (2) the higher calcium and phosphate levels of the secretions contained within; (3) the dependent position of the submandibular glands which leaves them prone to stasis; and (4) the increased mucoid nature of the secretion. In addition, since the submandibular and parotid glands' secretion is dependent on nervous stimulation, in its absence, secretory inactivity increases the risk of stone development.

When sialoliths form within the submandibular glands, they usually occur within the ductal system, predominantly in the proximal section of Wharton's duct or hilar area. These stones are more likely to produce symptoms indicative of inflammation, such as pain, than when stones form in the glandular parenchyma.[52] Sialoliths within the duct are also more likely to be calcified due to the increased alkalinity of submandibular saliva, increased calcium and phosphate concentrations, and increased mucin content.[47] Calcified sialoliths especially are most commonly found at the mylohyoid turn of the duct, due to the relative stasis at this approximately 90-degree turn, and at the orifice to Wharton's duct.

Up to 80% of parotid gland sialoliths and 20% of submandibular gland sialoliths are poorly calcified, and as such, may not be detected on plain film. Noncalcified obstructions may be due to fibrin or mucus plugs, especially in Stensen's duct and the secondary ducts of the parotid.[47]

Risk factors for sialolithiasis include hypovolemia, infection, inflammation, diabetes mellitus, Sjögren's syndrome, the use of diuretics and anticholinergic medications, trauma, gout, smoking, and a history of nephrolithiasis. There are

also reported associations between sialolith formation and chronic periodontal disease and between sialolith formation and higher salivary concentrations of calcium, magnesium, and phosphorus.[94,96] Some studies indicate that the saliva of patients with calcified sialoliths contains more calcium and less phytate (a potent inhibitor of hydroxyapatite crystallization found in wheat bran and seeds), than in that of a healthy group and in patients with purely organic sialoliths.[92]

With the exception of gout, in which the associated calculi consist mainly of uric acid, there is no proven link between sialolithiasis and development of stones in other areas of the body. There are, however, shared risk factors between sialolithiasis and urolithiasis (stones of the kidney, ureter, and urinary bladder), namely hypovolemia and diabetes mellitus, and there may be a familial predisposition.[97] Patients with hyperparathyroidism demonstrate an increased incidence of sialolithiasis and those with hyperparathyroidism and sialolithiasis show a greater incidence of nephrolithiasis than those without sialolithiasis, indicating that hypercalcemia may be a common contributing factor.[91]

Clinical Manifestations

Patients with sialoliths most commonly present with a history of acute, colicky, periprandial pain and intermittent swelling of the affected gland(s). The severity of symptoms is dependent on the extent of duct obstruction and whether secondary infection is present. Since the submandibular and parotid glands are encapsulated with limited space for expansion, their enlargement will likely result in pain. Typically, salivary gland swelling will be evident upon eating since the stone completely or partially blocks the flow of saliva resulting in salivary pooling within the ductal system. Where there is partial obstruction, swelling will subside when salivary stimulation ceases and output decreases.[98]

Sialolithiasis without infectious sialadenitis is predominately unilateral without drainage or overlying erythema, and presents without systemic manifestations such as fever. Often, there is a history of sudden onset swelling and pain. The involved gland is often enlarged and tender to palpation, and the soft tissue adjacent to the duct may be edematous and inflamed. Using bimanual palpation along the course of the involved duct directed from the affected gland towards its orifice, it may be possible to palpate or even express a stone.[99]

Chronic salivary stasis may lead to infection, fibrosis, and gland atrophy. If there is concurrent infection, there may be expressible suppurative or nonsuppurative drainage, and erythema or warmth of the overlying dermis. Fistulae, a sinus tract, or ulceration may also develop in the tissue overlying the stone. Other complications from sialoliths include acute sialadenitis, ductal stricture, and ductal dilatation.[100]

Imaging

Imaging modalities which can help visualize sialoliths include plain film radiography, ultrasonography, computed tomography including cone beam computed tomography, sialography, and sialendoscopy.

Plain Film

Plain film radiography can be a helpful initial imaging modality to visualize sialoliths. It is inexpensive, readily available, and has minimal radiation exposure; however, small and poorly calcified stones may not be readily visualized. Plain film is most useful in cases of suspected submandibular sialolithiasis using an occlusal film positioned 90 degrees from the floor of the mouth, or using panoramic film. Other calcified entities, some of which have a similar appearance to sialoliths, such as phleboliths (stones that lie within blood vessels), tonsoliths, calcified cervical lymphadenopathy, and arterial atherosclerosis of the lingual artery, can also appear on these films.[99]

Stones in the parotid gland can be difficult to visualize on plain film due to superimposition of anatomic structures and their tendency to be poorly calcified. The choice of radiographic views is important to minimize overlap: an AP view of the face, an occlusal film placed intraorally adjacent to Stensen's duct, or a panoramic film may be useful in these cases.

Computed Tomography (CT)

Of all the available imaging modalities, conventional CT demonstrates the highest accuracy in detection of salivary stones and is often the method of choice where it is readily available. It is capable of detecting very small and semicalcified calculi, but is associated with a high radiation exposure. In cases of suspected sialolithiasis, noncontrast imaging with a slice thickness of 0.2–0.5 mm is used since this can help distinguish sialoliths from similarly-appearing, small opacified blood vessels.[41] Studies have indicated, however, that the majority of calcifications detected on CT scans of the salivary glands represent incidentally-discovered parotid parenchymal calcifications not associated with sialadenitis, but rather due to etiologies such as alcoholism, chronic kidney disease, HIV infection, and autoimmune disease, among others.[101]

Cone Beam Computed Tomography (CBCT)

CBCT can be of great diagnostic value in the initial imaging of patients with suspected sialolithiasis as it is helpful not only in detection of sialoliths, but it can also provide accurate information on stone size and position. As it is relatively inexpensive, is increasing in availability, and has limited radiation exposure, it is often used as first-line imaging (or second-line after plain film) for patients with signs and symptoms consistent with sialolithiasis.[41]

The use of CBCT for the detection of sialoliths is associated with high specificity, sensitivity, positive and negative predictive values.[41] CBCT also has reduced superimposition and distortion of anatomic structures and higher sensitivity over two-dimensional radiography, and reduced radiation exposure, cost, and greater availability in offices and clinics over conventional CT.[102] The sensitivity and specificity of CBCT for this indication is also considered comparable or superior to conventional CT.[40]

Ultrasonography

Ultrasonography (US), typically transoral sonography using an intraoral transducer, is widely used as first-line imaging in cases of suspected sialolithiasis, especially in emergency and urgent care settings, since it allows rapid visualization of the course of the main ducts and body of the major salivary glands. Sialoliths characteristically produce hyperechoic areas with distal signal loss (posterior acoustic shadowing) and there may be accompanying dilatation or inflammation of the ductal system and enlargement of the involved gland.[103]

While noninvasive and less costly than other imaging, US may not always allow for accurate determination of the number of calculi where there are multiple stones. Stones that are semi-calcified and calculi less than 2 mm in diameter also may not be accurately depicted as they may not produce an acoustic shadow. Scarring or calcifications in the duct or adjacent blood vessels, adjacent normal anatomic structures, and even air bubbles within saliva, may erroneously be interpreted as sialoliths.

The reported sensitivity (77–94%) and specificity (80–100%) of US in identification of sialoliths varies widely among studies, and therefore the use of US alone may not be sufficient for definitive diagnosis.[104,105] Sensitivity may be enhanced with sonopalpation (digital palpation of the floor of mouth with simultaneous placement of the ultrasound probe extraorally), and concurrent administration of a sialogogue such as ascorbic acid, which promotes filling of the ducts with salivary secretions.[106]

Sialography

Conventional sialography, using panoramic, occlusal, and periapical radiographs, can be an appropriate first-line imaging approach where there is strong clinical suspicion of sialolithiasis.[39] It can help distinguish between mucus plugs, salivary stones, and ductal strictures, which are the most common findings in patients with obstructive salivary signs and symptoms. Contrast sialography, using an iodinated contrast media, can help visualize the parotid and submandibular glands' ductal systems and aid in differentiating calcified phleboliths from sialoliths since the former lie within a blood vessel while the latter occur within the duct or gland.

CBCT sialography is another supplementary noninvasive diagnostic technique which may be superior to conventional sialography with respect to imaging salivary gland parenchyma and sialoliths.[107] It may be especially useful where plain film sialography has been inadequate, such as in more complex cases of salivary duct obstruction.[108] Similar to CT or CBCT, CBCT sialography can determine the number and location of salivary stones, including those smaller than 2 mm in diameter.[56]

MR sialography provides high sensitivity, specificity, and positive and negative predictive values with respect to the detection of salivary gland stones.[109] It does not require ductal cannulation and does not employ a contrast medium, and can therefore be used in patients with iodine or contrast media allergies. It also does not employ ionizing radiation and can be used in patients with acute sialadenitis.

Sialendoscopy

Sialendoscopy can be employed for direct visualization and, often, simultaneous treatment of sialoliths of the parotid and submandibular glands. Mobile and smaller stones may be relatively easily removed, whereas larger stones may require prior fragmentation (see below).[110]

Management

During the acute phase of sialolithiasis, initial therapy is primarily supportive. Standard treatment often involves the use of analgesics, hydration, antibiotics, and antipyretics, as indicated. Sialogogues, massage, and heat applied to the affected area may also be beneficial. Smaller stones at or near the duct orifice can often be removed transorally by milking the gland, but deeper and larger stones may require sialendoscopy or surgical intervention.

The mainstay of treatment has shifted away from open surgical procedures such as gland resection to endoscopic-based, gland preservation methods such as interventional sialendoscopy. Preservation of glandular structure maintains normal facial fullness and contour and diminishes the risk of injury to adjacent nerves. This approach is also supported by several studies that have shown that glandular function is regained after stone removal, with few cases of recurrent sialolithiasis or complications.[111]

A series of CBCT scans may be performed on the day of surgery. A preoperative CBCT provides superior intraoperative orientation by allowing for determination of spatial topography, size, number, and location of calculus relative to the surrounding anatomic structures, and it minimizes the risk of calculus migration between CBCT evaluation and the beginning of surgery. A postoperative CBCT provides a means of confirming removal of all sialoliths.[112]

Interventional sialendoscopy is employed for removal of stones up to 4–5 mm in diameter and cases involving multiple smaller stones, especially those that lie freely in the

duct lumen. Larger stones may require fragmentation with shock wave impulses via intracorporeal lithotripsy (i.e., laser or pneumatic lithotripsy), or extracorporeal shock wave lithotripsy (ESWL), which facilitate retrieval or may permit passage of the fragments with physiologic salivary flow.[113,114] Treatment of sialoliths by ESWL may require multiple treatments and is contraindicated where there is complete distal duct stenosis, acute sialadenitis, or other acute inflammatory processes of the head and neck, in pregnancy, and in patients with cardiac pacemakers.[115]

To prepare for interventional sialendoscopy, dilation of the ductal opening or papillotomy is performed to allow introduction of surgical instruments such as the Dormia basket, graspers, or lasers. Saline or steroid instillation is performed to flush out debris and treat ductal inflammation.[116] Following removal of the stone, the endoscope is used to explore the duct and ensure all calculi have been removed. A stent may be placed to maintain ductal patency.[117]

Failing gland-sparing techniques and where there are fixed intraparenchymal stones, sialoadenectomy, such as superficial parotidectomy or transcervical submandibulectomy, may be required.[118] Very large stones and a longstanding history of recurrent sialadenitis may also be an indication for gland removal.

Some postoperative complications associated with parotidectomy include transient (2–76%) or permanent (1–3%) facial nerve injury, sensory loss of the greater auricular nerve (2–100%), and Frey's syndrome (8–33%). Risks associated with submandibular gland removal include temporary (1–2%) or permanent (1–8%) injury to the marginal mandibular nerve, temporary (1–2%) or permanent (3%) hypoglossal nerve palsy, or temporary (2–6%) or permanent (2%) lingual nerve damage. Other complications include hematomas, salivary fistulas, sialoceles, wound infection, hypertrophic scars, and inflammation caused by residual stones.[115]

Mucoceles and Ranulas

Mucoceles

Etiology and Pathogenesis

Mucocele is a clinical term that describes a swelling caused by the accumulation of saliva at the site of a traumatized or obstructed minor salivary gland duct. Although often called a "mucous retention cyst", this is a misnomer as the mucocele does not have an epithelial lining. Mucoceles can be classified histologically as extravasation types or retention types. Extravasation mucoceles develop secondary to trauma to a minor salivary gland excretory duct resulting in pooling of saliva in the adjacent submucosal tissue, whereas retention mucoceles are caused by obstruction of a duct, often by a sialolith, periductal scaring, or tumor, resulting in the accumulation of saliva and ductal dilation.[119]

Superficial mucoceles are a rare variant of mucocele that are typically smaller and more often appear as multiples. Development of superficial mucoceles has been attributed to the accumulation of sialomucins at the epithelial–connective tissue interface occurring idiopathically or secondary to trauma.[120] They have also been reported associated with oral lichen planus and lichenoid reactions, chronic graft-versus-host disease (cGVHD) following allogeneic bone marrow transplant, chronic minor oral trauma (e.g., use of an orthodontic splint), use of tartar-control toothpastes and alcohol-containing mouth rinses, smoking, taking alginate impressions, and in patients with oral cancer following chemoradiation therapy.[121,122] Superficial mucoceles have also been reported at the margins of excised oral cancer specimens.[123]

Epidemiology

The true incidence of mucoceles is difficult to definitively state since the term "mucocele" has been used to refer to both the extravasation and retention types and often it is unclear whether epidemiologic data has been reported for each type separately or in aggregate.[124] Mucoceles in general occur most commonly in patients aged 10 to 29 years which may reflect a higher prevalence of exposure to trauma or presence of parafunctional oral habits in this age group.[125] There is no significant gender predilection for the extravasation and retention type mucoceles. The extravasation type of mucocele is the more common histological subtype and it mainly affects the lower lip. The floor of mouth, ventral tongue, and buccal mucosa are other common sites of mucoceles, with the palate and retromolar area representing less frequent sites of involvement.[124]

Determination of the true incidence of superficial mucoceles is also challenging as these lesions are uncommon, and, because of their transient nature, they are often not biopsied or reported. They most commonly arise in women 30 years of age or older. The most commonly involved sites include the soft palate, retromolar pad, and buccal mucosa.[124]

Clinical Manifestations

Mucoceles present as discrete, smooth surfaced swellings that may or may not be painful. They range in size from a few millimeters to a few centimeters in diameter. Mucoceles occurring closer to the mucosal surface often have a characteristic blue hue, whereas deeper lesions are more diffuse and are usually covered by normal-appearing mucosa. The lesions may vary in size over time; superficial mucoceles in particular are frequently traumatized, causing them to drain and deflate. Mucoceles that continue to be traumatized are most likely to recur and may develop surface ulceration (Figure 9-14).

Figure 9-14 Mucocele of the lower right labial mucosa with surface ulceration.

Extravasation mucoceles appear most frequently in areas where trauma occurs: the lower lip, buccal mucosa, tongue, floor of the mouth, and retromolar region. These types of mucoceles are most common in children and teenagers. Retention mucoceles are more commonly found on the upper lip, palate, buccal mucosa, floor of the mouth, and rarely the lower lip, and usually afflict an older patient population. Distinctive-appearing mucoceles can also arise in the glands of Blandin and Nuhn on the ventral surface of the tongue. These have a characteristic appearance of a soft, fluctuant polypoid mass.[126] Superficial mucoceles typically appear as multiple, smaller (usually < 3mm) lesions of the soft palate and buccal mucosa. They are short-lived, burst easily, leaving an ulcerated surface, and have a tendency to recur. Diagnosis can often be made clinically.

Differential Diagnosis

Although the development of a bluish lesion after trauma is highly suggestive of a mucocele, other lesions (including salivary gland neoplasms, soft tissue neoplasms, and vascular malformations) should be considered in the differential diagnosis. Differential diagnoses to consider for superficial mucoceles include vesiculobullous diseases, including mucous membrane pemphigoid and bullous lichen planus. Biopsy for definitive diagnosis may be warranted.

Management

Small or superficially located mucoceles may spontaneously resolve whereas persistent lesions may require treatment. Conventional definitive surgical treatment of mucoceles involves removal of the entire lesion along with the feeder salivary glands and duct. Incomplete removal of the mucocele may result in recurrence. Surgical management can be challenging since it can cause trauma to adjacent minor salivary glands (leading to the development of a new mucocele), or to adjacent nerves, such as the branches of the mental nerve. Alternative treatments that have been used with varying degrees of success include electrosurgery, cryosurgery using liquid nitrogen, laser therapy and micromarsupialization, intralesional injections of corticosteroids, and sclerotherapy with pingyangmycin.[127–129]

Since the natural course of superficial mucoceles is typically self-limited, no treatment is usually necessary. Identification of a source of trauma or inciting agent and its elimination may prevent recurrence. Additional treatments that have been used include topical corticosteroids and laser therapy.[130] Persistence of the lesions or atypical appearance may prompt biopsy.[121]

Ranulas

Etiology and Pathogenesis

A form of mucocele located in the floor of the mouth is known as a ranula (Figure 9-15), named due to its resemblance to the underbelly of a frog (Latin rāna ["frog"]). Ranulas are believed to arise from the sublingual gland usually following mechanical trauma to its ducts of Rivinus, resulting in extravasation of saliva. Other proposed causes include an obstructed salivary gland duct (e.g., due to sialolith) or ductal aneurysm. The tendency of ranulas to develop in the sublingual gland is thought to be due to the gland's continuous salivary secretion which precludes effective sealing of mucous extravasation via fibrosis.

Ranulas are categorized anatomically as being oral ("simple," "superficial," "nonplunging"), plunging ("cervical," "diving"), or mixed, having both oral and plunging

Figure 9-15 Ranula of the right floor of mouth. *Source:* Courtesy of Dr. Michael D. Turner, New York University.

components.[131] The oral ranula remains confined to the sublingual space, while in the plunging ranula, extravasated mucus from ruptured sublingual gland acini passes around the posterior border of the mylohyoid muscle or through a hiatus in the muscle, and dissects along facial planes beyond the sublingual space.[132] There is also the rare congenital ranula, which may be detected *in utero*, which is speculated to develop due to narrowing and obstruction of the main sublingual duct or acini causing extravasation of mucous into the surrounding tissues.[133]

Epidemiology

Ranulas appear most commonly in the second and third decades of life but have been reported in a wide age range of patients including infants and the elderly. The incidence of ranulas appears to vary between populations. Studies indicate that those of Maori and Pacific Island Polynesian descent are 10 times more likely to develop plunging ranulas than Europeans. There is also a significantly greater incidence of plunging ranula in those of Asian descent, especially those with familial origins in China.[131]

While the oral ranula is more common in females, the plunging ranula has a distinct male predilection.[131] This too, however, appears to vary between populations. Studies from Asia and Finland indicate a male predominance, whereas in New Zealand, there appears to be an equal gender distribution.[134] Interestingly, oral ranulas tend to form on the left side, whereas plunging and mixed ranulas occur more often on the right side.[131] The reason for these patterns is unclear.

Trauma, surgery, or other manipulation of the floor of the mouth are risk factors for the development of ranulas. A congenital predisposition toward ranulas has been suggested associated with anatomic variation in the sublingual gland ductal system, dehiscence of the mylohyoid muscle, and presence of ectopic sublingual gland tissue.[135,136]

Clinical Manifestations

An oral ranula typically appears as a painless, slow-growing, fluctuant, movable mass in the floor of the mouth. Ranulas in the area of the sublingual caruncle may obstruct Wharton's duct causing a temporary swelling in the submandibular region upon gustatory stimulus. Usually, oral ranulas form to one side of the lingual frenulum, but if the ranula extends deeper into the soft tissue, it can cross the midline. As with mucoceles, oral ranulas located more superficially can have a bluish hue. Oral ranulas vary in size; most are less than 1 cm in diameter but they may reach up to and beyond 5 cm with larger lesions causing elevation or deviation of the tongue.

The plunging component of a ranula will present as a soft, fixed swelling of the neck often involving the submandibular space or deeper cervical fascial spaces. While most are painless, some patients experience pain. The lesions may undergo intermittent spontaneous drainage but never fully resolve. In a patient with an early mixed ranula, the intraoral swelling may present prior to the cervical swelling becoming clinically evident.[131] Congenital ranulas in a newborn present clinically in a similar manner to other ranulas. Additional signs in an infant may include feeding difficulties, airway compromise, failure to thrive, dysphagia, snoring, and obstructive sleep apnea.[137]

Differential Diagnosis

The diagnosis of a ranula is based on clinical examination, imaging, and, ultimately, excisional biopsy. The characteristic clinical appearance of the oral ranula makes its identification easy, but imaging is indicated to determine the extent of the lesion, for surgical planning purposes, and to help rule out other similarly appearing lesions such as a hemangioma, lymphangioma, dermoid cyst, or benign or malignant salivary gland neoplasm. Where there is a cervical swelling consistent with a plunging ranula, the differential diagnosis includes other causes of neck swelling such as a thyroglossal duct cyst, epidermoid cyst, and cystic hygroma, for example. Presence of both an oral and cervical swelling is highly suggestive of a mixed ranula.

Fine-needle aspiration biopsy, ultrasound, CT with contrast, and MRI have been used to characterize ranulas. Fine-needle aspiration biopsy will demonstrate inflammatory cells and mucus while biochemical analysis of aspirated fluid will show a high protein content and amylase. Ultrasound is often used for oral ranulas and to diagnose congenital ranulas *in utero*, while CT with contrast and MRI are suggested modalities for evaluation of suspected plunging ranulas.[138] MRI, in particular, allows for superior localization of the lesion and allows for evaluation of the associated ductal anatomy. Ultimately, definitive diagnosis requires excisional biopsy.

Management

While no standard treatment for ranulas has been established, for both oral and plunging ranulas, transoral resection of the sublingual gland is associated with the highest cure rate overall and is most likely to prevent recurrences.[119,139] While a transoral resection is the preferred approach for the isolated oral ranula, in the mixed ranula, a combined transcervical and transoral approach is often used to access the lesion below the mylohyoid muscle as this can be difficult using a transoral approach alone.[140]

Since resection of the sublingual gland is an invasive procedure requiring general anesthesia and is associated with complications such as nerve injury, damage to Wharton's duct, or bleeding, other treatments have been investigated. These include micromarsupialization or marsupialization to

form a drainage tract, injection of a sclerosing agent (e.g., OK-432) to induce fibrosis, aspiration only, and laser excision or cryosurgery, all of which are associated with varying degrees of success, recurrence, and complications. Reports of spontaneous regression of ranulas also exist and, therefore, some would advocate an initial period of surveillance.[137]

Congenital ranulas may be discovered on routine obstetric ultrasound allowing for optimal treatment planning. Management of the congenital ranula may involve the *ex utero* intrapartum (EXIT) procedure in which there is controlled partial delivery of the fetus, while maintaining placental circulation, to allow the airway to be secured. Once this has been accomplished, the neonate is delivered. A postnatal assessment is made once the patient's condition has stabilized to determine the appropriate definitive management of the ranula.[141]

Inflammatory and Reactive Conditions

Necrotizing Sialometaplasia

Etiology and Pathogenesis

Necrotizing sialometaplasia (NS) is a benign, self-limiting, reactive inflammatory disorder most frequently affecting minor salivary glands and, rarely, the major salivary glands and mucoserous glands of the upper respiratory tract. NS has also been reported associated with both benign and malignant neoplasms.[142] Clinically and histopathologically, NS can resemble malignancy and its misdiagnosis has resulted in unnecessary radical surgery.

Although the definitive etiology is undetermined, NS likely represents a local ischemic event leading to infarction, subsequent tissue necrosis, repair, and metaplasia. Infectious processes or an immune response to an unknown allergen have also been proposed to play a role.[143]

Epidemiology

NS has been reported to constitute about 0.03% of all biopsied oral lesions; however, as it is often self-limiting, it may not be biopsied and reported and therefore the true incidence is unknown. It has been reported in patients ranging in age from 17 to 80 years and has a male predominance especially in those older than 40 years.[144,145] The sites most often involved with respect to NS arising in the oral minor salivary glands are the palate, retromolar pad, gingiva, labial mucosa, tongue, and buccal mucosa.

Development of NS has been associated with smoking, local injury, blunt force trauma, denture wear, dental and surgical procedures, and administration of local anesthesia. It has been reported in pregnant patients and those with diabetes mellitus, sickle-cell disease, histories of cocaine or alcohol abuse, anorexia, bulimia, and chronic vomiting.[144]

Clinical Manifestations

Most often, NS presents as a painful, rapidly progressing swelling of the hard palate with central ulceration and peripheral erythema. The associated pain is often described as sharp and may precede mucosal changes. Numbness or anesthesia in the associated area may be an early finding. The lesions typically are of rapid onset and range in size from 1 to 3 cm.[146] They may develop anywhere salivary gland tissue exists, most frequently on the hard palate, retromolar pad, gingiva, labial mucosa, tongue, and buccal mucosa, but also on the tonsils, in the nasal cavity, trachea, maxillary sinus, and, rarely, the parotid gland.[144] Although the lesions are usually unilateral, bilateral cases have been reported. Lesions often develop shortly after trauma but there are reports of NS developing weeks after an inciting event or even in the absence of trauma.

Differential Diagnosis

NS of the hard palate clinically resembles salivary gland malignancies, particularly the mucoepidermoid carcinoma and adenoid cystic carcinoma, although the rapid onset of NS may be a distinguishing feature. At other sites, it may resemble other malignancies, such as squamous cell carcinoma or metastatic cancer, or other causes of ulceration, such as major aphthous stomatitis, secondary syphilis, and primary oral tuberculosis.

Pathology

Histopathologically, NS may present with an array of findings. Typically, there is necrosis of the salivary glands with preservation of the lobular architecture. Granulation tissue, and a mixed inflammatory cell infiltrate including lymphocytes, histiocytes, neutrophils, and eosinophils is often present. There may be pseudoepitheliomatous hyperplasia of the mucosal epithelium and squamous metaplasia of the salivary ducts. Most significantly, there are no malignant cells. In more chronic lesions, pseudoepitheliomatous hyperplasia and ductal metaplasia are more prominent and necrosis may not be as evident.[146]

Management

NS is usually a self-limiting condition resolving within 3 to 12 weeks. During this time, supportive and symptomatic treatment is usually adequate. Appropriate analgesics combined with use of an antiseptic mouthwash, such as 0.12% chlorhexidine gluconate, is recommended. Surgical intervention is typically not required; however, there are reports of resolution following debridement for particularly large lesions and those secondarily infected with bacterial species and *Candida*.[146]

Cheilitis Glandularis

Etiology and Pathogenesis

Cheilitis glandularis (CG) is a rare, chronic inflammatory disorder affecting the minor salivary glands and their ducts in which mucous and/or purulent discharge is secreted from dilated ductal openings. Although the etiology of CG is still undetermined, it has been suggested that it is an autosomal dominant hereditary disease. There is evidence that the expression and possibly the function of some of the aquaporin proteins in the minor salivary glands may be altered in CG, resulting in abnormalities in water flow leading to production of the characteristic thick discharge.[147]

Epidemiology

Because of its rarity, the true incidence and prevalence of GC is unknown. Most reports of CG have been in middle-aged and elderly men with fewer cases reported in women and children. The condition occurs more frequently in fair-skinned adults and patients with albinism. Proposed predisposing factors include poor oral hygiene, chronic exposure to sunlight (i.e., UV radiation) and wind, smoking, and an immunocompromised state.

Clinical Manifestations

CG presents with secretion of mucoid material or purulence from dilated ostia of swollen minor salivary glands. It most commonly affects the lower lip, but may involve both upper and lower lips, upper lip alone, buccal mucosa or palate, and in some cases, multiple sites simultaneously.[148] The discharge often adheres to the vermilion causing discomfort. Edema and focal ulceration may also be present.

CG has been subclassified into three clinical types: simple, superficial suppurative, and deep suppurative. In simple CG, there are multiple painless lesions, dilated ductal openings, and numerous small nodules that may be palpable. There is a lack of inflammation but mucinous material can be expressed on application of pressure. Infection of the simple type lesions may result in progression to the superficial or deep suppurative types. Superficial suppurative CG is characterized by superficial ulceration, painless crusting, swelling, induration and a mucinous exudate is often apparent at the ductal openings. In the deep suppurative type, infection of the deeper tissues results in abscess formation and fistulae.[149]

Differential Diagnosis

CG may present a diagnostic challenge to clinicians since its appearance is akin to orofacial granulomatosis and actinic cheilitis. The differential diagnosis of CG also includes multiple mucoceles, chronic sialadenitis, factitious cheilitis, and benign and malignant neoplasms of the minor salivary glands.

Pathology

The characteristic clinical and histopathologic presentation are used to make the diagnosis of CG. The histopathologic appearance may vary depending on the severity of disease but is generally nonspecific. Variably dilated and tortuous minor salivary gland ducts, accumulation of mucous in the ductal lumina, chronic sialadenitis, glandular fibrosis, oncocytic metaplasia, and mucous metaplasia may be present to variable degrees.[150]

Management

Where possible, predisposing factors should be addressed. Neutral lip balms, emollients, and sunscreens should be applied to vulnerable areas. Excessive exposure to sun and wind should be avoided. Conservative treatment of CG may involve use of topical, intralesional, or systemic steroids, systemic anticholinergics, systemic antihistamines, topical tacrolimus, and/or antibiotics. Refractory cases may require surgical intervention such as cryosurgery, vermillionectomy, and/or labial mucosal stripping.

Several reports document the development of squamous cell carcinoma in areas affected by CG, leading some to call CG a premalignant lesion.[148] Currently, the association between CG and squamous cell carcinoma is not well defined, but it does appear that co-occurrence of lower lip CG with actinic changes represent an increased risk of development of squamous cell carcinoma and therefore close clinical monitoring, with biopsy as warranted, is advised.[151]

External Beam Radiation-Induced Pathology

For a complete discussion on the effects of external beam radiation on the salivary glands, please refer to Chapter 8 "Oral Complications of Nonsurgical Cancer Therapies: diagnosis and Treatment".

Internal Radiation-Induced Pathology

Etiology and Pathogenesis

Radioactive iodine (^{131}I) [RAI] is standard treatment for papillary and follicular thyroid carcinomas following thyroidectomy, or in cases of suspected or known metastases to the thyroid. It may also be indicated for treatment of hyperthyroidism due to Graves' disease and hyperactive thyroid nodules. A significant portion of the RAI taken up by thyroid tissue is concentrated and secreted through the salivary glands resulting in radiation exposure and potential damage.[152] In contrast to external beam radiotherapy, RAI's effects within the oral cavity are limited to salivary gland tissue, where it causes relatively less glandular destruction.

Salivary gland toxicity due to RAI is related to cumulative dose.[153] Standard doses of RAI often cause obstructive

symptoms, while hyposalivation from parenchymal damage is more often observed with larger doses or repeated treatments. RAI can also lead to glandular fibrosis and permanent salivary gland hypofunction.[154] Acute side effects associated with RAI include ageusia, salivary gland swelling, and pain, while long-term side effects include recurrent and chronic sialadenitis with xerostomia, hyposalivation, stomatitis, and dental caries.[155]

Clinical Manifestations

The effect of RAI on the salivary glands can be mild to severe and is gland dependent. Patients may be asymptomatic or complain of parotid gland swelling (usually bilaterally), pain, xerostomia, and decreased gland function, as early as after the first treatment.[156] Signs and symptoms of the effects of RAI on salivary flow may initially go unnoticed as the more radioresistant submandibular and sublingual glands compensate for the decreased function of the parotid glands.[157]

Symptoms of acute, early sialadenitis usually abate within a few days after RAI but salivary gland swelling may persist. This may be accompanied by obstructive symptomatology with swelling and pain during salivary stimulation, not unlike that associated with sialolithiasis. The patient may also complain of a salty taste.[156] Ageusia or dysgeusia immediately following RAI may be temporary or, at higher doses, permanent.

Diagnosis

Diagnosis of RAI-induced salivary gland pathology can be established in a patient with a history of ^{131}I administration along with symptoms of chronic salivary gland dysfunction. Salivary gland scintigraphy using IV technetium 99m pertechnetate can be used to determine the extent of parenchymal damage and assess the acinar and ductal function of both the parotid and submandibular glands.[157,158]

Prevention and Management

RAI-induced salivary gland injury is irreversible; however, residual functioning salivary gland tissue is often present and responsive to therapy.[157] Following administration of ^{131}I, patients should undergo an aggressive salivary stimulation routine employing sugar-free lozenges, sour candies, and gums to stimulate salivary flow and aid in clearing the ^{131}I, thereby potentially decreasing damage.[156] Stimulation of salivary flow by these means should not be initiated within the first 24 hours after ^{131}I therapy, however, as this may increase the salivary gland side effects.[159]

Pilocarpine and cevimeline used before and after RAI may decrease transit time through the salivary glands, thereby diminishing exposure. Avoidance of anticholinergic medications during RAI, where possible, is also helpful. In cases of RAI-associated sialadenitis, external massage of the gland or use of duct probing to encourage outflow of retained saliva and debris may be indicated. Antibiotics may be necessary if infection is suspected due to the presence of suppuration or fever.[156]

Sialendoscopy has shown some promise in relieving obstructive symptoms and improving salivary flow in patients with early ^{131}I-induced sialadenitis by means of duct dilation and removal of mucus plugs and debris.[155] Following completion of RAI, patients with persistent xerostomia and/or hyposalivation should be counselled and managed appropriately (see section: Management of Xerostomia and Hyposalivation).

IgG4-Related Disease

Etiology and Pathogenesis

In 2003, Kamisawa and Okamoto proposed the existence of a new clinicopathologic entity: IgG4-related disease (IgG4-RD). The basis of their proposal was the observation that there were several multiorgan, inflammatory, mass-forming lesions with increased IgG4-positive plasma cells and shared histopathologic findings. These conditions have since been observed in nearly every organ system including the salivary and lacrimal glands.

The features common to all IgG4-RDs are elevated serum and tissue levels of IgG4, a characteristic histologic appearance, and response to immunosuppressive treatment. Chronic sclerosing sialadenitis (previously known as the "Küttner Tumor") and Mikulicz's disease (bilateral parotid and lacrimal gland enlargement) are now considered manifestations of IgG4-related disease.[160] The definitive etiopathogenesis of IgG4-RD is not known. Both IgG4 and T cells have been implicated, but their exact role is not established.[161]

Epidemiology

Because of its relatively recent recognition, the true incidence and prevalence of IgG4-RD have not been established. IgG4-RD typically presents in adults in their fifth, sixth, and seventh decades, although IgG4-RD has been reported in children.[161] Men tend to be affected more often than women overall, but studies indicate that Asian patients and women are at increased risk for head and neck disease. Risk factors have also not been well established. Antecedent malignancy, tobacco and asbestos exposure, and other environmental exposures, especially occupational antigens (e.g., solvents), have been suggested.[162]

Clinical Manifestations

IgG4-RD can present in a myriad of ways, but at its onset, it often appears in an indolent fashion and may be discovered incidentally. Patients may present with manifestations isolated to a single organ, or in multiple organ systems

simultaneously or metachronously.[162] The majority of patients will present with a nonpainful mass of the head and neck region but some will present with systemic signs and symptoms such as weight loss, fever, and malaise.[163] Lymphadenopathy, when present, is often symmetric with mildly enlarged, well-defined lymph nodes around the affected organ or organs.[162] The most common sites of lymphadenopathy are the supraclavicular, cervical, and submandibular regions.[164]

IgG4-RD of the salivary glands presents in the following decreasing order of prevalence: submandibular, parotid, sublingual, and minor salivary glands.[165] A typical presentation is a single nontender, persistently (> 3 months) enlarged gland, but involvement of bilateral glands has been described. The saliva secretory function of the gland may be normal or slightly reduced.

Differential Diagnosis

IgG4-RD of the head and neck has numerous mimics depending upon the organ system involved. Differential diagnosis with respect to salivary gland involvement may include salivary gland neoplasms including lymphoma, systemic diseases such as Sjögren's syndrome and sarcoidosis, infectious sialadenitis, metastatic cancer, granulomatosis with polyangiitis, and eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome).[164]

Imaging and Pathology

The diagnosis of IgG4-RD can be challenging as the extent of disease may be variable, there can be a wide spectrum of presentation, and it can clinically mimic many other pathoses. Diagnosis is dependent upon clinical examination, imaging, serological and histopathologic findings. Proposed diagnostic criteria suggest that definitive diagnosis can be reached only when three criteria are fulfilled: evidence of diffuse/localized swelling or mass in one or more organs, elevated serum IgG4, and a marked lymphoplasmacytic infiltration and fibrosis with IgG4+ plasma cells upon histopathologic examination.[166,167]

Imaging, particularly US, CT, and MRI, can be helpful in diagnosis and determining the extent of disease, while 18F-fluorodeoxyglucose positron emission tomography (FDG-PET)/CT may be useful for staging patients and for evaluating response to treatment.[164] It has been recommended that patients with IgG4-related disease also undergo a systemic workup at diagnosis to determine the extent of disease and to screen for non-Hodgkin lymphoma, as IgG4-RD may be a predisposing condition.[168]

Management

Treatment for IgG4-RD is dependent upon the extent and severity of disease. Close clinical observation only may be appropriate for patients with mild submandibular swelling or asymptomatic lymphadenopathy. Surgery may be considered where disease is confined to a single gland. High-dose corticosteroid therapy is often the first-line medical treatment and can help improve salivary gland function. Steroid-sparing agents, such as mycophenolate mofetil, tacrolimus, cyclophosphamide, azathioprine, and 6-mercaptopurine, are also used along with the anti-CD20 antibody rituximab.[164]

Viral Diseases

The viruses responsible for the majority of virally-induced salivary gland enlargement are the mumps paramyxovirus, cytomegalovirus (CMV), HIV, and hepatitis C virus (HCV). Echoviruses, the Epstein–Barr virus (EBV), parainfluenza viruses, and choriomeningitis virus infections have also been linked to reports of nonsuppurative salivary gland enlargement. Here we will highlight the more common viral salivary gland diseases.

Paramyxovirus Mumps (Epidemic Parotitis)

Etiology and Pathogenesis

Mumps is an acute viral infection caused by an enveloped, single stranded RNA-containing paramyxovirus. The virus can be found in saliva and urine and is transmitted by inhalation of infectious droplets, by direct contact, or by autoinoculation (i.e., interaction with virus-laden fomites followed by contact with the nose or mouth). The mechanism behind the development of mumps parotitis is unknown but it has been hypothesized that it results from lymphocytic infiltration and destruction of periductal cells leading to obstruction of salivary gland ducts.[169]

The Centers for Disease Control and Prevention (CDC) began recommending mumps vaccination for children in 1977. Live-attenuated mumps vaccines are currently provided as the MMR (measles, mumps, and rubella) vaccine and more recently combined with the varicella vaccine (MMRV).[170] Current guidelines call for initial vaccination at 12–15 months of age and a second dose at 4–6 years of age. All persons born during or after 1957 are advised to receive between one and three doses.[171]

Prior to the development of the vaccine, viral mumps was among the most common infectious salivary gland diseases. Despite widespread vaccination campaigns, mumps has made a comeback in many countries including those that had previously reported good control. Recent outbreaks have occurred in the United States, the United Kingdom, Sweden, the Netherlands, Canada, Australia, Belgium, and a number of other countries.[170] Therefore, viral mumps should be considered in all cases of acute nonsuppurative salivary gland

inflammation in both vaccinated and unvaccinated patients. Outbreaks among vaccinated populations may be due to declining immunity and may prompt health authorities to recommend additional doses of vaccine among susceptible patients. Postexposure prophylaxis with the MMR vaccine is not recommended, however.

Complications of mumps include meningitis and encephalitis; mumps encephalitis has an approximately 1.5% mortality rate.[172] Deafness, myocarditis, thyroiditis, pancreatitis, hepatitis, and oophoritis are additional complications. Males may develop epididymitis and orchitis, resulting in testicular atrophy and diminishment in fertility if the disease occurs in adolescence or later.

Epidemiology

Mumps only became a nationally reportable disease in the United States in 1968, but there were an estimated 212,000 cases in the United States in 1964. A vaccine was recommended for routine use in the United States in 1977, after which time, reports of mumps decreased rapidly; approximately 3000 cases were reported annually in 1983 to 1985. Since then, several mumps outbreaks among highly vaccinated populations have been reported. Most recently, from January 2016 to June 2017, US health departments reported 150 outbreaks involving 9200 cases.[171]

In the absence of preventive measures, mumps typically occurs most frequently in childhood, especially in children between 5 and 9 years of age. Although mumps can occur in any age group, adolescents, young adults, and, generally, those in close-contact settings (e.g., on college campuses, in dormitories, prisons, summer camps, military garrisons, and ships) are considered at increased risk, and have mainly been involved in outbreaks.[173] Prolonged, close contact with an infected patient, underimmunization, or lack of immunization are risk factors.

Clinical Manifestations

Viral mumps typically presents with a 1 to 2 day prodrome of headache, fever, fatigue, anorexia, myalgia, and malaise followed by nonpurulent salivary gland enlargement. About 25% of cases present with unilateral salivary gland swelling, with swelling eventually developing in the contralateral gland; 95% of symptomatic cases involve the parotid gland only, while about 10% of cases involve the bilateral submandibular and sublingual glands concomitant with parotid gland involvement.[172] A minority of cases involve the submandibular glands alone.

Onset of glandular enlargement is sudden and the gland is painful to palpation with edema of the overlying skin and duct orifice. Glandular swelling increases over the next few days, lasting about 1 week. Trismus and pain with salivation, particularly if there is partial duct obstruction, is common. Where parotid enlargement is severe, the mandibular angle may be obscured and there may be superolateral lifting of the ear.[173]

Differential Diagnosis

An odontogenic infection causing facial swelling should be ruled out. The location and configuration of the swelling can help distinguish the cause (Figure 9-16). Other causes of parotitis, including other forms of viral parotitis (e.g., due to CMV, HIV, and hepatitis C virus), must also be considered.

Laboratory Findings

The CDC advises collection of both a buccal swab and blood specimen as soon as possible in all patients with clinical signs and symptoms consistent with mumps. Viral detection can be performed using molecular assays, such as real time reverse transcription quantitative PCR (RT-qPCR), and culturing in cell lines. To obtain a buccal swab specimen during

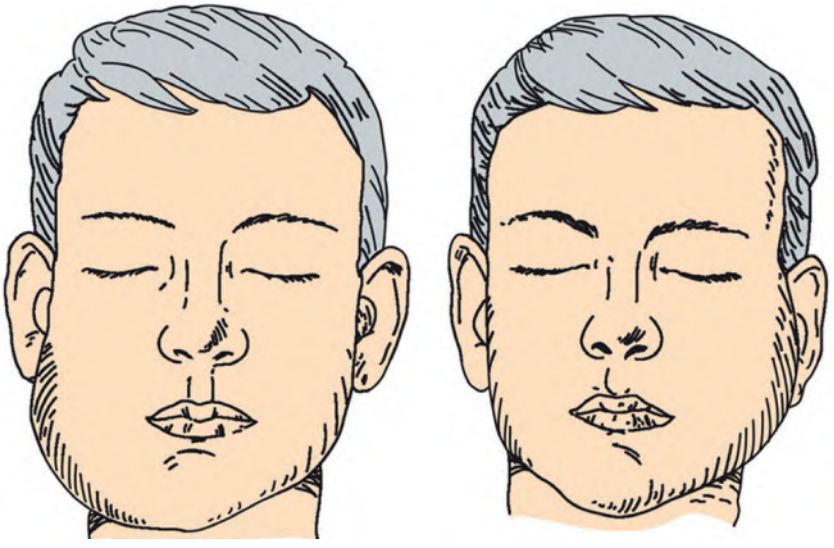

Figure 9-16 Left: right-sided facial swelling of typical location and configuration associated with abscessed mandibular molars. Right: Left-sided facial swelling of typical location and configuration associated with viral mumps affecting the parotid gland.

an acute infection, the patient's parotid gland is massaged for 30 seconds to express infected saliva and a swab is rubbed along the buccal mucosa near Stensen's duct. The swab is placed in 2 mL of a standard viral transport medium and shipped to the laboratory at 4 °C.[171]

Management

Treatment of viral mumps is supportive and may involve the use of analgesics, antipyretics, and antiemetics. Mumps is considered contagious 2 days prior to and 5 days after the onset of parotid swelling.[174] To prevent spread of infection, the CDC recommends that mumps patients are isolated and standard and droplet precautions are followed for 5 days after parotitis onset. Mumps is a nationally reportable disease in the United States and the CDC advises reporting of all cases to the appropriate state or local health department.[171]

CMV Infection

Etiology and Pathogenesis

Human cytomegalovirus (CMV) is a genus in the order *Herpesvirales*. The human betaherpesvirus 5 (HHV-5), commonly referred to as CMV, is the species which commonly infects salivary glands and is the major cause of non-EBV infectious mononucleosis in the general population. Infection presumably occurs as a result of exposure of mucosal surfaces to infectious virus. The virus attaches to and enters susceptible epithelial cells where it undergoes lytic replication. The resulting progeny virions are then released to infect the adjacent submucosal cells. Persistent infection occurs due to dissemination of these virions into tissues that support and harbor them, including the salivary glands. Tissue damage occurs due to direct viral cytopathic effects and host response. As with other members of the *Herpesvirales*, CMV can become latent after initial infection and may reactivate when favorable conditions present.

The majority of CMV infections are asymptomatic, especially in healthy individuals; however, in immunocompromised patients and neonates, infection can be life threatening. Transmission from children to adults or between children typically occurs through fomites, urine, saliva, and respiratory secretions. Between 11% and 24% of children attending daycare centers have CMV in their saliva and a large percentage of healthy adults have serum antibodies to the virus.[175,176]

CMV can be cultured from blood, saliva, feces, respiratory secretions, urine, and other body fluids. Horizontal transmission can occur through blood transfusion, solid organ transplant, hematopoietic stem cell transplant, and sexual contact. High rates of seropositivity are found in men who have sex with men, intravenous drug users, sex workers, and individuals who have undergone multiple transfusions.[177]

Transplacental transmission in the neonate can result in a congenital syndrome involving prematurity, low birth weight, and various congenital malformations. The mortality rate has been estimated at less than 5% of cases in symptomatic neonates.[178] Perinatal infection occurs in 1–3% of all live births and is thought to be due to transmission from breast milk, saliva, fomites, or urine.[179]

Clinical Manifestations

In the young, otherwise healthy adult, acute CMV infection presents as a mild, self-limiting, mononucleosis-like disease. Patients will commonly experience fever, malaise, and myalgia but pharyngitis and cervical lymphadenopathy are seen less frequently than in EBV-associated mononucleosis. Acute sialadenitis, presenting as diffuse, painful swelling of the parotid and submandibular glands with associated xerostomia, may also occur. CMV infection in immunocompetent patients has been associated with colitis, encephalitis, myocarditis, and other organ-specific complications.[180]

In the acute infection in neonates, the child will appear ill within days of infection. The child may develop a sepsis-like syndrome with associated hepatosplenomegaly, abnormal blood counts with lymphopenia, neutropenia, and thrombocytopenia, abnormal transaminases, and pneumonitis.[181] Acute CMV infection can also cause parotitis in infants.[182]

Long-term sequelae of early postnatal CMV infection include neurological problems such as sensorineural hearing loss. Developmental tooth defects may also be a consequence including diffuse enamel hypoplasia, attrition, enamel hypomaturation, and yellow discoloration of dentin.[183]

In immunocompromised adults, the impaired immune system permits viral replication resulting in a disseminated infection. Patients taking immunosuppressive medications and patients with hematologic abnormalities or HIV infection are particularly susceptible to severe CMV infections. Infection may result from reactivation of endogenous virus or receipt of an infected transplanted organ or blood product. Oral and maxillofacial manifestations of CMV in immunosuppressed patients include persistent oral ulcerations and major salivary gland infections, with or without concomitant alterations in salivary flow. In patients with HIV, the degree of CMV-induced sialadenitis and/or xerostomia has been found to be proportional to the HIV load and inversely proportional to the CD4+ T-cell count.[182]

Laboratory Findings

Several diagnostic modalities for CMV are available, including serology, qualitative and quantitative PCR, and histopathology. The choice of test may be based on the status of the patient's immune system. Diagnosis of primary CMV infection in immunocompetent hosts is usually made using serologic studies using an ELISA to detect the presence of CMV-specific IgG or IgM. Diagnosis in immunocompromised patients relies on clinical history, presentation, and

quantitative PCR tests for detecting viral DNA. Histopathologic examination of CMV-infected tissue may show large, atypical cells with inclusion bodies, resulting in a characteristic "owl eye" appearance. However, as these cells may be scarce and undetectable, CMV-specific immunohistochemistry staining is recommended.[184]

Management and Prevention

Most cases of primary CMV infection in immunocompetent adults present with minimal or no symptoms. In those with a symptomatic, mononucleosis-like infection, the disease typically lasts a few days to weeks and therefore only supportive, symptomatic care (i.e., analgesics, rest, and hydration) is required. Antiviral therapy is usually not indicated.[180]

Immunocompromised patients, including transplant recipients, are at particular risk for CMV infection and reactivation. CMV prophylaxis in patients undergoing transplant may involve the use of valganciclovir or ganciclovir. In November of 2017, letermovir, a CMV-terminase inhibitor, was approved by the FDA for CMV prevention in hematopoietic cell transplant recipients.[185]

Transplant recipients who develop CMV disease may be required to discontinue immunosuppressive therapy and start antiviral treatment with ganciclovir, valganciclovir, foscarnet, or cidofovir. Adjunctive treatment may involve the use of cytomegalovirus immune globulin or intravenous immune globulin (IVIG). The choice of antiviral agents is influenced by the severity of disease, level of viremia, patterns of drug resistance, and response to treatment, among other factors. The length of treatment is dependent on CMV viral load (monitored on a weekly basis) and clinical signs and symptoms. Treatment continues until clinical signs and symptoms of CMV disease have completely resolved and at least two consecutive negative samples are obtained.[185,186]

HIV-Associated Salivary Gland Disease

Etiology and Pathogenesis

The term HIV-associated salivary gland disease (HIV-SGD), coined by Schiødt et al. in 1989, has been used to describe major salivary gland enlargement and/or xerostomia in HIV patients in the absence of xerogenic agents, medications, and diseases known to cause xerostomia.[187]

Both neoplastic and non-neoplastic salivary gland lesions occur with increased frequency in HIV-positive patients. Neoplasms include Kaposi's sarcoma and lymphoma of the salivary glands, which have a predilection for the parotid glands and intraparotid lymph nodes.[188] Non-neoplastic conditions often involve lymphocytic enlargement, particularly of the parotid gland, and may be referred to as cystic lymphoid hyperplasia (CLH), benign lymphoepithelial lesions (BLELs), benign lymphoepithelial cysts (BLECs), and diffuse infiltrative lymphocytosis syndrome (DILS). Many of these conditions present clinically in a similar fashion. Salivary gland swelling in the setting of HIV or AIDS can also arise due to bacterial, fungal, or viral (e.g., Hepatitis C, mumps) infections, and in patients undergoing antiretroviral therapy.[189]

Since the advent of highly active antiretroviral therapy (HAART) in the mid-1990s, the prevalence of AIDS and many HIV-associated oral lesions has decreased; with respect to HIV-SGD, however, the findings are variable. Some studies indicate an increase in HIV-SGD, particularly in developed countries, other studies show no change, and yet further studies indicate a decrease.[190,191] It is speculated that these disparities could be related to variations in HAART protocol, patient response, or an increase in life expectancy due to improved medical management. There is a male predilection for HIV-SGD; a finding consistent in both the pre-HAART and HAART eras.[188]

Clinical Manifestations

Typically, HIV-SGD presents as a unilateral or a bilateral diffuse swelling of the major salivary glands, which may or may not be painful, and which may be accompanied by generalized lymphadenopathy. When the labial minor salivary glands are affected, features of sialadenitis are present. The patient may also experience xerostomia/hyposalivation, keratoconjunctivitis sicca, and arthralgias.

Cystic lymphoid hyperplasia (CLH) is the most common HIV-associated salivary gland lesion and has been variably termed benign lymphoepithelial lesions (BLEL) or benign lymphoepithelial cysts (BLEC). CLH most commonly affects the parotid glands where it will present as bilateral nontender, slowly progressing swellings. It may also occur in the other major salivary glands, minor salivary glands, tonsils, and cervical lymph nodes.[192] As it can be the initial presentation of HIV infection, prompt identification is important.

Diffuse infiltrative lymphocytosis syndrome (DILS) is a multisystem syndrome in HIV-infected patients in which sicca syndrome occurs with extraglandular manifestations typically involving the lung, gastrointestinal tract, kidney, liver, muscle, or nerves. Because of its clinical presentation, it is often referred to as "Sjögren-like syndrome". Patients with DILS may present with sicca syndrome coupled with bilateral parotitis, lymphadenopathy, and, if the nervous system is involved, unilateral or bilateral facial nerve palsy. DILS typically occurs in patients with uncontrolled or untreated HIV infection, but it can occur independently of CD4+T-cell counts.[193] The diagnostic criteria for DILS, as initially defined by Itescu et al., require the patient to demonstrate all of the following: HIV-1 seropositivity, bilateral salivary gland enlargement or xerostomia persisting for > 6 months, and histologic confirmation of salivary or lacrimal

gland lymphocytic infiltration in the absence of granulomatous or neoplastic involvement.[194]

Imaging and Pathology

Persistent salivary gland enlargement in a patient with HIV warrants further investigation by imaging and possibly biopsy. Imaging modalities employed for evaluation of salivary gland enlargement where HIV-SGD is suspected may include US, CT, and/ or MRI. Pathologic findings on US of parotid glands affected by HIV may be of one of four recognized patterns: lymphocytic aggregations, lymphoepithelial cysts, fatty infiltration, or lymphadenopathy only.[195]

Differential Diagnosis

Since the clinical presentation of DILS, Sjögren's syndrome, and IgG4-RD are often similar, appropriate salivary, ophthalmologic, and serologic evaluation may be required to allow for differentiation. While salivary flow may be compromised in all three disorders, anti-SSA and anti-SSB autoantibodies are usually negative in DILS and IgG4-RD.

Biopsy may be indicated to help differentiate DILS from other causes of salivary gland enlargement, such as Kaposi's sarcoma, IgG4-RD, Sjögren's syndrome, and lymphoma. Indeed, patients with HIV have a higher incidence of non-Hodgkin lymphoma and DILS can resemble lymphoma histopathologically.[196] In DILS, there is a preponderance of CD8+ T-cells in contrast to CD4+ infiltrates that predominate in Sjögren's syndrome or IgG4 positive plasma cells predominant in IgG4-RD.

Management

HIV-SGD-related xerostomia and hyposalivation can be managed with optimized hydration, use of sugar-free lozenges, candies, and gums, dry mouth products and saliva substitutes, or other pharmacologic agents such as sialogogues (see section: Management of Xerostomia and Hyposalivation). Patients with salivary hypofunction should also be encouraged to follow a rigorous daily oral hygiene regimen incorporating the use of topical neutral fluoride and to maintain a regular schedule of dental examinations and hygiene appointments.

Treatment with HAART can result in the resolution of the histologic changes associated with DILS and CLH, but use of systemic steroids may be necessary for DILS unresponsive to HAART.[193] Other approaches and treatments for CLH have included: (1) close observation; (2) repeat aspiration; (3) antiretroviral medication; (4) sclerosing therapy (e.g., with bleomycin, sodium morrhuate, alcohol, tetracycline, or doxycycline); (5) radiation therapy; and (6) surgery.[197,198] Use of external beam radiation therapy (24 Gy in 1.5 Gy doses) has been reported with some success, but it is associated with acute mucositis, radiation dermatitis, altered taste, and xerostomia.[199]

Hepatitis C Virus Infection

Etiology and Pathogenesis

The hepatitis C virus (HCV) is an enveloped, single-stranded RNA virus of the family Flaviviridae. Infection with the virus is associated with extrahepatic manifestations such as sialadenitis and sicca syndrome. HCV is also a known oncogenic virus; chronic infection is associated with the development of hepatocellular carcinoma and there is a convincing link between chronic HCV infection and B-cell non-Hodgkin lymphoma (NHL).[200]

HCV is sialotropic, as well as being hepatotropic and lymphotropic. The virus appears to infect and replicate in the epithelial cells of the salivary gland acini. Sialadenitis is thought to develop due to a host response against ductal cells expressing viral antigens.[201] Chronic antigenic stimulation by the virus is speculated to trigger B-cell proliferation resulting in the development of lymphoma.

The majority of HCV-associated lymphomas are extranodal and involve the gastrointestinal tract and salivary glands, most commonly the parotid glands.[202,203] MALT lymphoma is the most common histotype among the primary lymphomas of the salivary glands and represents 1.7–8.6% of all salivary gland tumors and about 1% of all NHL cases.[204,205]

Clinical Manifestations

HCV infection has many extrahepatic manifestations, including sialadenitis and chronic enlargement of the salivary glands. Xerostomia, hyposalivation, and sicca syndrome are common among patients with chronic infection.[206] The reported prevalence of xerostomia ranges from 10% to 35.3% and that of hyposalivation ranges from 13% to 33%.[207] The prevalence of HCV-related sicca syndrome in patients with chronic HCV infection ranges from 4% to 57%; the large range may reflect differences in diagnostic criteria.[208]

Acute HCV infection is defined by the presence of clinical signs or symptoms of hepatitis within 6 months of presumed HCV exposure. These symptoms can include jaundice, nausea, dark urine, and right upper quadrant pain. Most patients who are acutely infected, however, are asymptomatic. Chronic HCV infection is slowly progressive and may not result in clinically apparent liver disease. Patients may be asymptomatic or present with mild, nonspecific symptoms including fatigue, nausea, anorexia, myalgia, arthralgia, weakness, and weight loss.

Because of the attendant increased risk of NHL in patients with HCV infection, any persistent glandular swelling despite treatment or the presence of salivary glands that feel indurated or nodular should undergo imaging and biopsy to rule out lymphoma or other pathology.

Laboratory Findings

The diagnosis of HCV infection is established by serologic detection of anti-HCV antibodies by ELISA and HCV RNA

by PCR. HCV RNA is first detectable in serum within days to eight weeks following exposure, while development of antibodies may be delayed up to several years in patients who have subclinical infection.

Management

The introduction of oral direct-acting antiviral agents (DAA) for hepatitis C in 2011 has changed treatment significantly. Cure rates of greater than 95% have been reported with a favorable safety profile and fewer contraindications for treatment than previous regimens. Duration of treatment is typically between 8 and 12 weeks. Prior to the use of DAA, patients with HCV received interferon alone, interferon with ribavirin, or pegylated-interferon with ribavirin for up to 48 weeks. The sustained virological response rate was inferior to DAA and was associated with numerous side effects and a reduction in quality of life.[209]

While there are no studies on the impact of DAA on HCV-associated salivary gland disease, it is speculated that rates will decline. In addition, pegylated interferon/ribavirin therapy was associated with xerostomia and temporary salivary gland hypofunction, while no such side effects with DAAs have been reported.[210] When present, hepatitis C-associated sialadenitis and xerostomia are treated symptomatically while treatment for HCV-associated lymphoma of the salivary glands is dependent on the histotype, and may be treated with chemotherapy, including DAAs.[209]

Bacterial Sialadenitis

Acute and Chronic Bacterial Sialadenitis

Etiology and Pathogenesis

Acute bacterial sialadenitis refers to a sudden-onset swollen and painful infected salivary gland, while chronic bacterial sialadenitis indicates a persistent, recurrent, or refractory infection. Bacterial sialadenitis is most common in patients with salivary gland hypofunction or with conditions that inhibit salivary flow.[211] Reduced salivary flow results in diminished mechanical flushing permitting bacteria to colonize the oral cavity where they may invade the salivary duct in a retrograde fashion and establish an infection. Recurrent infections can occur in a susceptible gland where ductal strictures developed following an episode of acute bacterial sialadenitis.[99]

Risk factors for bacterial sialadenitis include dehydration, use of xerogenic drugs, salivary gland diseases, nerve damage, ductal obstruction, irradiation, and chronic systemic diseases such as diabetes mellitus and Sjögren's syndrome; however, the majority of bacterial infections occur in patients with disease- or medication-induced salivary gland hypofunction. Poor oral hygiene can also increase the risk of infection. Elderly and infirm adults are particularly susceptible to bacterial sialadenitis due to the frequent combination of medication-induced salivary hypofunction and poor oral hygiene. Thus, although suppurative parotitis can affect persons of any age, it is predominately a disease of the middle aged and elderly.[99]

A retrograde bacterial parotitis can also occur as a complication of general anesthesia. It develops secondary to markedly decreased salivary flow during anesthesia, often because of the use of anticholinergic drugs and relative dehydration. Although the incidence has decreased significantly in the era of perioperative antibiotics, parotitis still complicates between 1 in 1000 and 1 in 2000 operative procedures. It usually occurs within 2 weeks of the procedure, with major surgeries comprising the greatest risk.[99]

Although bacterial sialadenitis occurs most frequently in the parotid glands, it can occur in any of the salivary glands. The antimicrobial activity of certain mucins, found in the saliva of the submandibular and sublingual glands, may competitively inhibit bacterial attachment to the ductal epithelium, thereby decreasing the risk. The serous parotid gland saliva also contains fewer protective lysozyme and IgA antibodies.[99] Anatomy may also play a role: tongue movements tend to clear the floor of the mouth and protect Wharton's duct, whereas the orifices of Stensen's ducts are susceptible to heavy bacterial colonization.[212]

Complications of bacterial sialadenitis include facial nerve palsy, sepsis, mandibular osteomyelitis, internal jugular vein thrombophlebitis, and respiratory obstruction.[99]

Clinical Manifestations

Patients with acute bacterial sialadenitis usually present with a sudden onset of salivary gland enlargement. Approximately 20% of cases are bilateral. The involved gland is enlarged, warm, painful, indurated, and tender to palpation, and there may be erythema of the overlying dermis.[213] If Stensen's duct is involved, it may appear erythematous and edematous. These findings may be accompanied by fever, chills, malaise, trismus, and dysphagia. The presence of dry oral mucosa may indicate systemic dehydration.

Clinical examination of the involved glands should include bimanual palpation along the path of the excretory duct. In approximately 75% of cases, purulent discharge may be expressed from the ductal orifice (Figure 9-17). Drainage from the gland may be absent, however, if there is ductal obstruction (e.g., by sialolith) or in early-stage disease.

Rarely, an abscess may develop in the setting of chronic bacterial sialadenitis. Due to the dense capsule surrounding the submandibular and parotid glands, it is difficult to determine based on physical exam alone whether an abscess has formed. A maxillofacial CT with intravenous contrast is the

Figure 9-17 Acute bacterial sialadenitis with purulent discharge from the left Stensen's duct expressed upon massage of the left parotid gland.

most sensitive and commonly used imaging modality for differentiating an abscess from other salivary gland pathology.

Differential Diagnosis

Differentiating between viral and bacterial parotitis can be challenging. In general, viral infections are bilateral, affect younger patients, have prodromal symptoms, do not involve purulent drainage, and patients appear less unwell. Although systemic symptoms follow the development of a symptomatic gland in bacterial suppurative parotitis, the order is usually reversed in viral parotitis. Sialendoscopy, US, CT, MR sialography, or percutaneous aspiration may be helpful to rule out other causes of salivary gland infections, cysts, obstructions, and neoplasms.[99]

Laboratory Findings

Bacterial parotitis is largely a clinical diagnosis. If purulent discharge can be expressed from the duct orifice, samples should be collected to undergo culture and sensitivity assays for aerobes, anaerobes, fungi, and mycobacteria, taking care to avoid contamination with intraoral flora, and a second specimen should be sent for Gram staining.[214] A complete blood count with differential may show leukocytosis with neutrophilia.

Infections are often polymicrobial; however, *Staphylococcus aureus* is by far the most commonly isolated pathogen in bacterial parotitis; institutionalized patients are particularly susceptible to infections caused by methicillin-resistant *S. aureus* (MRSA). Other common aerobes include *Haemophilus influenzae*, *Streptococcus viridans*, *Streptococcus pneumoniae*, and *Escherichia coli*. Typical anaerobes are the Gram-negative bacilli (including pigmented *Prevotella* and *Porphyromonas* species), *Fusobacterium* and *Peptostreptococcus* species.[214] *Actinomyces* species, *Mycobacterium tuberculosis*, and atypical mycobacteria are rarer causes of infection.[99]

Management

Treatment for bacterial sialadenitis involves addressing the signs and symptoms of infection, eliminating the causative bacteria, rehydration, and resolving glandular obstruction where present. Initially, this may involve the use of analgesics, fluids, heat application, glandular massage, oral hygiene products, and sialogogues. Glandular massage can be performed by instructing the patient to empty the affected parotid or submandibular gland several times a day by gently pressing the skin overlying the gland and proceeding in a forward (ventral) direction. Once the gland is no longer painful, the patient may begin to stimulate the gland using, for example, a sugar-free lemon candy, in between massaging sessions.

Antibiotic therapy may be necessary if there are signs and symptoms of systemic spread of infection. This is typically started empirically and modified later based on culture results or if there is no response to treatment. Appropriate regimens should include coverage for *S. aureus* as well as oral polymicrobial aerobic and anaerobic infections. It is estimated that up to 75% of infections are caused by β-lactamase-producing bacteria, and, therefore, treatment with antistaphylococcal penicillin, a combination β-lactamase inhibitor, or a first-generation cephalosporin is appropriate. Macrolides such as azithromycin with metronidazole can be used for those with a penicillin allergy. Intraductal instillation of penicillin or saline may also be considered for chronic bacterial parotitis or submandibular sialadenitis.[215]

Anti-inflammatory agents including steroids may help to reduce pain and swelling. Where possible, medications implicated in salivary gland hypofunction should be discontinued. With the above measures, significant improvement should be observed within 24 to 48 hours. If this does not occur, or where abscess formation is evident, incision and drainage may be considered, but this is typically reserved for exceptional cases.[99,213]

Neonatal Suppurative Parotitis

Etiology and Pathogenesis

Neonatal suppurative parotitis (NSP), also known as acute suppurative parotitis, is a rare condition in the neonate often attributed to infection by *S. aureus* or other Gram-positive cocci, Gram-negative bacilli, or anaerobic bacteria. Several

reports have also implicated MRSA. Risk factors include dehydration, male gender, low birth weight, immune suppression, ductal obstruction, oral trauma, and structural abnormalities of the parotid gland.[216]

Clinical Manifestations

NSP may affect neonates between the ages of 2 to 4 weeks. Presentation includes swelling of the affected gland or glands with overlying erythema which may be accompanied by systemic signs including fever, poor oral intake, and irritability.[216]

Diagnosis

Diagnosis of NSP is reliant on the presence of parotid swelling, which may be unilateral or bilateral, and expression of a purulent exudate from Stensen's duct with identification of pathogenic bacteria on culture. Diagnosis may be aided by ultrasound examination which may show an enlarged gland and hypoechoic areas characteristic of parotitis. Ultrasound may also help determine whether there is an additional glandular mass or abscess.[212]

Management

Treatment of NSP involves antibiotics with supportive therapy including optimizing hydration. Antimicrobial therapy is based on culture and sensitivity assays of the exudate. If an intraglandular abscess is present, surgical drainage may be necessary.[212] Complications associated with NSP include facial palsy, recurrent infection, bacteremia, sepsis, and respiratory distress. Although potential morality has been associated with NSP, no deaths have been reported in the English-language literature since 1970, possibly due to improvement in antibiotic therapy.[216]

Juvenile Recurrent Parotitis

Etiology and Pathogenesis

Juvenile recurrent parotitis (JRP) is a nonobstructive, recurrent inflammatory parotitis in children of unknown etiology. It is characterized by recurrent episodes of painful parotid gland swelling, most commonly unilateral, often accompanied by fever and malaise, hyposalivation, and xerostomia. Although most cases of JRP are idiopathic, recurrent episodes of parotitis may in fact represent an underlying variable immunodeficiency, HIV infection, or Sjögren's syndrome and therefore distinguishing JRP from these aforementioned conditions is paramount.

There is no standard definition of JRP. Multiple criteria sets have been proposed but none are universally accepted. Some have proposed including children up to the age of 16 years and those with 2 or more episodes of unilateral or bilateral swelling over the previous 6 months while excluding patients with dental malocclusion, Sjögren's syndrome, congenital IgA deficiency, and obstructive causes of swelling (i.e., sialolithiasis), as these are believed to be associated conditions with an etiopathogenesis distinct from that of JRP.[217]

The definitive etiology behind the inflammation central to JRP is unknown. It appears, however, that this inflammation leads to decreased salivary flow, which promotes ductal metaplasia resulting in a more mucinous secretion, which further decreases salivary flow. Thus, factors that diminish salivary flow (e.g., systemic dehydration) or otherwise perturb flow (e.g., congenital duct abnormalities, autoimmune duct destruction), and those that promote inflammation (e.g., infection), are thought to be contributory and result in a reinforcing cycle of glandular inflammation and decreased salivary flow.

Because the etiology of JRP is ultimately unknown and there is no standard definition of the disease, there is no agreement on risk factors and associated conditions. Factors that are proposed to increase susceptibility to JRP include a congenital malformation of Stensen's duct, dental malocclusion, poor oral hygiene, IgA deficiency, and/or an IgG subclass deficiency, and HIV infection. Allergies, diseases such as sarcoidosis, or an autoimmune process have also been proposed to increase the risk of JRP. It is unclear, however, which of these represent true risk factors and which are associated, rather than causative, conditions.[217]

Epidemiology

After mumps, JRP is the most common inflammatory disease of the salivary glands in childhood. However, due to the lack of defining criteria, it is not possible to determine its true incidence and prevalence. There are two peak ages of onset: one at 2–5 years and the other at 10 years, and there appears to be a male predominance. Recurrence rates vary tremendously depending upon the study but have been reported to be up to 30 times per year with a mean of 1.5 episodes per year.[218]

Clinical Manifestations

The patient with JRP may present with unilateral or bilateral painful parotid gland swelling and fever and may complain of malaise, xerostomia, and dysphagia due to hyposalivation. The swelling may cause blunting of the mandibular angle and there may be discharge of white, mucinous saliva upon compression of the involved gland. These signs and symptoms typically last 2–7 days, with a median of 3 days, or may persist for weeks.[218]

A patient with a long history of JRP or one who has suffered from many recurrent episodes may manifest signs and symptoms of chronic hyposalivation such as xerostomia, dry, cracked, or atrophic lips, desiccated oral soft tissues, and an increase in dental caries and oral fungal infections. The patient may be intolerant of coarse, salty, or spicy foods due to the condition of the dry oral mucosa.

The diagnosis of JRP is based on presenting medical and dental history, physical exam, laboratory findings, and supportive imaging findings. Imaging modalities may include ultrasound, MRI, MR sialography, computed tomography, and sialendoscopy (see below). Culture and sensitivity assays of discharge from the affected gland should also be performed to help rule out an infectious cause.

Differential Diagnosis

Differential diagnoses include causes of bacterial and viral parotitis, especially mumps—even in the vaccinated patient. Diffuse infiltrative lymphocytosis syndrome (DILS), associated with HIV in particular, has a similar clinical presentation. Other causes to consider include other immune deficiencies such as an IgA deficiency, autoimmune disorders such as Sjögren's syndrome, and systemic diseases such as sarcoidosis and IgG4-RD. Sialolithiasis should also be considered along with salivary gland neoplasms. Eating disorders such as anorexia nervosa and bulimia may also present with similarly enlarged glands due to a noninflammatory sialadenosis.

Imaging and Laboratory Findings

Ultrasonography, because of its availability, ease of use, noninvasiveness and lack of radiation exposure, is often the first imaging modality used in the evaluation of a patient suspected of having JRP. Findings supportive of JRP include heterogeneous glandular enlargement, with areas of hypoechogenicity of 2 to 4 mm representing sialectasis or lymphocytic infiltration. There may be enlarged intraglandular lymph nodes and microcalcifications. These findings may be present even when the disease is quiescent. Sialography can also be employed to diagnose JRP since it allows visualization of fine branches of Stensen's duct and can highlight anatomic abnormalities.

Once ultrasound or sialography have been used to initially evaluate the patient, sialendoscopy is often used to confirm the diagnosis and provide treatment. Sialendoscopy allows for assessment of the anatomy over the course of Stensen's duct as well as detection of sialoliths, sialectasis, and ductal stenoses. Findings supportive of JRP include pale-appearing ductal walls, diminished ductal vascularity, areas of stenosis, and fibrinous debris or mucus plugs.[218]

Magnetic resonance imaging and magnetic resonance sialography have also been used. They represent noninvasive methods of evaluating the ductal and parenchymal portions of the parotid gland. MR sialography in particular allows for differentiation between the inflammation present in JRP from infiltrative diseases such as lymphoma. Computed tomography (CT) or CT sialography can be employed to evaluate the glandular parenchyma and adjacent structures and are superior at depicting calcifications such as sialoliths. CT, however, comes at the expense of radiation exposure.

Laboratory exams are important for ruling out other causes of recurrent parotitis including Sjögren's syndrome and HIV-related salivary gland disease. In addition to standard lab tests such as a complete blood count with differential, an HIV test and/or autoantibody panel may be warranted. A swab of expressed discharge from the affected gland may also allow differentiation from an infectious cause of parotitis.

Management

There is currently no standard treatment for JRP. There is a tendency for spontaneous remission of the disease near the onset of puberty or late adolescence; however, some patients will continue to experience swelling episodes into adulthood.

Treatment for acute episodes aims to relieve symptoms and prevent parenchymal damage and may include glandular massage, optimization of hydration, application of heat to the affected gland, mouth rinses, sialogogues, or chewing gum. Medical therapy may include analgesics, non-steroidal anti-inflammatory drugs, corticosteroids, and antibiotics.

Sialendoscopy has quickly become the first-line interventional approach and can be performed under local or general anesthesia. It provides a means of washing out intraductal debris, including sialoliths, addressing stenotic Stensen's ducts where present, and allows for installation of antibiotics or steroids into the ductal system. Parotidectomy and duct ligation have also been suggested in select cases.[218]

Systemic Conditions with Salivary Gland Involvement

Diabetes Mellitus

Diabetes mellitus (DM) is a common endocrine disorder that produces multiple metabolic abnormalities and may lead to microvascular and macrovascular complications. Many patients with uncontrolled diabetes report dry mouth and experience salivary hypofunction. In general, patients with poorly controlled DM tend to experience greater salivary gland dysfunction than well-controlled patients or controls.[219]

The etiology of diabetic salivary gland dysfunction may be related to multiple issues, including an underlying salivary gland pathology, such as alterations in salivary gland basement membranes or the microcirculation to the glands.[219] Poor glycemic control, poor hydration, autonomic nervous system dysfunction, and the effect of certain medications may also result in salivary gland dysfunction. Xerostomia in those with DM could also be attributed to thirst (polydipsia), a common, and sometimes presenting, manifestation of diabetes.

Anorexia Nervosa and Bulimia Nervosa

Salivary gland enlargement (sialomegaly), especially of the parotid glands, can occur in patients with the eating disorders anorexia nervosa and bulimia nervosa. The glandular enlargement is noninflammatory and non-neoplastic in nature and may be termed sialadenosis. It is speculated that this enlargement occurs due to nutritional deficiencies and/or the habit of repeated induced vomiting or other factors. Sialomegaly secondary to bulimia occurs in 10–68% of patients with bulimia and correlates directly with the number of daily episodes of vomiting.[220]

These eating disorders can also influence salivary flow and composition. Patients may suffer from hyposalivation and xerostomia, which may be related to dehydration secondary to vomiting or withholding food and drink. Hyposalivation and xerostomia may also occur due to the use of certain medications, such as antidepressants, used not only in treatment of the disorders but also for mood disorders—a common comorbidity.

Sialomegaly due to bulimia may resolve spontaneously when patients return to an optimal weight and re-establish healthy dietary habits, but this may take a long time. Conversely, in anorexia nervosa, salivary gland enlargement can persist despite a return to normal weight.[221] Relapse of the eating disorder can also lead to a recurrence of sialomegaly.

Conservative treatments for eating disorder-associated sialomegaly include the use of salivary stimulation in the form of sugar-free sour candy, application of heat, and optimizing hydration. Pilocarpine hydrochloride (5–15 mg/day) has also been used with limited success. When sialomegaly persists, it can be of cosmetic concern and negatively affect the patient's self-esteem. Superficial parotidectomy has been used in select cases although its use is controversial.[222]

Eating disorders are often difficult to diagnose because of the secretive nature of the conditions. To facilitate early diagnosis and treatment, clinicians should be aware of the common associated clinical findings (i.e., dental erosion, xerostomia, salivary gland enlargement, mucosal erythema, and cheilitis). Patients should be queried diplomatically if an eating disorder is suspected and an appropriate medical referral made.

Chronic Alcoholism

Chronic alcoholism is one of the primary causes of sialadenosis, an asymptomatic, bilateral, noninflammatory, persistent enlargement of the salivary glands, usually affecting the parotid glands. Salivary gland enlargement in these patients is thought to result from an ethanol-induced peripheral autonomic neuropathy resulting in disordered salivary gland metabolism and secretion.[223] Interestingly, sialadenosis attributable to alcohol occurs only in the presence of some form of liver disease and therefore its presence should prompt medical referral.[224] Chronic alcoholism is also associated with a reduction in parotid gland salivary flow and saliva-buffering capacity.[225] The exact etiology of decreased salivary flow is not definitively known but is thought to be due to dehydration and poor nutrition.[226]

Dehydration

Dryness of the oral cavity can be a result of suboptimal levels of salivary flow or excess evaporation of saliva, which can occur due to mouth breathing, for example. Hyposalivation, and concomitant xerostomia, may reflect systemic dehydration since normal salivary output requires movement of water from the systemic circulation through acinar cells into the salivary ductal system and into the mouth. Both stimulated and unstimulated parotid salivary flow rates were shown to decrease in studies in which healthy subjects underwent a controlled 24-hour dehydration followed by rehydration.[227]

Clinical signs of dehydration include dryness of the mucous membranes of the nose and mouth and longitudinal furrowing of the oral tongue.[227] When systemic dehydration is suspected, patients should be questioned regarding their daily fluid intake and urine output (taking into account dehydrating beverages such as coffee and alcohol) their daily sodium intake, and the use of dehydrating medications such as diuretics, laxatives, and antihistamines.

Requirements for daily water intake will vary based on an individual's body size, activity level, and additional factors. Risk of dehydration tends to be greater in the elderly for a number of reasons, including decreased fluid intake secondary to impaired thirst mechanisms and increased likelihood of use of dehydrating medications. Patients may also restrict fluid intake where there is fear of incontinence.[228] Patients with xerostomia should be counseled that reliance on thirst sensation alone to stimulate water intake may be inadequate. Rather, they should be advised to take frequent sips of water throughout the day to prevent dehydration and alleviate xerostomia.

Medication-Induced Salivary Dysfunction

Medications can have a number of adverse effects on salivary gland function. The most well-known of these are hyposalivation and xerostomia. More than 400 drugs with xerogenic potential have been identified, including antidepressants, anticholinergics, antispasmodics, antihistamines, antihypertensives, sedatives, bronchodilators, and newer targeted therapies and immunotherapies (e.g., immune checkpoint inhibitors). Attempts have been made to compile a comprehensive list of medications with documented effects on salivary

Table 9-3 Common drug categories associated with salivary hypofunction.

Sedatives and anxiolytics

gland function.[15] Table 9-3 summarizes the drug categories most commonly associated with salivary hypofunction.

Due to insufficient clinical investigations, relatively few drugs have been shown definitively to reduce salivary gland function. Some drugs may not actually cause impaired salivary output but produce alterations in saliva composition that lead to the perception of oral dryness. Other medications may affect only the unstimulated output, leaving stimulated function intact.

The pathogenesis of medication-induced salivary dysfunction differs with different classes of drugs. Anticholinergic drugs, the most well-recognized drug class associated with hyposalivation, inhibit acetylcholine binding to muscarinic receptors on salivary gland acinar cells preventing water movement through the ductal system and into the mouth. Other medications such as antihistamines and the alpha- and beta-blocker antihypertensives also inhibit neurotransmitter binding to the salivary gland acinar cells or perturb ion transport pathways, resulting in changes in the quantity and/or composition of salivary secretion.[229]

Medication-induced salivary hypofunction is more common in the elderly and they are more likely to be engaged in polypharmacy (generally defined as taking five or more medications), which further increases the likelihood of salivary hypofunction. A critical review of a patient's medications (both prescribed and over the counter), supplements, and herbal preparations is warranted to identify xerogenic agents and determine if the drug in question is still appropriate. Perhaps due to a lack of follow-up or if a patient has seen multiple health-care providers, the initial indication for a medication may no longer be applicable or there may be other redundancies in their prescribed medications. Communication with the patient's health care providers, therefore, can help optimize their medication regimen and diminish side effects.

Ideally, medication-induced salivary dysfunction would be alleviated by discontinuation of the drug(s) or substitution with a similar drug with little or no effect on the salivary glands. Additional strategies may include altering when the drug is administered. For example, if nocturnal xerostomia disrupts sleep, medications could be taken earlier in the day when xerostomia may be managed. Alternatively, if xerostomia is problematic during the day, taking a medication at night might resolve this issue. Lowering or dividing drug doses where possible may also help to minimize salivary gland effects. All proposed changes should be discussed with the prescribing clinician to determine the optimal strategy. Where change in medications is not feasible, the patient should be counselled in the management of hyposalivation and xerostomia (see section: Management of Xerostomia and Hyposalivation).

Drug-Induced Parotitis

Drug-induced parotitis, although rare, has been reported with numerous drugs but has only been definitively linked with a few. The most commonly associated medicines are iodine-containing drugs such as those used as imaging contrast media: hence the term "iodide mumps".[230] Other drugs include the antineoplastic drug L-asparaginase, clozapine, and phenylbutazone.[231]

Most cases of drug-induced parotitis are bilateral due to the systemic distribution of the drug, but unilateral cases have been reported. With respect to the antipsychotic clozapine, there are two competing theories as to the pathogenesis of reported parotitis. One theory proposes that it is the immunomodulating properties of clozapine that sensitize mononuclear blood cells leading to a sialadenitis. The second hypothesis posits that clozapine-induced hypersalivation results in a chronic inflammatory state leading to parotid sialolithiasis and subsequent parotitis.[232] In the majority of cases of drug-induced parotitis, the condition resolves with discontinuation of the causative agent.

Parotid Lipomatosis

Parotid lipomatosis is the salivary gland manifestation of lipodystrophy syndrome associated with long-term highly active antiretroviral therapy (HAART) for HIV/AIDS. It has been associated specifically with the first-generation protease inhibitors indinavir, nelfinavir, ritonavir, fosamprenavir, and saquinavir mesylate.[233]

Parotid lipomatosis presents as a painless, progressive enlargement of the parotid glands which can become a cosmetic concern. MRI of the parotids will show fatty replacement without cystic changes or masses. Histologically, there will be an infiltration of the normal glandular parenchyma with benign-appearing adipocytes. Case reports on treatment for parotid lipomatosis describe the use of bilateral

total superficial parotidectomy via a facelift approach. Long-term follow-up is advised due to the likelihood of recurrence.[234]

End-Stage Renal Disease

Patients undergoing hemodialysis for end-stage renal disease are likely to experience xerostomia and/or hyposalivation for a number of reasons. It is estimated that salivary flow is decreased in these patients typically by 20–55%.[235] The identified causes of hyposalivation include salivary gland atrophy and fibrosis, polypharmacy (it is estimated that a patient on hemodialysis takes an average of twelve daily medications, many with xerogenic potential), fluid intake restrictions, and the effects of the dialysis procedure. The cause of the salivary gland atrophy and fibrosis is unknown but salivary flow was found to be inversely related to the degree of atrophy and fibrosis. Optimal fluid management is paramount in the treatment of hemodialysis patients since both fluid overload and dehydration are linked to increased morbidity. With these factors in mind, management of xerostomia and hyposalivation should be closely coordinated with the patient's nephrology care team.[236]

Immune Conditions

Sjögren's Syndrome

Etiology and Pathogenesis

Sjögren's syndrome (SS) is a chronic autoimmune disease characterized by oral and ocular dryness, lymphocytic infiltration, dysfunction, and destruction of exocrine glands. Although the salivary and lacrimal glands are most commonly affected, SS can have widespread and diverse manifestations. Dryness may also affect other mucosal areas such as the skin, nasopharynx, throat, trachea, and vagina. Signs of systemic autoimmune disease with musculoskeletal, pulmonary, gastric, hematologic, dermatologic, renal, hepatic, and neurologic manifestations may also be evident in patients with SS. SS patients also frequently experience fatigue, arthralgias, myalgias, peripheral neuropathies, and dermatoses.

The definitive etiology of SS is unknown. There appear to be genetic and nongenetic, immune and nonimmune, environmental, and epigenetic factors involved in disease susceptibility and the disease process. Genetic studies have identified an association with HLA haplotypes and genes involved in both innate and adaptive immunity. Many studies have also explored the role of hormonal factors and viral infections in a genetically susceptible host. While it is unlikely that one unifying theory will account for all facets of this complex disease, there is developing evidence that salivary gland epithelial cells stimulated by interferons and other cytokines trigger and maintain chronic immune activation resulting in a vicious cycle of autoimmunity in a genetically susceptible host. This results in an autoimmune epithelitis which affects exocrine glands as well as various other organs. It is hoped that a greater understanding of its etiopathogenesis will generate future targeted therapeutics, preventive measures, and possibly even a cure. [237]

SS is classified as primary or secondary. Primary Sjögren's syndrome (pSS) occurs in the absence of another autoimmune disease, whereas secondary SS occurs in conjunction with another autoimmune disease such as systemic lupus erythematosus, rheumatoid arthritis, or scleroderma. It is for this reason that secondary Sjögren's syndrome may be referred to as "Sjögren's syndrome associated with another autoimmune disease" or polyautoimmunity. Recently, there have also been cases of Sjögren's syndrome/sicca syndrome reportedly triggered by the class of cancer immunotherapies known as immune checkpoint inhibitors. The phenotype observed in these cases is distinct from that of idiopathic cases and further study into the etiopathogenesis is warranted (see section: Sjögren's Syndrome/Sicca Syndrome Triggered by Cancer Immunotherapies).

Epidemiology

SS is now considered the second most common autoimmune disease after rheumatoid arthritis. Epidemiologic studies indicate some geographic variation in SS incidence and prevalence. A systematic review and meta-analysis of population-based studies from Europe, North America, and Asia indicates a pooled incidence rate for pSS of 6.92 per 100,000 person-years.[238] pSS predominantly affects women between the ages of 30 and 70 years of age, with a peak incidence between the ages of 55 and 65 years. pSS often appears in men after the age of 65 years resulting in the average overall age at diagnosis for men and women of 56.2 years. The female/male ratio incidence rate for pSS is 9.15; however, the rate of SS is likely higher in males than currently estimated since males tend to develop a different pattern of autoantibodies and are often missed using current classification criteria.[238,239] Although there is no clear consensus that disease severity is worse in males, several studies have reported more frequent extraglandular manifestations in men.[240]

Younger individuals and children may also be affected. In children, in particular, SS can initially present as recurrent episodes of parotitis which may be attributed to juvenile recurrent parotitis (JRP). Women with SS are also at an increased risk of having offspring with congenital heart block due to autoantibody-mediated damage to the atrioventricular node. This occurs in approximately 2% of infants born to women with anti-Ro/SSA antibodies and 3% of infants born to women with anti-La/SSB antibodies. Thus,

counseling seropositive women with SS of childbearing age regarding this risk becomes necessary.[241]

Clinical Manifestations

Patients with SS may experience the full spectrum of oral complications resulting from decreased saliva production.[242] Virtually all patients complain of dry mouth and attendant difficulties in speaking, tasting, and swallowing, and report the need to drink liquids throughout the day or to swallow foods. Xerostomia may first become evident with nocturnal awakening with thirst and the need to have chewing gum or lozenges to stimulate saliva production. Other associated complaints include dysgeusia or hypogeusia, coughing episodes, a globus sensation, dysphagia, and choking. The mucosa may be painful and sensitive to spices, heat, and coarse foods. Patients often have dry, cracked lips and angular cheilitis or oral candidiasis may be present.

Intraorally, the mucosa may be pale and dry, friable, or furrowed. Minimal salivary pooling is seen, and the saliva that is present tends to be thick and ropy. The tongue is often smooth (depapillated), but may be deeply fissured and painful. Mucocutaneous candidal infections are common, particularly of the erythematous form. Due to the lack of lubricating saliva, traumatic or frictional injury is increased and removable prostheses are not as well tolerated due to a reduction in retention usually afforded by saliva.

Reports of swollen salivary glands are common in the SS population (Figure 9-18) and indeed the 2002 American-European Consensus Group (AECG) criteria for SS by Vitali et al. contains within its patient questionnaire inquires as to whether the patient has experienced swollen salivary glands.[64] Glandular enlargement can be unilateral or bilateral, acute, intermittent or chronic and may occur due to one of many causes. Retrograde salivary gland infection due to stasis, inflammation, or obstruction due to sialolithiasis or mucus plugging can all result in glandular swelling. If the swelling is due to a stone or mucus plug, it often subsides if the patient passes calculus or a mucus plug into the mouth—in which case they may describe encountering a piece of sand or gravel in the mouth or experience a sour taste from the mucus plug.

Intermittent or persistent salivary gland swelling may also represent an inflammatory sialadenitis from lymphocytic infiltration of the salivary glands. Sialadenosis or fatty infiltration of the glands will also present as salivary gland swelling and can develop in SS patients on chronic or frequent intermittent corticosteroids or with metabolic disorders. Finally, glandular swelling may represent a lymphoma; 5–10% of patients with SS will develop this malignancy, most commonly a mucosa-associated lymphoid tissue (MALT) lymphoma.[243] A patient with persistent glandular swelling or the presence of salivary glands that feel indurated or nodular should undergo imaging and likely biopsy to rule out lymphoma.[244]

Figure 9-18 Chronic unilateral parotid salivary gland enlargement in a patient with Sjögren's syndrome.

An oral burning sensation, stomatitis, or glossodynia is a common complaint in SS patients and is most likely secondary to a fungal infection. However, it may be due to a parafunctional habit, hematinic deficiencies, allergies, oral lesions, burning mouth syndrome, or SS-associated neuropathy. The prevalence of peripheral nervous system involvement in SS has been estimated at 5–20% and is most commonly reported as an excruciating, burning pain of the extremities, or, when the cranial nerves are involved, may present as a trigeminal sensory neuropathy which can manifest as oral or facial numbness, paresthesia or dysesthesia, or, conceivably, a burning sensation of the mouth and/or tongue.[245]

Changes in volume and composition of saliva may lead to a significantly increased caries index which may be the initial sign alerting a clinician to suspect SS. The saliva of patients with SS has a much lower pH and buffering capacity, which, coupled with delayed sugar clearance due to diminished salivary flow, leads to an increased rate of decay. Patients with SS also tend to have higher levels of cariogenic and acidophilic bacteria such as *Lactobacillus acidophilus* and *Streptococcus mutans*. The decay pattern in patients with SS is also distinctive: caries develop at root and facial surfaces and cusp tips (locations usually more resistant to decay), as well as tooth-restoration interfaces.

Gastro-esophageal reflux disease (GERD) is a common comorbidity in SS patients and may result in, or contribute to, heartburn, hoarseness, chronic cough, nausea, chest pain, and dysphagia. Uncontrolled or unrecognized GERD also places the patient at increased risk of dental erosion, which, coupled with the already increased risk of dental decay, places the patient at an even greater risk of tooth structure loss.

Primary biliary cholangitis [PBC] (formerly known as primary biliary cirrhosis) is an autoimmune disease of the bile ducts leading to bile duct destruction, cholestasis, and liver failure which frequently occurs in patients with SS. PBC and SS share a number of common features. They have similar pathogenic mechanisms involving apoptosis leading to organ-specific, immune-mediated injury directed against the small bile ducts and salivary gland epithelia, respectively and they both have a female predominances. In the early phase of PBC, pruritus and fatigue are common complaints and there may be skin hyperpigmentation. End-stage signs include jaundice, ascites, hepatic encephalopathy, and upper GI bleeding.[246] Clinicians should be aware of these presenting signs and symptoms in order to make the appropriate prompt referrals.

Diagnosis

Currently, there is no set of clinical, laboratory, histopathologic, or imaging findings that serve as a gold standard for diagnosis of SS, rather classification criteria, intended for research purposes, have been proposed which may serve to guide further diagnostic testing. A variety of classification criteria sets have been developed and newer sets continue to be proposed to reflect our changing understanding of the disease. These classification criteria are not universally applied, however, and a patient may be diagnosed with SS without fulfilling them.

The most recognized of these criteria are the 2002 American-European Consensus Group (AECG) criteria by Vitali et al.,[64] the 2012 American College of Rheumatology classification criteria of the Sjögren's International Collaborative Clinical Alliance (SICCA) [ACR-SICCA] by Shiboski et al.,[65] and the joint collaboration of the ACR and the European League Against Rheumatism (EULAR) which established the 2016 ACR/EULAR criteria (Table 9-4).[66] The latter criteria set is currently considered the leading one.

The criteria sets share three common goals: to demonstrate objective evidence of: (1) dry eyes; (2) salivary gland involvement; and (3) provide proof of autoimmunity in order to differentiate SS from other causes of dryness and salivary gland dysfunction. Some key differences between these classification criteria involve whether sicca symptoms are taken into account, recommendations for autoantibody testing, evaluation of dry eyes, and assessment of salivary gland involvement. The 2016 ACR/EULAR criteria recognizes that patients may not always present with oral or ocular symptoms and that this should not result in automatic dismissal from further evaluation where there is a high index of suspicion. In addition, criteria for salivary gland imaging was included in the 2002 criteria set but omitted from more recent sets.[244]

Table 9-4 The 2016 American College of Rheumatology/European League Against Rheumatism Sjögren's syndrome classification criteria.[66] (Used with permission from John Wiley and Sons)

Item	Weight/score
The classification of primary Sjögren's syndrome (SS) applies to any individual who meets the inclusion criteria[a], does not have any of the conditions listed as exclusion criteria[b] and has a score of ≥4 when the weights of the five criteria items below are summed	
Labial salivary gland with focal lymphocytic sialadenitis and focus score of ≥1 foci/4 mm[c]	3
Anti-SSA/Ro-positive	3
Ocular staining score ≥5 (or van Bijsterveld score ≥4) in at least one eye[d, e]	1
Schirmer's test ≤5 mm/5 min in at least one eye[d]	1
Unstimulated whole saliva flow rate ≤0.1 mL/min[d, f]	1

[a] These inclusion criteria are applicable to any patient with at least one symptom of ocular or oral dryness, defined as a positive response to at least one of the following questions: [1] Have you had daily, persistent, troublesome dry eyes for more than 3 months? [2] Do you have a recurrent sensation of sand or gravel in the eyes? [3] Do you use tear substitutes more than three times a day? [4] Have you had a daily feeling of dry mouth for more than 3 months? [5] Do you frequently drink liquids to aid in swallowing dry food?—or in whom there is suspicion of SS from the European League Against Rheumatism Sjögren's syndrome Disease Activity Index questionnaire[247] (at least one domain with a positive item).

[b] Exclusion criteria include prior diagnosis of any of the following conditions, which would exclude the diagnosis of Sjögren's syndrome and participation in Sjögren's syndrome studies or therapeutic trials because of overlapping clinical features or interference with criteria tests: [1] history of head and neck radiation treatment; [2] active hepatitis C infection (with confirmation by PCR), [3] acquired immunodeficiency syndrome, [4] sarcoidosis, [5] amyloidosis; [6] graft-versus-host disease; [7] immunoglobulin G4-related disease.

[c] The histopathologic examination should be performed by a pathologist with expertise in the diagnosis of focal lymphocytic sialadenitis and focus score count, using the protocol described by Daniel et al.[248]

[d] Patients who are normally taking anticholinergic drugs should be evaluated for objective signs of salivary hypofunction and ocular dryness after a sufficient interval without these medications in order for these components to be a valid measure of oral and ocular dryness.

[e] Ocular Staining Score described by Whitcher et al.[249] or by the van Bijsterveld score described by van Bijsterveld.[250]

[f] Unstimulated whole saliva flow rate measurement described by Navazesh and Kumar.[20]

Definitive diagnosis of SS can present a challenge. According to the Sjögren's syndrome foundation, there is an average lag of 2.8 years between onset of symptoms and diagnosis. Some reasons for delay include under-recognition of the signs and symptoms (particularly the extraglandular [systemic] manifestations, and in the absence of sicca symptoms), and under-referral to relevant specialists.[244]

In the evaluation of patients, salivary flow is usually measured in the office by calculation of a whole mouth unstimulated salivary flow rate as described above (see section: Sialometry). Assessment of stimulated salivary flow should also be performed as this indicates the relative functional capacity of the salivary glands and can help determine whether sialogogues are likely to be of benefit.

Ocular signs are assessed using the Schirmer's test in which normal tear production should result in wetting of ≥ 15 mm of a paper strip inserted under the lower eyelid for 5 minutes where wetting of ≤ 5 mm in at least one eye is considered to be a positive (abnormal) test. Alternative tests using vital dyes may be performed by an ophthalmologist and include the use of fluorescein to determine the integrity of the corneal epithelium, and rose bengal or lissamine green used for evaluating the integrity of the conjunctiva. Ocular symptoms consistent with dry eyes include complaints of a burning sensation, grittiness, itching, redness, mucous exudate, photophobia and glare, with symptoms typically worsening throughout the day.

The labial MSGB is considered to be the best sole diagnostic criterion for the salivary component of SS (Figure 9-19).[72] There is growing evidence to suggest that a histological examination should be performed in all SS patients (even those who otherwise fulfil the criteria), as it provides additional prognostic information with respect to the development of severe systemic involvement and lymphoma as well as allowing for monitoring disease and treatment response.[251,252]

A grading system for quantifying the salivary histologic changes seen in the minor glands is as follows: (1) the numbers of infiltrating mononuclear cells are determined, with an aggregate of 50 or more cells termed a focus; (2) the total number of foci and the surface area of the specimen are determined; and (3) the number of foci per 4 mm^2 is calculated which generates the focus score (FS).[253] The FS ranges from 0 to 12 with a FS of ≥ 1 considered positive for salivary gland involvement consistent with SS and 12 denoting confluent infiltrates. Acinar degeneration, with the relative preservation of ductal structures, may also be observed (Figure 9-20).

Parotid gland biopsy has been proposed as an alternative to the MSGB. The parotid gland biopsy presents several advantages over the MSGB including facilitating monitoring

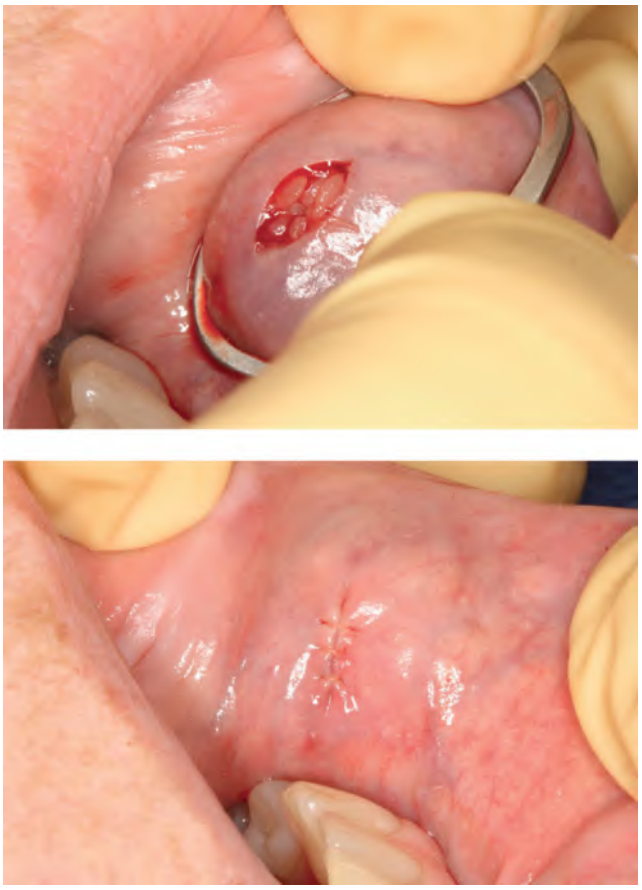

Figure 9-19 Top: Minor salivary gland biopsy of the lower labial mucosa illustrating how the minor salivary glands are readily accessible under the mucosal surface. Bottom: Primary closure after dissection and removal of the superficial minor salivary glands.

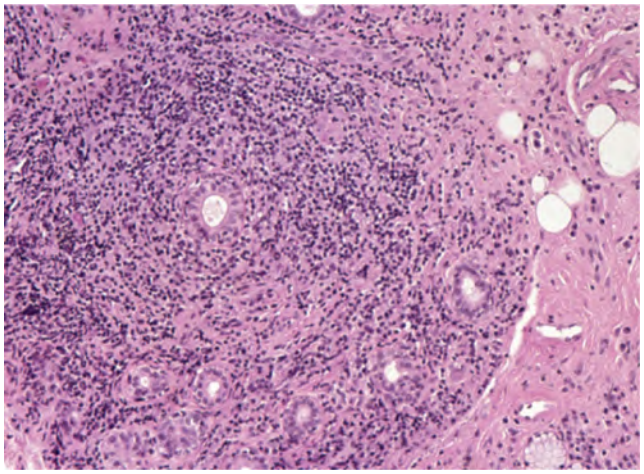

Figure 9-20 Histomicrograph of a biopsy of a labial minor salivary gland with features supportive of a diagnosis of Sjögren's syndrome including generalized chronic lymphocytic sialadenitis with fibrosis, atrophy of the gland parenchyma, and cystic dilatation of ducts.

of disease progression and treatment effect because it permits procuring multiple specimens or repeat biopsy from the same gland. Histopathologic results can also be compared with other data derived from the same gland (e.g., ultrasound, computed tomography, MRI). Furthermore, parotid gland biopsies permit detection of benign lymphoepithelial lesions (LELs), a characteristic histologic feature seen in the major salivary glands in SS, lymphomas, or other salivary gland pathology.[254] Finally, the parotid gland biopsy is considered a relatively simple procedure and there have been no reports of permanent morbidity, in contrast to the relatively high morbidity rate associated with the MSGB due to the risk of permanent damage to the sensory nerves of the lower lip.[71]

Histopathologically, in the affected parotid gland, epimyoepithelial islands with lymphoid stroma and LELs may be present in addition to the characteristic lymphocytic infiltration. Histologic criteria for diagnosis of SS using a parotid gland biopsy requires one of the following two criteria: (1) a FS ≥ 1 per 4 mm^2 of glandular parotid tissue (including adipose tissue) regardless of the presence of benign LELs; or (2) small lymphocytic infiltrates not fulfilling the criterion of a FS of ≥ 1, in combination with the presence of benign LELs.[255]

Imaging

Although both sialography and scintigraphy were included as part of the 2002 AECG classification criteria, both the 2012 ACR-SICCA and 2016 ACR/EULAR classification criteria have no imaging component. Sialography remains the best performing diagnostic imaging technique with respect to SS. It has an accuracy greater than that of MRI and ultrasound and will highlight characteristic changes associated with SS. MRI or CT can also be helpful, particularly in the assessment of enlarged glands and lymphadenopathy. MRI is preferable to CT unless a stone is suspected or other calcified structure requires visualization since it provides superior soft tissue resolution. Tc 99m radionuclide scintigraphy studies may also be used to determine salivary gland function; however, scintigraphy, in spite of being an optional part of the 2002 AECG criteria, scored poorly when compared with sialography, MRI, and ultrasound.[256]

Examination by ultrasound may be useful in a patient with SS to characterize the extent of salivary gland involvement, and to identify patients at risk for complications such as lymphoma.[36] A number of abnormalities detected by ultrasound have been associated with pSS, most significantly parenchymal inhomogeneity, especially when observed in bilateral salivary glands. Ultrasound can also reliably distinguish pSS from conditions that may have a similar clinical presentation such as IgG4-RD.[257] While the role of ultrasound in the diagnosis and response to treatment in SS is still being established, research groups have proposed its inclusion into classification criteria, and there are international efforts underway to optimize and standardize a scoring system.[258–260]

Serology

Primary and secondary SS patients often have prominent serologic signs of autoimmunity and other serologic abnormalities including the presence of certain autoantibodies, hypergammaglobulinemia, an elevated sedimentation rate, decreased white blood cell count, hypocomplementemia, and monoclonal gammopathies.[261]

The marker antibodies, anti-Ro/SSA and anti-La/SSB, are detected in 50–70% of patients with SS and can occur in one of three patterns: anti-SSA with anti-SSB, anti-SSA alone, or anti-SSB alone. Anti-SSB most frequently occurs with anti-SSA, since they share epitopes, but isolated anti-SSB is rare. As such, the presence of anti-SSB antibodies alone is not considered serologic proof of autoimmunity using the 2016 ACR/EULAR criteria. Since anti-SSA may occur in 1.7–17.5% of normal individuals, and may be present with other autoimmune conditions such as SLE, additional objective measures for diagnosis are required.[262]

The presence of these autoantibodies is associated with a higher rate of extraglandular manifestations and more active immunological status when compared with seronegative SS cases. Anti-SSA/SSB-positive patients with SS are more likely to have severe hypergammaglobulinemia and cryoglobulinemia, and are at an increased risk of developing lymphoma. Circulating levels of anti-SSA/SSB do not correlate with disease activity but the IgA anti-SSA titer appears to be associated with the rate of lymphocyte glandular infiltration.[263]

The association between vitamin D levels and SS has been explored. Vitamin D deficiency is relatively frequent in patients with primary SS and there is speculation that this deficiency plays a role in the pathogenesis of the disease.[264] Low levels of vitamin D in patients with SS might also play a significant role in the development of extraglandular manifestation such as lymphoma and peripheral neuropathy. Since patients with primary SS are at an increased risk of non-Hodgkin B cell lymphoma (NHL) and there is some evidence that a low dietary intake of vitamin D is also associated with an increased risk of NHL, it is recommended that patients with SS undergo evaluation of vitamin D levels and appropriate supplementation.[263]

Because monoclonal gammopathy is predictive of a poor outcome in primary SS patients, screening should be included in both the diagnostic and follow-up laboratory profiles. Monoclonal gammopathy is associated with a higher prevalence of parotid enlargement, extraglandular features, hypergammaglobulinemia, cryoglobulinemia and related

markers (e.g., rheumatoid factor, hypocomplementemia), and an overall poor prognosis due to development of neoplasia and death.[265]

Lymphoma

The development of a non-Hodgkin B cell lymphoma (NHL) is the most important hematologic complication of pSS. This type of lymphoma is estimated to develop in 5–10% of SS patients with the lifetime risk accumulating over time.[266] pSS patients have somewhere between a 7- and 20-fold increased relative risk of lymphoma over the general population, although some studies suggest this may be an overestimation.[267,268] There is a particularly significantly increased incidence of NHL observed among men with SS as well as in patients with persistent salivary gland swelling. Additional recognized risk factors include having a salivary gland biopsy focus score of $\geq 3/4\ mm^2$ or the presence of ectopic germinal centers (GC) within the biopsy.[269] The presence of these GCs has also been correlated with increased clinical disease severity, and increased positivity for anti-SSA/Ro and anti-SSB/La antibodies.[270]

The most common NHL affecting SS patients is a low-grade marginal zone B-cell lymphoma of the mucosa-associated lymphoid tissue (MALT). However, the more aggressive diffuse large B-cell lymphoma (DLBCL) is also found in SS patients. Some studies have found up to 10% of SS-associated MALT lymphomas transform into DLBCL. NHL in these patients tends to arise where SS is most active, often in the parotid and submandibular glands. Here, NHL most commonly presents as a unilateral, persistent, sometimes indurated and nodular swelling of the gland. The lymph nodes, orbits, nasopharynx, stomach, thyroid, and lungs are other common sites of development. Typically, the course of NHL is more indolent and without B symptoms (e.g., fever, weight loss, or night sweats) in the majority of patients.[267]

Since salivary gland lymphomas associated with SS often progress slowly, close clinical monitoring of all SS patients is necessary. This involves periodic physical examination (including a thorough head and neck examination) and assessment of immunoglobulin levels. Suspicious signs associated with NHL lymphoma in SS patients in addition to unilateral or bilateral salivary gland enlargement include lymphadenopathy, palpable purpura, splenomegaly, leg ulcers secondary to vasculitis, mixed cryoglobulinemia, and low C4 (complement component 4) levels.[270]

Clinical suspicion for lymphoma warrants a biopsy for further investigation. Incisional biopsy of extranodal tissue should be performed along with excisional lymph node biopsies if appropriate. Where salivary gland lymphoma is suspected, histopathologic analysis is often combined with techniques such as flow cytometry and fluorescence *in situ* hybridization for definitive diagnosis and characterization. Diagnosis of lymphoma requires prompt referral to an oncologist where further assessment will likely include evaluation of Waldeyer's ring, full body imaging, blood work including a complete blood count and chemistry panel, among other examinations.[271]

Management

There is currently no cure for SS and are no effective means of inducing remission. Goals of treatment are focused on alleviation of symptoms, prevention of sequelae of oral and eye dryness, and, where present, addressing systemic manifestations. As there is often a poor correlation between the severity of ocular symptoms and the results of objective tests for keratoconjunctivitis sicca, regardless of symptom severity, every patient should see a cornea or dry eye specialist at least once for a comprehensive evaluation.[244]

Treatment depends upon disease extent and symptom severity taking into account their effect on quality of life. Although there are no data from large randomized controlled trials to support use of any currently available pharmacologic therapy that effectively modifies the course of the disease, symptomatic management should be offered to every SS patient.[244] Comprehensive management requires a collaborative multidisciplinary approach involving referral to specialists to address the glandular and extraglandular manifestations specific to the patient and to tailor treatment to the organs or systems involved.

Agents used in the treatment of SS can be categorized as topical, for which there is strong supporting evidence, and systemic, for which there is limited data from randomized controlled trials to guide use.[272] Agents may include topical oral products (saliva substitutes), topical ocular agents (artificial tear drops, topical nonsteroidal anti-inflammatory drugs, topical corticosteroids, topical cyclosporine A, serum tear drops), oral muscarinic agonists (pilocarpine, cevimeline), hydroxychloroquine, oral glucocorticoids, immunosuppressive agents (cyclophosphamide, azathioprine, methotrexate, leflunomide, mycophenolate mofetil), and biological therapies (rituximab, abatacept, belimumab).[273] Here, we will highlight some common approaches to treatment, focusing on oral signs and symptoms. For a more comprehensive overview of treatment, please refer to the Suggested Reading list.

Management of Hyposalivation and Xerostomia in SS

Prior to the initiation of treatment for hyposalivation and xerostomia, baseline evaluation of unstimulated and stimulated whole salivary flow is recommended (see section: Sialometry). Management in SS patients revolves around the use of symptomatic therapies such as secretagogues, oral rinses and gels, mouthwashes, artificial saliva, and water

sipping (see section: Management of Xerostomia and Hyposalivation), and prevention of the sequelae of hyposalivation (e.g., dental caries), such as by the use of high-potency fluoridated toothpastes.

Mechanical stimulation (e.g., chewing gum) can provide some increased saliva production in SS patients with residual salivary gland capacity. In a systematic review investigating the safety and efficacy of treatments in pSS patients, there was no evidence that chewing gum had any more or less efficacy than saliva substitutes in reducing dry mouth symptoms. There was also no strong evidence to support any one specific oral topical therapy (e.g., lozenges, sprays, mouth rinses, gels, oils, chewing gum, and/or toothpastes) over another. As there are no definitive effective topical treatments, the focus of treatment should be on improving the patient's xerostomia rather on increasing saliva production.[272] Patients should be encouraged to try a number of different agents since response may differ between individuals.

Trial of nonpharmacologic agents should be attempted prior to consideration for systemic agents. There are two FDA-approved medications for dry mouth in SS: pilocarpine and cevimeline. These parasympathomimetic secretagogues have demonstrated the greatest reduction in xerostomia in SS patients with residual gland function. Both pilocarpine and cevimeline are muscarinic agonists which induce a transient increase in salivary output. Cevimeline is reported to have increased specificity to M3 muscarinic receptors compared with pilocarpine, which might result in a lowered potential for side effects. Cevimeline also tends to have a faster onset of effect than pilocarpine.[274]

In a retrospective study comparing side effect profiles and discontinuation rates of pilocarpine and cevimeline in patients with pSS, patients were more likely to continue with cevimeline than pilocarpine long term, mostly due to fewer reported side effects (primarily sweating). It was also found that therapeutic failure of one secretagogue did not necessarily predict similar results with the other and, in fact, those who had changed from one secretagogue to the other were more likely to continue treatment for the long term. This implies that it is reasonable to encourage patients to consider trying the alternative agent after initial treatment failure.[275] Common side effects of these medications include sweating, flushing, urinary urgency, nausea, and gastrointestinal discomfort. Although these side effects are frequent, they are rarely severe or serious, but they may be significant enough to be intolerable to patients.

Pilocarpine and cevimeline are contraindicated in patients with uncontrolled asthma, narrow-angle glaucoma and acute iritis, and in patients who are pregnant or breastfeeding. They should be used with caution in patients with significant cardiovascular disease, Parkinson's disease, asthma, or chronic obstructive pulmonary disease. Pilocarpine is recommended at 20–30 mg per day, and cevimeline up to 90 mg per day, both in divided doses. When introducing these medications, one approach to minimize side effects is to start with a low dose taken after meals and increase slowly on a weekly basis until the target dose is achieved.[244] To further minimize side effects, a patient may even start with a very low dose, for example using a 2.5 mg dose of pilocarpine, by dividing a 5 mg tablet.

Although a systematic review concluded that there was very limited evidence to support the use of these medications in pSS patients, it was deemed that a trial for up to 12 weeks (given the potential for delayed response), should be offered to all patients where response to nonpharmacologic therapy is inadequate. Interestingly, although these oral secretagogues are not indicated for keratoconjunctivitis sicca, there is some evidence that they may be effective in alleviating dry eye symptoms as well.[276,277]

Interventional Sialendoscopy

A few studies have demonstrated that sialendoscopy, including irrigation of the ductal system with saline or a saline/corticosteroid solution, may improve salivary gland function and alleviate symptoms such as xerostomia in SS patients. Ductal strictures and mucus plugs (common findings and major causes of obstruction and recurrent sialadenitis among patients with SS) can also be addressed with interventional sialendoscopy.[69]

Systemic Treatments

Systemic glucocorticoids Systemic glucocorticoids (e.g., methylprednisolone) are used at the minimum dose and length of time necessary to control active systemic disease in SS patients; their frequent use is not supported by reliable scientific data. Glucocorticoids at high doses are believed to downregulate the immune inflammatory process within the salivary and lacrimal glands.

Immunosuppressive agents Immunosuppressive agents, such as leflunomide, methotrexate, azathioprine, mycophenolate mofetil, and cyclophosphamide can act as steroid-sparing agents in patients systemic disease who may require long-term therapy. Since there are no clinical trials comparing the safety and efficacy of these agents, there are no standard treatment recommendations.[273]

Antimalarial Agents The antimalarial agent hydroxychloroquine has been used in SS patients to address acute musculoskeletal pain based upon its comparable use in other autoimmune diseases such as systemic lupus erythematosus. Some studies have demonstrated the efficacy of hydroxychloroquine in reducing sicca and constitutional symptoms such as fatigue and arthromyalgia. However, in a randomized, placebo-controlled trial, the use of hydroxychloroquine in

pSS patients did not improve symptoms during 24 weeks of treatment compared with a placebo.[278]

Hydroxychloroquine has been reported to increase salivary flow rate and reduce some inflammatory indices such as ESR and C-reactive protein, and results in an improved immunologic profile with respect to rheumatoid factor, anti-Ro/SSA, and anti-La/SSB. Owing to its antineoplastic properties, hydroxychloroquine also has the potential to reduce the risk of lymphoma development in those with SS.[263] It may be prescribed during pregnancy in women with SS as it is considered safer than many alternative treatments.

Biological Therapies It is now well established that both B- and T-cells are involved in the pathogenesis of SS hence the use of biological therapies such as rituximab, a monoclonal antibody developed against the surface B-cell molecule CD20. Rituximab is the most frequently used biological agent and the most widely studied B-cell targeted therapy for SS.[279] The majority of studies have indicated that rituximab demonstrated at least some systemic effect and therefore, it may be considered for patients with severe, refractory systemic disease.[280] Belimumab is another B-cell targeted therapy which inhibits B-cell activating factor (BAFF). Studies have indicated that belimumab resulted in improvements in parotid swelling and was effective in patients with disease refractory to rituximab.[273]

Therapeutic investigation is now shifting from focusing on B-cell depletion to biologicals targeting cytokines, T-cells, and intracellular signaling pathways. Studies are now exploring the effect of monoclonal antibodies targeting the BAFF-receptor and the association between B-cell depletion and BAFF inhibition. Research is also focused on treatment for lymphomas related to SS, searching for predictive factors of biological response and identification of biomarkers which will help identify predictors of poor outcomes.[273,281]

Sjögren's Syndrome/Sicca Syndrome Triggered by Cancer Immunotherapies

Recently, there have been reports of cases of Sjögren's syndrome/sicca syndrome triggered by the class of cancer immunotherapies known as immune checkpoint inhibitors (ICIs) (e.g., PD-1 inhibitors nivolumab and pembrolizumab, PD-L1 inhibitor durvalumab, and CTLA-4 inhibitor ipilimumab) used to treat melanoma, lung cancer, and kidney cancer, among other neoplasms.[282] This phenomenon is considered an immune-related adverse event: side effects associated with the increased activity of the immune system by ICIs that can involve multiple organ systems including the skin, liver, and lungs, gastrointestinal tract, endocrine, nervous, and musculoskeletal systems. Up to 80% of patients receiving ICIs experience adverse events; the overall prevalence of all types of systemic immune-related adverse events is reported as less than 1%; however, the reported prevalence is much higher (2.5%) in patients receiving combination therapy compared with those treated with a single ICI.[283]

The etiopathogenesis of this phenomenon is unknown but it is suspected there may be a genetic predisposition. It is possible that some cases represent a latent SS, especially in women of middle age, and that the cancer diagnosis and initial development of SS was coincidental. This highlights the importance of evaluation of pre-existing autoimmune signs and symptoms prior to initiating biological therapy. The presence of a pre-existing autoimmune disease does not necessarily preclude treatment with an ICI, but the patient must be made aware of the risk of exacerbation or development of new signs and symptoms and should be under the close collaborative clinical care of their rheumatologist, oncologist and oral medicine specialist.[284]

The phenotype observed in cases of Sjögren's syndrome/sicca syndrome triggered by ICIs is distinctly different from that of idiopathic cases of SS. In the former, 50% occurred in males, the mean age at diagnosis is approximately 10 years older, and there is often an abrupt onset within the first 3 months of ICI treatment.[282] There is also a lower frequency of both oral and ocular dryness and a lower frequency of abnormal ocular tests. With respect to MSGB histopathology, the typical focal lymphocytic sialadenitis seen in the idiopathic form of SS was observed in half of cases biopsied. However, this infiltrate was composed mainly of CD3+ T cells with a slight predominance of CD4+ over CD8+ T cells and a virtual absence of B cells, in contrast to the lymphocytic infiltrate in idiopathic Sjögren's syndrome, which is composed mainly of CD20+ B cells, with variable germinal center formation and number of CD3+ T cells, and a slight predominance of CD4+ over CD8+ T cells.[283] There is also a much lower prevalence of SS-associated serum autoantibodies (52% antinuclear antibody, 20% anti-Ro/SSA, 9% rheumatoid factor, 8% anti-La/SSB), when compared with idiopathic primary SS.[282]

Patients who developed Sjögren's syndrome/sicca syndrome triggered by ICIs were also more likely to require treatment for severe symptoms and systemic disease manifestations including the use of second- and third-line therapies. Management may also include discontinuation of the ICI(s), especially where there is significant involvement of internal organs, corticosteroids, and/or limited use of immunosuppressive/immunomodulatory agents. Although, with treatment, some patients reported a subjective improvement, none reported complete resolution of their sicca symptoms and few patients returned to normal salivary flow rates. It is likely that many of these patients will experience long-term salivary hypofunction and will therefore require ongoing close follow-up.[285]

Chronic Graft-Versus-Host Disease (cGVHD)

cGVHD is a complex clinical entity that occurs following bone marrow transplantation. It develops within several months of hematopoietic stem cell transplantation (HSCT) in approximately 25–80% of patients.[286] Hyposalivation, xerostomia, and keratoconjunctivitis sicca, some of the more common manifestations of cGVHD, occur due to infiltration of the salivary and lacrimal glands respectively by autoreactive T lymphocytes.[287]

Salivary gland involvement in cGVHD tends to develop rapidly and be very severe, while recovery often does not occur until at least 1 year following transplantation. Changes in both saliva composition and quantity have been observed. The histopathologic changes observed in cGVHD can resemble those seen in Sjögren's syndrome: lymphocytic infiltration of the minor salivary glands, parenchymal destruction, and fibrosis. In general, treatment of cGVHD consists of the use of immunosuppressive agents such as methylprednisolone and cyclosporine. Treatment of hyposalivation and xerostomia with pilocarpine has also been reported.[288]

Granulomatous Conditions

Tuberculosis

Tuberculosis (TB) is a bacterial infection, usually caused by *Mycobacterium tuberculosis*, characterized by granulomatous inflammation with variable degrees of necrosis. Although the lungs are most commonly affected, other tissues, including the salivary glands, may be involved. Salivary gland tuberculosis has been reported in both the major salivary glands, most commonly the parotid and submandibular glands, and in the minor salivary glands.[289] Salivary gland TB is usually confined to the intraglandular and periglandular lymph nodes; involvement of the salivary gland parenchyma is rare and usually represents spread from the adjacent lymph nodes.[290]

TB of the major salivary glands has a varied clinical appearance. Most commonly, it presents as a slow-growing, firm mass with a variable degree of fixation. Diffuse glandular enlargement and acute sialadenitis may be seen if there is parenchymal involvement. It may alternatively present as a peri-auricular fistula, abscess or with cyst formation.[291] Salivary gland enlargement may occur as part of a characteristic symptom complex (i.e., weakness, weight loss, and cough) or in the absence of systemic symptoms, and the patient may complain of xerostomia.

Salivary gland TB may present a diagnostic challenge in the absence of additional signs and symptoms of TB. The clinical appearance is sometimes indistinguishable from that of some salivary gland neoplasms and sarcoidosis.[289] Where TB of the salivary gland is suspected, investigation requires review of the patient's medical and dental history, physical examination, imaging, microbiologic tests, molecular biologic assays, and histological evaluations such as fine-needle aspiration cytology (FNAC). Imaging and FNAC are often inconclusive, however, necessitating an open biopsy.[290]

Definitive diagnosis of TB requires the isolation and identification of mycobacteria. PCR when applied to FNAC specimens can enhance specificity and sensitivity. Using PCR-based salivary assays, evidence of *M. tuberculosis* was found in 98% of infected patients, representing a detection rate significantly better than culture (17%), suggesting that in the future, salivary tests may be helpful for the diagnosis of TB.[292]

Treatment of salivary gland TB requires standard multidrug chemotherapy using a combination of antibiotics including isoniazid, rifampicin, pyrazinamide, and ethambutol. Additional chemotherapy and salivary gland surgery may be required to treat persistent salivary gland disease.[293,294]

Sarcoidosis

Sarcoidosis is a chronic granulomatous condition of unknown etiology in which T lymphocytes and mononuclear phagocytes cause destruction of affected tissue. It most commonly first appears in the lungs, skin, and lymph nodes, but any organ system can be affected. Salivary gland involvement is seen in an estimated 5–10% of those with sarcoidosis.[295]

With respect to the salivary glands, clinical presentation varies from a complete lack of symptomatology to xerostomia or painful glandular swelling, which may be unilateral, bilateral, or synchronously affect multiple glands. Parotid gland swelling is the most common presentation while clinically silent disease is most often discovered in the minor salivary glands upon biopsy.

Because there are numerous pathoses that can clinically mimic sarcoidosis of the salivary glands, such as tuberculosis, Sjögren's syndrome, lymphoma, and salivary gland tumors, evaluation to rule out other processes is warranted. In particular, when sarcoidosis affects both the salivary and lacrimal glands, patients may present with xerostomia/hyposalivation and keratoconjunctivitis sicca, not unlike that of Sjögren's syndrome.

Heerfordt's syndrome (uveoparotid fever) is a form of sarcoidosis that involves parotid gland swelling, inflammation of the uveal tract of the eye (uveitis), chronic fever, and facial nerve palsy. The typical glandular presentation of Heerfordt's syndrome is bilateral, painless, and firm enlargement of the parotid glands with diminished salivary output. Unilateral salivary gland enlargement has also been reported.[296]

The diagnosis of sarcoidosis is based upon supporting clinical features and the presence of non-necrotizing granulomas in a biopsy specimen; the imaging features of salivary gland sarcoidosis are nonspecific.[295] Examination of a minor salivary gland biopsy specimen and laboratory assays including calcium levels, autoimmune serologies, and serum

angiotensin-converting enzyme (ACE) levels, can confirm or refute the diagnosis of sarcoidosis and help differentiate it from other similarly presenting pathoses such as Sjögren's syndrome.[297]

Treatment of sarcoidosis may range from observation only to the use of systemic corticosteroids and/or immunosuppressive steroid-sparing agents such as methotrexate, azathioprine, leflunomide, and mycophenolate mofetil. The tumor necrosis factor-alpha (TNF-alpha) antagonists infliximab and adalimumab may be used in cases refractory to steroids or immunosuppressive therapy.[298] Salivary gland involvement of sarcoidosis is usually responsive to systemic treatment but surgical excision of granulomatous tissue may be required. Sarcoidosis-associated xerostomia may be treated symptomatically (see section: Management of Xerostomia and Hyposalivation).

Crohn's Disease

Crohn's disease is an inflammatory condition of the gastrointestinal tract which can present with oral signs that may precede intestinal manifestations. Apart from the more commonly known serpiginous lesions of pyostomatitis vegetans, there are reports of Crohn's disease involving the minor salivary glands of the oral cavity, clinically appearing as a saliva-draining cutaneous fistula associated with the parotid gland duct, or as multiple submucosal nodules.[299,300] Histopathologically, these nodules were composed of non-necrotizing granulomas within the walls of the minor salivary gland ducts. Additional findings in the minor salivary glands were foci of lymphocytes within the stromal connective tissue and signs of acinar atrophy and ductal hyperplasia.[301]

Often, both the oral lesions and gastrointestinal symptoms of Crohn's disease resolve after appropriate therapy, which may include the use of antibiotics, glucocorticoids, sulfasalazine, azathioprine, 6-mercaptopurine, methotrexate, or biological agents, such as the TNF-alpha inhibitors infliximab or adalimumab.

Granulomatosis with Polyangiitis

Granulomatosis with polyangiitis (GPA), formerly known as Wegener's granulomatosis, is an immune-mediated vasculitis of the small- and medium-sized vessels characterized by necrotizing granulomatous inflammation. It most commonly affects the upper and lower respiratory tracts, lungs, and kidneys.

The head and neck are involved in nearly 90% of GPA cases with the most commonly affected areas being the nose, eyes, ears, and mouth. Although rare, salivary gland enlargement may be the initial manifestation of GPA allowing for prompt treatment and thereby possibly preventing irreversible organ damage. Salivary gland involvement is typically accompanied by manifestations in other organs, but there are reports of isolated parotid gland involvement. With respect to the major salivary glands, GPA usually affects the parotid or submandibular glands in a unilateral or bilateral fashion. A combination of parotid and submandibular gland involvement has been reported in a few cases.[302]

GPA affecting the salivary glands will present as a painful or painless glandular swelling and there may be accompanying neurologic manifestations such as facial nerve weakness or hearing loss. A cutaneous fistula overlying the parotid gland has been reported in many cases. Depending on the extent of disease, the patient may also present with rhinitis, severe rhinorrhea, epistaxis, sinusitis, a "saddle nose" deformity, nonspecific oral ulcerations, or hyperplastic gingival lesions with petechial hemorrhages known as "strawberry gingivitis." Related constitutional symptoms include fever, migratory arthralgias, malaise, anorexia, and weight loss. Where there is lung involvement, hoarseness, cough, and dyspnea may be present.

Diagnosis of GPA is made through a combination of clinical, laboratory, and histopathologic analyses. An open biopsy is indicated if a fine-needle aspiration biopsy is nondiagnostic. Cytoplasmic antineutrophil cytoplasmic antibodies (c-ANCA) levels are highly specific but have variable sensitivity dependent on disease activity. c-ANCA may be negative in 15–33% of patients, especially where there is renal involvement.[303] Effective management of GPA can result in resolution of salivary gland swelling and pain and may involve the use of glucocorticoids, methotrexate, cyclophosphamide, rituximab, and plasmapheresis.

Sialorrhea

Sialorrhea (hypersalivation or ptyalism) is defined as excessive salivation and is the result of either increased saliva production or decreased saliva clearance. Sialorrhea can lead to drooling (i.e., excess saliva beyond the lip margin). Drooling is considered normal in children less than 4 years of age prior to the development of oral neuromuscular control. Primary sialorrhea is defined as true salivary hyperfunction resulting in drooling. Secondary sialorrhea results in drooling due to impaired neuromuscular control (such as with a swallowing disorder) and/or a sensory processing disorder in which the presence of saliva is not properly detected and, as a result, not effectively cleared from the oral cavity. Impairment in the oral phase of swallowing may lead to anterior drooling (saliva leaving the oral cavity) while dysfunction of the pharyngeal phase of swallowing may lead to posterior drooling (saliva leaking into the hypopharynx), which increases the risk of aspiration.

Sialorrhea may be observed associated with neurological diseases such as amyotropic lateral sclerosis (ALS), cerebral palsy, and Parkinson's disease, or with neoplasms of the

upper aerodigestive tract. It can be associated with certain medications[15] (Table 9-5), hyperhydration, infant teething, the secretory phase of menstruation, heavy metal poisoning (e.g., mercury, selenium), organophosphorus (acetylcholinesterase) poisoning, nausea, obstructive esophagitis, neurologic changes such as in a cerebral vascular accident (CVA), and central neurologic infections.[304]

Sialorrhea as a manifestation of GERD is often referred to as "water brash" or "acid brash" and may be particularly evident during pregnancy. Sialorrhea may also be part of a constellation of signs and symptoms of autonomic dysfunction associated with infection with the rabies lyssavirus. Other conditions that can be associated with sialorrhea include Down syndrome, fragile X syndrome, and autism.[304] Minor hypersalivation may result from local oral irritations, such as aphthous ulcers or an ill-fitting oral prosthesis. Idiopathic paroxysmal sialorrhea is a rare condition in which there are paroxysms of increased salivary flow occurring 1 or 2 times per week for a duration of 2 to 5 minutes preceded by a prodrome involving nausea or epigastric pain.[305]

Table 9-5 Medications and conditions that can cause hypersalivation and drooling.

Medications
Pilocarpine
Cevimeline
Bethanechol
Clozapine[1]
Olanzapine[1]
Venlafaxine[1]
Clobazam[1]
Digoxin
Lithium[1]
Nitrazepam
Physostigmine
Risperidone[1]
Neurologic diseases
Parkinson's disease
Wilson's disease
Amyotrophic lateral sclerosis
Down syndrome
Fragile X syndrome
Autism
Cerebral palsy
Organophosphate poisoning
Heavy metals
Arsenic
Iron
Lead
Mercury
Selenium
Thallium
Hyperhydration
Ill-fitting dentures
Rabies
Secretory phase of menstruation

Key: 1- may also cause xerostomia.

Clinical Presentation

When sialorrhea results in drooling, it can result in social embarrassment and affect a patient's quality of life. In particularly severe cases and where there is impaired swallowing, partial or total airway blockage may lead to inhalation of oral contents and aspiration pneumonia. Sialorrhea can also lead to perioral irritations, malodor, and traumatic ulcerations that can become secondarily infected by fungal or bacterial organisms.

Diagnosis

As there is a multitude of causes of sialorrhea, it is essential to obtain the history of hypersalivation along with a complete medical history and review of medications. A systematic head and neck evaluation should be performed including a cranial nerve examination, noting the presence of any head/neck/oral masses and lesions, and neuromuscular dysfunction. An evaluation of the condition of removable intraoral prostheses should also be performed.

Salivary flow rates should be obtained to determine if the sialorrhea is due to an overproduction of saliva (see section: Sialometry). The normal rate of unstimulated salivary output from all glands is approximately 0.3–0.4 mL/minute. Collection of unstimulated whole saliva using a drainage method into a preweighed container that results in more than 1.0 mL/minute suggests a greater than normal production of saliva. If examination indicates that the cause of sialorrhea is due to a problem in secretion clearance or there is a complaint of dysphagia or odynophagia, further imaging to rule out an obstructive cause (e.g., esophageal stricture or tumor) is necessary and a swallowing study may be indicated.

Blood samples should be obtained and evaluated for heavy metals and organophosphate pesticides if there is suspicion of toxicity. Women of childbearing age should be evaluated for potential pregnancy. If the onset of sialorrhea is acute, a CT scan of the brain may be required to rule out a CVA or a central nervous system mass or infection.

Management

Treatment for sialorrhea should take into consideration the etiology, risks and benefits of treatment, and the effect on quality of life. There are several categories of treatments: physical therapy, medications, surgery, and radiation therapy. Additional strategies may involve changes in diet or medications, oral habits, and behavior modification.

The management of drooling may require a multidisciplinary approach incorporating speech-language pathologists, physiotherapists, or occupational therapists, for example. Physical therapy can be used to improve neuromuscular control (but requires patient cooperation) and may involve the use of oral-motor exercises and intraoral devices such as palatal training devices.

Drug-based treatments for sialorrhea are prescribed based on etiology. If the patient is experiencing sialorrhea secondary to a pharmaceutical agent, alternate medications should be considered. If the therapeutic regimen cannot be altered or in other circumstances, a compatible xerogenic agent (e.g., glycopyrrolate, scopolamine, benztropine, amitriptyline, atropine, or diphenhydramine hydrochloride) may be added.[306] A glycopyrrolate oral solution has been approved in the United States for drooling in children with neurologic conditions. Intraoral tropicamide films are also available, which provide short-term relief of sialorrhea and have been used in patients with Parkinson's disease experiencing sialorrhea.[307] The anticholinergic effects of these medications downregulate acetylcholine resulting in decreased saliva secretion via the parasympathetic nervous system. They have side effects, however, which may make them intolerable to some patients.

Sialorrhea that occurs secondary to chronic nausea (e.g., during chemotherapy) can be treated with an antiemetic. Sialorrhea due to GERD is a protective buffering response to acids encountered in the oral cavity. Under most circumstances, when the GERD is appropriately managed, the sialorrhea resolves.

Botulinum toxins (BoNT) A and B are also used for the management of sialorrhea. They have proven efficacy, fewer side effects than anticholinergic medications, and their use can decrease the risk of aspiration pneumonia in people with neurologic diseases.[308] BoNT works by inhibiting the presynaptic release of acetylcholine and other neurotransmitters at the neuroglandular junction. BoNT-A injections have been used to treat sialorrhea in adults with Parkinson's disease, head and neck cancer, stroke, and other neurodegenerative diseases. It is also used for sialorrhea in children with cerebral palsy or other neurologic diseases.

The therapeutic effects of BoNT-A when injected into the salivary glands can extend for 3 to 6 months. Since they are the greatest contributors to saliva volume, the submandibular and parotid glands are the most commonly injected sites. Injection into these glands is performed using ultrasound guidance but, currently, there is no consensus on dosage or injection technique. The commonly reported side effects include injection site pain, difficulty chewing, increased saliva thickness, xerostomia, and rarely a transient dysphagia. There is also a risk of facial nerve trauma. Some limitations to BoNT injection include cost, necessity for retreatment, and possible need for sedation in the pediatric or uncooperative patient. Repeat injection may lead to antibody formation and diminishing efficacy.[309]

Surgical intervention is reserved for the most severe cases of sialorrhea that are refractory to conservative and pharmacologic therapy. There are a number of surgical techniques that have been used to treat sialorrhea, particularly in patients with poor or deficient neuromuscular function, such as in children with cerebral palsy. Several surgical strategies have been used including decreasing nervous stimulation to the salivary glands by denervation, re-routing or blocking salivary flow by transposition or ligation of the salivary ducts respectively, or excision of salivary gland tissue. These techniques are successful in reduction of drooling approximately 80% of the time, with occasional postoperative complications such as ranula formation, pain, and numbness.[310] There is also the risk of hyposalivation, and its attendant complications, and severe xerostomia, particularly with gland excision.

Radiation therapy is rarely used for sialorrhea and is typically reserved for elderly patients or those who are not candidates for surgery or other medical therapies (e.g., patients with amyotrophic lateral sclerosis (ALS) or Parkinson's disease).[311] Side effects include hyposalivation and xerostomia, mucositis, dermatitis, pain, and increased salivary viscosity, and there is an increased risk of development of radiotherapy-associated neoplasia.[312]

MANAGEMENT OF XEROSTOMIA AND HYPOSALIVATION

Treatments for dry mouth may be divided into four main categories: (1) preventive therapies; (2) symptomatic (palliative) treatment; (3) local or topical salivary stimulation; and (4) systemic salivary stimulation. For treatment of the underlying disorder associated with hyposalivation, please see section: Specific Diseases and Disorders of the Salivary Glands. Successful management of xerostomia and hyposalivation often involves a combination of agents tailored to the patient's needs. Management approaches are summarized in Table 9-6.

Preventive Therapies

The use of topical fluorides in a patient with salivary gland hypofunction is critical to prevent dental caries since, where there is hyposalivation, there may be insufficient saliva to effectively remineralize the enamel. There are many different fluoride therapies available, from low-concentration over-the-counter fluoridated mouth rinses to more potent, highly concentrated prescription fluorides (e.g., 1.1% neutral sodium fluoride) that are applied by brush or in a custom

Table 9-6 Management of xerostomia.

Management Approach	Examples
Preventive therapies	Supplemental neutral fluoride; remineralizing agents
Symptomatic (palliative) treatments	Water; saliva substitutes
Local or topical salivary stimulation	Sugar-free gums and candies
Systemic salivary stimulation	Parasympathomimetic secretagogues (e.g., cevimeline and pilocarpine)

carrier. Oral health care practitioners may also apply fluoride varnishes in the office; the dosage, method, and frequency of application (from daily to weekly) should be determined based on the patient's ability to perform oral home care and caries risk.[313] In a patient with dry mouth, neutral fluoride, rather than acidulated phosphate fluoride (APF), should be used. The low pH of acidulated agents (pH ~ 3) may irritate dry, sensitive mucosa. In addition, assuming the patient has an extensive restorative history, APF will etch composite restorations, including glass ionomer cements, and corrode porcelain surfaces.

Patients with hyposalivation require frequent dental visits (at least every 3–4 months) and must work closely with their dentist and hygienist to maintain optimal oral health. Time should be allotted to review instructions in optimal brushing and flossing techniques, discuss the use of other devices such as oral irrigators and interdental brushes, and establish a personalized home care regimen. Recommended practices include brushing at least twice a day and at least daily use of floss or interdental devices. The antiseptic chlorhexidine, used as a mouth rinse twice daily, can reduce cariogenic microbial load and is effective as a chemical plaque control agent. It can be especially helpful in patients with high levels of *Streptococcus mutans* (i.e., $\geq 10^6$ colony forming units per mL of saliva). The dispensing pharmacy should be requested to provide the patient with a chlorhexidine solution formulated without alcohol.

In the absence of the remineralizing properties of saliva, tooth demineralization proceeds unchecked, speeding the loss of tooth structure. In the presence of lesions of demineralization, remineralizing products, such as those containing calcium and phosphate, may be of benefit. Increased salivary calcium and phosphate levels can reduce enamel solubility, enhance remineralization and thereby protect against caries development. Casein phosphopeptide-amorphous calcium phosphate (CPP-ACP) complex is reported to have anticariogenic effects. It can reduce enamel demineralization and promote remineralization by buffering free calcium and phosphate ions. ACP is incorporated into plaque and dental surfaces and maintains a state of supersaturation with respect to tooth enamel. Remineralizing products can be applied by the patient or caregiver to cleansed teeth just prior to the application of a high-potency fluoridated product.

Patients with dry mouth may also experience an increase in oral infections, particularly mucosal candidiasis. This is often of the erythematous form where the patient may present with redness of the mucosa and complaints of a burning sensation or soreness of the intraoral soft tissues. Angular cheilitis, usually seen as persistent cracking and erythema at the corners of the mouth, is also common. A high index of suspicion should be maintained, and appropriate treatment should be instituted. Patients with salivary gland dysfunction, however, may require prolonged treatment and periodic retreatment to eradicate oral fungal infections.[242] Patients should also be advised of the potential increased risk of development of oral candidiasis if they are to undergo a course of treatment likely to promote a fungal overgrowth, such as with systemic antibiotics or intraoral steroids.

Symptomatic Treatment

Patients should be encouraged to sip water throughout the day to help moisten the oral cavity and clear debris from the mouth. Since wettability of the oral mucosa and enamel by water is poor, any relief of xerostomia is usually very temporary.[13] In addition, since drinking copious amounts of water may effectively wash away saliva and disrupt sleep due to nocturia, patients should be advised instead to use small sips of water frequently throughout the day. The use of water with meals can also make chewing and forming a food bolus easier, facilitate swallowing, and may improve taste perception. Patients may find a sugar-free beverage is more palatable than water but should be advised that frequent use of sugar-free carbonated drinks is not recommended as their acidity is high which may promote tooth demineralization.

As a function of normal diurnal variation and positional changes, salivary flow decreases significantly at night, when supine, and during sleep. In individuals with secretory hypofunction, desiccation of the mucosa may result in nocturnal awakening preventing restorative sleep. The use of room humidifiers may lessen discomfort markedly. Similarly, patients should be counseled to avoid low humidity and air-conditioned environments where possible. Mouth breathing, where present, will typically exacerbate nocturnal symptoms and may require a medical evaluation to determine if there is a correctable cause such as nasal congestion caused by allergies or sinus polyps.

Patients using continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP) machines may

find that their use causes or exacerbates oral dryness. Use of a humidifier with the device, changing from a nasal pillow or nasal mask to a full face mask, or use of a chin strap to prevent mouth breathing are some strategies that could be explored. Oral dryness with use of these machines can also be caused or exacerbated by an ill-fitting mask.

There are a myriad of products available for dry mouth (e.g., mouthwashes, gels, sprays, lozenges), but patients should be cautioned to avoid products containing alcohol, sugar, or strong flavors that may irritate sensitive, dry mucosa. Moisturizing and lubricating products may provide additional comfort and help prevent friction-associated lesions. Some commercially-available preparations contain aloe vera which has purported humectant properties. Alternatively, topical use of aloe vera juice alone may provide temporary relief of dryness. Patients may also find rinsing with a neutral edible oil such as flax seed, coconut, or olive oil before bedtime or around meals provides moisture and lubrication.

Salivary substitutes, also known as oral rehydrating agents, are topical agents that maintain lubrication of the mucosa and may or may not have a saliva-stimulating effect. Agents incorporating salivary substitutes may be found in a range of products including lubricating gels, mouthwashes, lozenges, toothpastes, and oral sprays. These are typically composed of a mix of buffering agents, cellulose derivatives (to promote adherence to the mucosa and provide moisture), and flavoring agents. Ingredients in these products may include animal mucin, carboxymethyl cellulose, hydroxypropyl methylcellulose, hydroxyethylcellulose, and polyglycerylmethacrylate. Other agents that have been investigated include xanthan gum, linseed (flax seed) extract, and aloe vera.[314]

Saliva substitutes may have a positive effect on nocturnal oral dryness without appreciable side effects. Clinical trial data have not shown a significant difference in efficacy between some salivary substitutes and a placebo although some randomized control trials show improvement in oral symptoms. Although there is no reported superiority in preparations with mucin versus carboxymethylcellulose-containing substitutes, mucin-containing agents tend to be preferred by patients. These agents tend to have at most a very transient effect and therefore require frequent re-application.[263]

Salivary Stimulation

Local or Topical Stimulation

Both chewing and taste (especially sour and sweet tastes), stimulate salivary flow and thus the use of sugar-free chewing gums, mints, or candies, can be effective in temporarily relieving symptoms in patients who have remaining salivary gland function. Patients with dry mouth must be advised to avoid products that contain sugar or other fermentable carbohydrates (e.g., honey, high fructose corn syrup) due to the increased risk of dental caries. Instead, patients should be encouraged to try products using xylitol, a sugar alcohol that inhibits *Streptococcus mutans,* or other sweeteners including those made from the botanical species *Stevia rebaudiana*, *Siraitia grosvenorii* (monk fruit or *luo han guo*), and the sugar alcohol erythritol.

Attempts to develop a "salivary pacemaker" to stimulate saliva flow has generated some intriguing devices. There are 2 FDA-approved neuroelectrostimulating devices: the Salitron™ system, which employs a handheld probe placed on the dorsal tongue for 5 minutes three times daily, and the Saliwell GenNarino™, a removable, remote-controlled mouth guard. The Salitron™ system, which was reported to be cumbersome due to its bulky size, is no longer manufactured but may still be in use. More recently, implantable devices, such as the Saliwell Crown™, constructed in the form of an oral osteointegrated implant with an embedded wetness sensor, have been developed. These devices monitor oral dryness and provide an automatic or patient-controlled stimulus to the adjacent tissue resulting in salivation.[315] While these "pacemaker" devices show promise without cholinergic side effects, their routine use has been hampered by cost and insurance limitations.[244]

Acupuncture-like transcutaneous electrical nerve stimulation (ALTENS) is a needle-free, noninvasive treatment involving application of mild electric currents to acupuncture points. It has shown similar reduction in xerostomia as oral pilocarpine, with fewer side effects, in a study of patients with radiation-induced xerostomia. Although this treatment may be well tolerated, ALTENS devices are not widely available and may require clinic visits twice weekly for 12 weeks.[316] A study using a similar commercially available device (which may allow patients to administer treatment at home) has recently shown promise, but further studies are required.[317]

Many studies have explored the effect of acupuncture on salivary flow, and while some studies report a small increase in saliva production in patients with dry mouth following radiotherapy with few reported adverse effects, comprehensive systematic reviews have yet to show any definitive, nonbiased results. Further well-constructed clinical trials are required before definitive recommendations for its use can be made.

Systemic Stimulation

Pilocarpine HCl (Salagen®) and cevimeline (Evoxac®) are FDA-approved oral sialogogues. They are muscarinic acetylcholine receptor agonists mainly targeting M1 and M3 receptor subtypes. These subtypes are found not only in salivary glands but are also widely distributed throughout the body.

As a result, use of these sialogogues may also result in side effects such as sweating, flushing, hypotension, blurred vision, nausea, and stomach ache.[274]

Pilocarpine HCl is indicated specifically for the relief of xerostomia following radiotherapy for head and neck cancers and for patients with Sjögren's syndrome. It is safe and effective for patients with diminished salivation who have some remaining secretory function. The recommended dose is 5.0 or 7.5 mg taken three or four times daily, but patients may benefit from starting with 2.5 mg (by dividing a 5 mg tablet) to minimize side effects. Salivary output increases within 20 minutes of administration, reaches a maximum within 1 hour, and the duration of action is approximately 3 to 5 hours. At least 12 weeks of uninterrupted therapy may be necessary to assess whether a beneficial response will be achieved. Pilocarpine is contraindicated in patients with uncontrolled asthma, narrow angle glaucoma, and acute iritis and should be used with caution in patients with significant cardiovascular or pulmonary disease, cholelithiasis, or biliary tract disease.

Cevimeline HCl is indicated for the treatment of oral dryness in Sjögren's syndrome patients. It has a stronger affinity for M3 receptors, which may account for its fewer reported side effects and lower failure rate in first time users.[275] It is typically prescribed at 30 mg taken three times daily. Cevimeline is contraindicated in patients with uncontrolled asthma, narrow angle glaucoma, and acute iritis and should be used with caution in patients with significant cardiovascular or pulmonary disease, a history of cholelithiasis, or nephrolithiasis.

SALIVARY GLAND TUMORS

Salivary gland tumors account for 3% to 10% of all head and neck tumors.[318] Approximately 75–80% of salivary gland tumors arise in the parotid glands, 10–15% arise in the submandibular glands, and the remaining tumors develop in the sublingual or minor salivary glands. Generally speaking, the relative proportion of malignant neoplasms is greater the smaller the gland: that is, a neoplasm in the parotid gland is more likely to be benign than one arising in a minor salivary gland. Around 15–32% of tumors of the parotid glands, 41–45% of tumors of the submandibular glands, and 70–90% of tumors of the sublingual glands are malignant. With respect to tumors of the minor salivary glands, the risk of malignancy is site dependent: approximately half of tumors arising on the palate are malignant whereas up to 90% of those of the floor of mouth are malignant.[319]

Table 9-7 A list of some common benign and malignant salivary gland tumors.

Benign	Malignant
Pleomorphic adenoma	Mucoepidermoid carcinoma
Papillary cystadenoma lymphomatosum (Warthin's Tumor)	Adenoid cystic carcinoma
Oncocytoma	Acinic cell carcinoma
Basal cell adenoma	Polymorphous adenocarcinoma
Canalicular adenoma	Epithelial-myoepithelial carcinoma
Myoepithelioma	Salivary duct carcinoma
Sebaceous adenoma	Carcinoma ex-pleomorphic adenoma
Ductal papilloma	Clear cell carcinoma

Overall, the pleomorphic adenoma is the most common benign salivary gland tumor while the mucoepidermoid carcinoma is the most common malignant salivary gland tumor. While 15% to 25% of salivary gland tumors in adults are malignant, 25% to 50% of those in children and adolescents are malignant.[320] A partial list of the most common benign and malignant salivary gland neoplasms is presented in Table 9-7.

Certain clinical signs and symptoms are more likely to be associated with a malignant neoplasm of the salivary glands. These include ulceration of the overlying mucosa, fixation of the mass to deeper tissue planes, multiple masses within a single gland, induration, and lymphadenopathy. Additional findings such as otalgia, dysphagia, odynophagia, trismus, paresthesia, a history of cancer or cachexia, may further raise suspicion for malignancy.

Treatments for salivary gland neoplasms include surgery, radiotherapy (including brachytherapy), chemotherapy, and biological therapy. Clinicians should be cognizant of the increased risk of development of second cancers in patients who have previously received radiotherapy to the head and neck.

The taxonomy of salivary gland tumors is dynamic. New entities and variant morphologies are proposed while other entities have been removed or collapsed into other categories. Clinicians are advised to consult an up-to-date publication for further details on the classification of salivary gland tumors.[321]

ACKNOWLEDGMENTS

We thank Philip C. Fox, DDS, FDS, RCSEd for his significant contribution to this chapter.

Temporomandibular Disorders

Richard Ohrbach, DDS, PhD, OdontDr (h.c.)
Thomas Sollecito, DMD, FDS RCS(Ed)
Temitope Omolehinwa, BDS, DScD
Martin S. Greenberg, DDS, FDS RCS(Ed)

This chapter focuses on the assessment and management of disorders of the masticatory system. The masticatory apparatus is a specialized unit that performs multiple functions, including those of suckling, cutting and grinding food, swallowing, and communication. The loss of these functions, particularly in association with pain, is characteristic of masticatory system disorders and causes significant distress that can be severely disabling.

The term *temporomandibular disorder(s)* (TMD) used in this chapter is a collective term embracing a number of clinical problems that involve the masticatory muscles, the temporomandibular joints (TMJs), and associated structures.[1] These disorders are characterized by: (1) facial pain in the region of the muscles of mastication, TMJs, or both; (2) limitation or deviation in mandibular movements; (3) hyperalgesia of the musculoskeletal structures; and (4) TMJ sounds during jaw movement and function.[2] "TMD" is not a diagnosis, but refers to any of many different disorders. Differentiating subtypes of muscle and joint disorders according to validated diagnostic criteria has often been sidestepped in favor of ad hoc assessment methods and ad hoc diagnoses. Adequate evidence supporting valid diagnostic approaches now exists[3] and such approaches are recommended.[4] In the past, disorders of the masticatory system were generally treated as one condition or syndrome, with no attempt to identify different muscle or joint disorders and link those to the chief complaint as well as targeted therapy. Use of a validated approach should lead to a better understanding of the natural course, more accurate predictions of prognosis, and more effective treatments. This chapter

Burket's Oral Medicine, Thirteenth Edition. Edited by Michael Glick, Martin S. Greenberg, Peter B. Lockhart, and Stephen J. Challacombe.

presents a general but evidence-based approach to the diagnostic assessment and nonsurgical management of the most common TMDs. Some of the less common disorders are also considered in order to better draw attention to the salient characteristics of the common disorders and why the general therapeutic guidelines for the common disorders remain the most sensible.[4]

BACKGROUND

Anatomy

Temporomandibular Joint

The TMJ is a complex joint comprised of bone, ligament, and an articular disc. The bony components include the mandibular condyle and the glenoid fossa of the temporal bone. The mandibular condyle forms the lower part of the bony joint and is generally elliptical in shape, although variations are common.[5,6] The articulation is formed by the mandibular condyle occupying a hollow in the temporal bone (the mandibular or glenoid fossa). The S-shaped form of the fossa and eminence, as viewed sagitally, starts developing at about 6 years of age and continues into the second decade[7] (Figures 10-1 and 10-2). The bony elements are enclosed and connected by a fibrous capsule.

The fibrous joint capsule is lined with synovial tissue, a vascular connective tissue which extends to the boundaries of the articulating surfaces. The synovial membrane consists of macrophage-like type A cells and fibroblast-like type B cells identical to those in other joints. The macrophage-like type A cells react with antimacrophage and macrophage-derived substances, including the major histocompatibility class II molecule, and show a drastic increase in their number

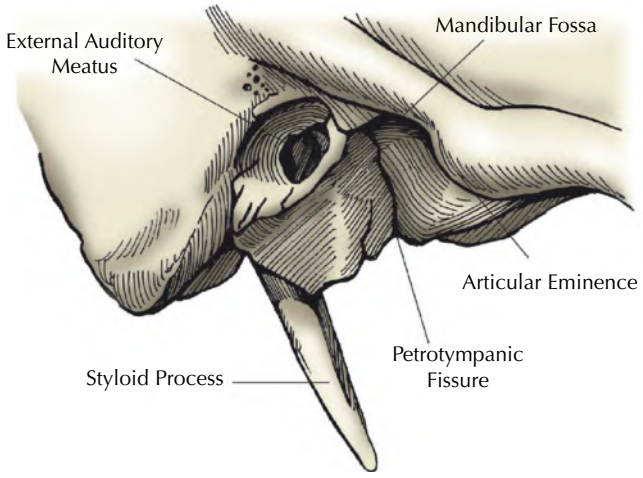

Figure 10-1 The S-shaped form of the fossa and eminence. The mandibular condyle occupies the space of the fossa, with enough room to both rotate and translate during mandibular movements.

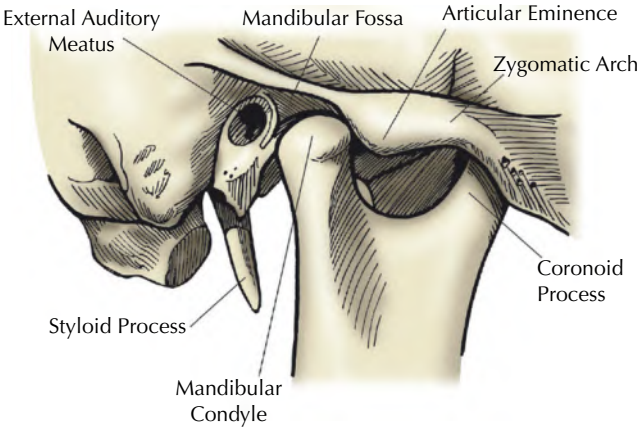

Figure 10-2 The articulation is formed by the mandibular condyle occupying a hollow in the temporal bone (the mandibular or glenoid fossa) during wide mouth opening; the condyle rotates around an axis and glides, causing it to move beyond the anterior border of the fossa, the articular eminence.

in the inflamed synovial membrane.[8] The joint cavity is filled with synovial fluid. Synovial fluid is a filtrate of plasma with added mucins and proteins. Its main constituent is hyaluronic acid. Fluid forms on the articulating surfaces and decreases friction during joint compression and motion.[9] Joint lubrication is achieved by mechanisms described as weeping lubrication and boundary lubrication. Weeping lubrication occurs as fluid is forced laterally during compression and expressed through the unloaded fibrocartilage.[10] As the adjacent areas become loaded, the weeping lubrication aids in reducing friction. Boundary lubrication is a function of water that is physically bound to the cartilaginous surface by a glycoprotein.[11] Collectively, the fluid dynamics depend on appropriate loading and unloading of the joint through normal function in order to maintain continuous lubrication as well as maintenance of the tissue health.[12]

Fibrocartilage, instead of the expected hyaline cartilage, covers the articulating surface of the joint. Fibrocartilage is less distensible than hyaline cartilage due to a greater number of collagen fibers including Type 1 collagen. The matrix and chondrocytes are decreased because of the larger irregular bundles of collagen fibers.[13] The fibrocartilage found on the articulating surfaces of the TMJ is thought to provide more surface strength against forces in many directions while allowing more freedom of movement than would be possible with hyaline cartilage. This covering is thickest on the posterior slope of the articular eminence and on the anterior slope of the condylar head; these are the areas thought to receive the greatest functional load. The thinnest part of the fibrocartilage covering is on the roof of the mandibular fossa. Fibrocartilage has a greater repair capacity than hyaline cartilage which may affect how the TMJ responds to degenerative changes.[13,14]

The TMJ articulation is a joint that is capable of both hinge-type movements and gliding movements. During wide mouth opening, the condyle rotates around a hinge axis and then translates as it glides, causing it to move beyond the anterior border of the fossa, which is identified as the articular eminence.[15]

Articular Disc

Dense fibrous connective tissue primarily made up of dense collagen of variable thickness is referred to as a disc and occupies the space between the fibrocartilage coverings of each of condyle and mandibular fossa (Figures 10-3 and 10-4). The disc consists of collagen fibers, cartilage-like proteoglycans,[16] and elastic fibers.[17] The disc contains a variable number of cells that resemble fibrocytes and fibrochondrocytes.[18] Collagen fibers in the center of the disc (often referred to as the intermediate zone) are oriented perpendicular to its transverse axis functionally aligned with loading on that zone. The collagen fibers become interlaced as they approach the anterior and posterior bands, and many fibers are oriented parallel to the mediolateral aspect of the disc. Cartilage-like proteoglycans contribute to the compressive stiffness of articular cartilage.[19] The disc is primarily avascular and has little sensory innervation. The disc is thinnest in the intermediate zone and thickens to form anterior and posterior bands represented as a "bow tie" in sagittal sections. This arrangement is considered to help stabilize the condyle in the glenoid fossa.[5] Over time, discs may exhibit changes in this conformation; the central intermediate zone may become elongated or nonexistent, the anterior band may become thinner, or the posterior band may become either thinner or thicker. These conformation changes, while presumably affecting the ideal function of the disc in stabilizing the condyle during loading, are currently regarded as a variation on normal in the absence of any clinical manifestation of disordered function.[20]

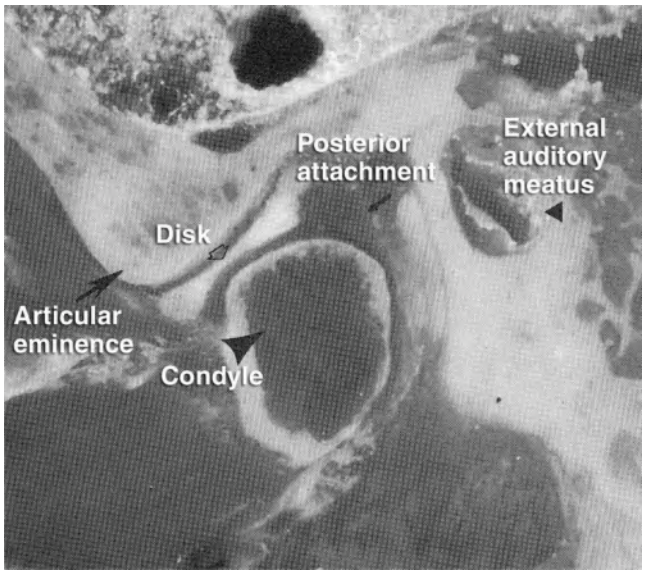

Figure 10-4 A cadaver section through the temporomandibular joint shows the relationship of the condyle, fossa, and articular disc.

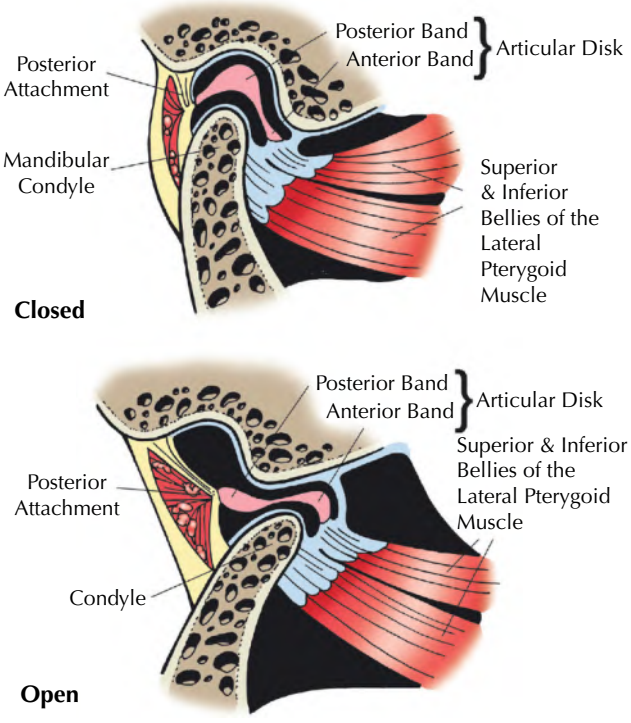

Figure 10-3 The temporomandibular joint is capable of hinge-type rotational movements and gliding translational movements. The articular disc has ligamentous attachments to the mandibular fossa and condyle. The disc's attachments create separate superior and inferior joint compartments.

The disc provides an interface for the condyle as it glides across the temporal bone. The disc is attached by ligaments to the lateral and medial poles of the condyle. The ligaments consist of both collagen and elastic fibers.[21] These ligaments permit rotational movement of the disc on the condyle during mouth opening and closing. The disc and its attachments divide the joint into upper and lower compartments that normally do not communicate. The passive volume of the upper compartment is estimated to be 1.2 mL and that of the lower compartment is estimated to be 0.9 mL.[21] The roof of the superior compartment is the glenoid (mandibular) fossa, whereas the floor is the superior surface of the disc. The roof of the inferior compartment is the inferior surface of the disc and the floor is the articulating surface of the mandibular condyle.[21] At its margins, the disc blends with the fibrous capsule. Muscle attachments inserting into the anterior aspect of the disc have been observed in a relatively small number of individuals.[22] Fibers of the posterior one-third of the temporalis muscle and of the deep masseter muscle may

attach on the anterolateral aspect, and fibers of the superior head of the lateral pterygoid have been observed to insert into the anteromedial two-thirds of the disc.[22]

Retrodiscal Tissue

Loose connective tissue occupies the space behind the disc and condyle. It is often referred to as the posterior attachment or retrodiscal tissue. The posterior attachment is a loosely organized system of collagen fibers, branching elastic fibers, fat, blood and lymph vessels, and nerves. Synovium covers the superior and inferior surfaces. The attachment has been described as being arranged in two lamina of dense connective tissue[23] but this has been challenged.[24] Between the lamina, a loose areolar, highly vascular, and well-innervated tissue has been described. Both superior and inferior lamina arise from the posterior band of the disc. The superior lamina attaches to the squamotympanic fissure and tympanic part of the temporal bone and consists primarily of elastin.[23,25] The inferior lamina inserts into the inferior margin of the posterior articular slope of the condyle and is composed mostly of collagen fibers.[23]

Temporomandibular Ligaments

Capsular Ligament

The capsular ligament is a thin inelastic fibrous connective tissue envelope that attaches to the margins of the articular surfaces (Figure 10-5). The fibers are oriented vertically and do not restrain joint movements. The medial capsule is composed of loose areolar connective tissue.[24] The capsule and the lateral discal ligament join and attach to the lateral aspect of the neck of the condyle.[26]

Lateral Temporomandibular Ligament

The lateral temporomandibular ligament is the main ligament of the joint, lateral to the capsule but not easily separated from it by dissection. Its fibers pass obliquely from bone lateral to the articular tubercle in a posterior and inferior direction and insert in a narrower area below and behind the lateral pole of the condyle (Figure 10-5). However, various studies were unable to confirm a distinct structure separate from the capsule.[21,26]

Accessory Ligaments

The sphenomandibular ligament arises from the sphenoid bone and inserts on the medial aspect of the mandible at the lingula. The stylomandibular ligament extends from the styloid process to the deep fascia of the medial pterygoid muscle. It is thought to become tense during protrusive movement of the mandible and may contribute to limiting protrusive movement.[5]

Muscles of Mastication

The primary muscles of mastication are the paired masseter, medial and lateral pterygoids, and temporalis muscles (Figures 10-6, 10-7, 10-8). Mandibular movements toward

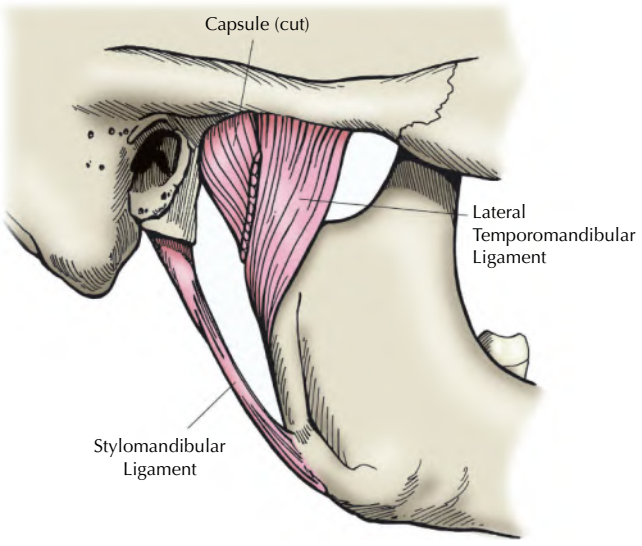

Figure 10-5 The capsular ligament is a thin, inelastic, fibrous connective tissue envelope, oriented vertically, that attaches to the margins of the articular surfaces. The temporomandibular ligament is lateral to the capsule. Its fibers pass obliquely from bone lateral to the articular tubercle in a posterior and inferior direction to insert in a narrower area below and behind the lateral pole of the condyle.

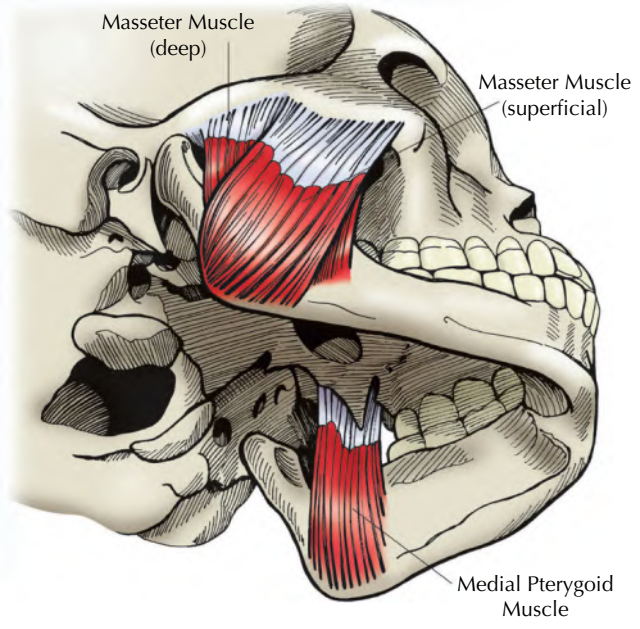

Figure 10-6 The masseter and medial pterygoid muscles have their insertions at the inferior border of the mandibular angle. They join together to form a sling that cradles the ramus of the mandible and produces the powerful forces required for chewing. The temporalis muscle is attached to the lateral skull. The muscle fibers converge to insert on the coronoid process and anterior aspect of the mandibular ramus.

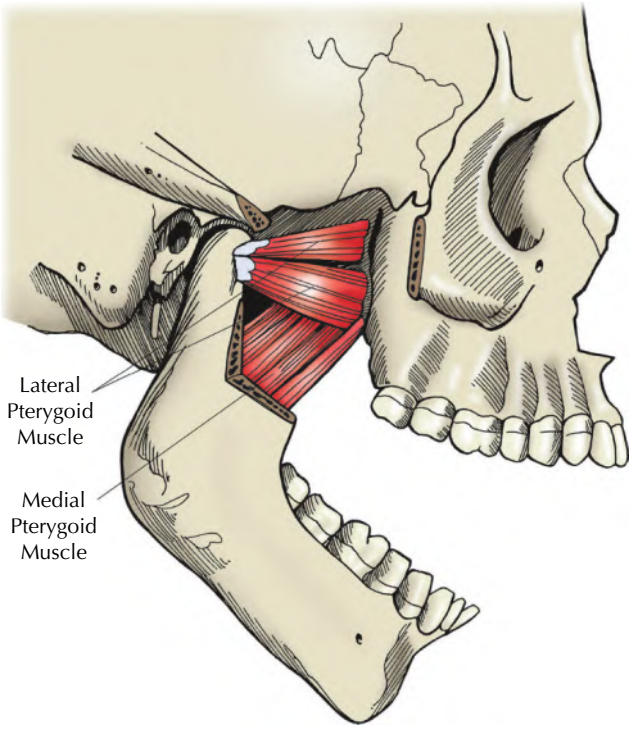

Figure 10-7 The lateral pterygoid muscle is the main protrusive and opening muscle of the mandible. The inferior part originates from the outer surface of the lateral pterygoid plate of the sphenoid and the pyramidal process of the palatine bone. The superior part originates from the greater wing of the sphenoid and the pterygoid ridge. They insert into the anteromedial aspect of the condylar neck. Some of the fibers insert into the most anterior medial portion of the disc.

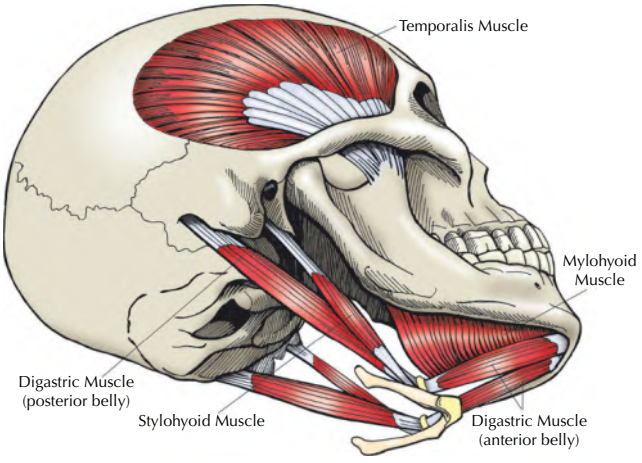

Figure 10-8 The digastric muscle is a paired muscle with two bellies. The anterior belly attaches to the lingual aspect of the mandible at the parasymphysis and courses backward to insert into a round tendon attached to the hyoid bone. The mylohyoid and geniohyoid muscles contribute to depressing the mandible, while the infrahyoid muscles stabilize the hyoid bone during mandibular movement.

the tooth contact position are performed by contraction of the masseter, temporalis, and medial pterygoid muscles.[27]

Masseter contraction contributes to moving the condylar head toward the anterior slope of the mandibular fossa (Figure 10-6). The posterior part of the temporalis contributes to mandibular retrusion. Unilateral contraction of the medial pterygoid contributes to a contralateral movement of the mandible. The masseter and medial pterygoid muscles have their insertions at the inferior border of the mandibular angle. They join together to form a sling that cradles the mandible and produces the powerful forces required for chewing. The masseter is divided into deep and superficial parts. The deep masseter in some individuals overlaps the anterior aspect of the TMJ, such that pain localized to the pre-auricular region may be associated with masseter, TMJ, or both structures. The temporalis muscle is attached to the lateral skull and has been divided into anterior, middle, and posterior parts. The muscle fibers converge into a tendon that inserts on the coronoid process and anterior aspect of the mandibular ramus. The anterior and middle fibers are generally oriented in a straight line from their origin on the skull to their insertion on the mandible. The posterior part traverses anteriorly and then curves around the anterior root of the zygomatic process before insertion.

The lateral pterygoid is the main protrusive and opening muscle of the mandible. The inferior head is the main section responsible for lateral jaw movements when the teeth are in contact.[28] The lateral pterygoid is arranged in parallel-fiber units, whereas the elevator muscles are multipennate in structure. This differential arrangement allows greater displacement and velocity in the lateral pterygoid vs. greater force generation in the elevator muscles.[29]

The lateral pterygoid muscle arises from two heads (Figure 10-7). The inferior head originates from the outer surface of the lateral pterygoid plate of the sphenoid bone and the pyramidal process of the palatine bone. The superior head originates from the greater wing of the sphenoid bone and the pterygoid ridge. The fibers of the upper and lower heads course posteriorly and laterally, fusing in front of the condyle,[30] and inserting into the anteromedial aspect of the condylar neck. Although some of the fibers insert into the most anterior medial portion of the disc (or capsule), most of the lateral pterygoid fibers insert into the condyle.[30] The superior part of the insertion consists of an identifiable tendon inserting through fibrocartilage. The inferior part of the insertion consists of muscle attached to periosteum.[31] Debate continues about the functional anatomy of the lateral pterygoid. The superior head is thought to be active during closing movements, and the inferior head is thought to be active during opening and protrusive movements.[32,33] However, substantial variability across individuals appears to account for some of the debate.[34,35] Translation of the condylar head

onto the articular eminence is produced by contraction of the lateral pterygoid.

The accessory muscles of mastication are relatively smaller and their function is more indirect and perhaps complex. The digastric muscle is a paired muscle with two bellies. The anterior belly attaches to the lingual aspect of the mandible at the parasymphysis and courses backward to insert into the hyoid bone. Contraction produces a depression and retropositioning of the mandible. The mylohyoid and geniohyoid muscles contribute to depressing the mandible when the infrahyoid muscles stabilize the hyoid bone. These muscles may also contribute to retrusion of the mandible. The omohyoid muscle arises from the scapula and inserts on the hyoid bone and serves to lower and stabilize the hyoid bone. Together with the digastric muscle, the omohyoid muscle lowers the jaw when active and is not active in a jaw resting position (Figure 10-8).[36] The buccinator attaches inferiorly along the facial surface of the mandible behind the mental foramen and superiorly on the alveolar surface behind the zygomatic process. The buccinator fibers are arranged horizontally; anteriorly, fibers insert into mucosa, skin, and lip. The buccinator helps position the cheek during chewing movements of the mandible and contracts in order to maintain the food bolus on the posterior teeth during chewing. The functional activity of these accessory muscles depends on simultaneous activation of the primary masticatory muscles for stabilizing the position of the mandible which, given the basal functions of the masticatory system, has implications with respect to the functional limitation and disability often associated with a TMD.

Vascular Supply of Masticatory System Structures

The external carotid artery (ECA) is the main blood supply for the structures of the masticatory system. The ECA leaves the neck and courses superiorly and posteriorly, embedded in the substance of the parotid gland, sending two important branches, the lingual and facial arteries, to the region. At the level of the mandibular condylar neck, the external carotid bifurcates into the superficial temporal artery and the internal maxillary artery. These two arteries supply the muscles of mastication and the TMJ. Arteries within the temporal bone and mandible also send branches to the capsule.[5]

Nerve Supply of Masticatory System Structures

The masticatory structures are innervated primarily by the trigeminal nerve, but cranial nerves VII, IX, X, and XI and cervical nerves 2 and 3 also contribute. The peripheral nerves synapse with nuclei in the brainstem that are associated with touch, proprioception, and motor function. The large spinal trigeminal nucleus occupies a major part of the brainstem and extends to the spinal cord. The spinal trigeminal nucleus is thought to be the main site for the reception of impulses from the periphery involved in pain sensation. The mandibular division of the trigeminal nerve supplies motor innervation to the muscles of mastication and the anterior belly of the digastric muscle. The auriculotemporal nerve, a branch of the mandibular portion (V3) of the trigeminal nerve, provides innervation of the TMJ (Figure 10-9). The deep temporal and masseteric nerves supply the anterior portion of the joint. About 75% of the time, the masseteric nerve, a branch of the maxillary division of the trigeminal nerve (V2), innervates the anteromedial capsule of the TMJ. In about 33%, a separate branch from V2 comes through the mandibular notch and innervates the anteromedial capsule.[37] These nerves are primarily motor nerves, but they contain sensory fibers distributed to the anterior part of the TMJ capsule. The autonomic nerve supply is carried to the joint by the auriculotemporal nerve and by nerves traveling along the superficial temporal artery.[38]

Epidemiology

Between 65 and 85% of people in the United States experience one or more symptoms of a TMD during their lives, but the symptoms are self-limiting for most individuals and resolve without professional intervention.[39] Incidence of first lifetime onset of a painful TMD appears to be between 2–4% per annum.[40–43] Although the prevalence of one or more signs of mandibular pain and dysfunction is high in the population, only about 5 to 7% have symptoms severe enough to require treatment.[39,44,45]Among those who

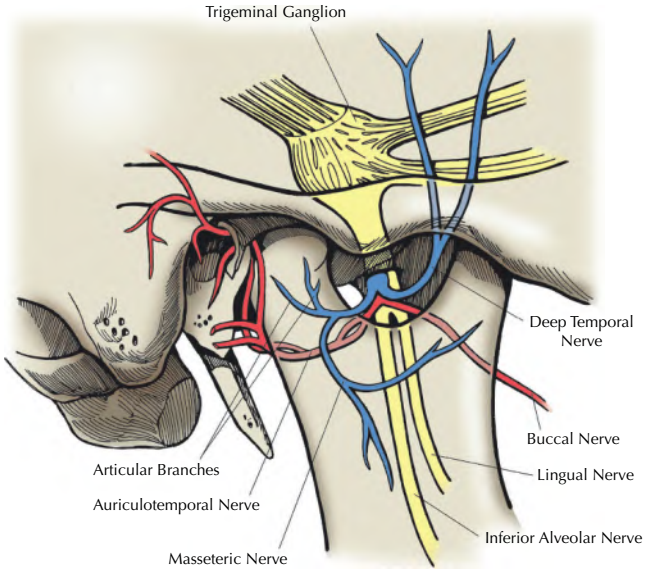

Figure 10-9 Branches of the auriculotemporal nerve supply sensory innervation of the TMJ. This nerve arises from the mandibular division in the infratemporal fossa and sends branches to the capsule of the joint.

develop a TMD, approximately 12% experience prolonged pain that results in disability,[39] and more recent estimates indicate that between 25–50% of individuals with acute painful TMD develop chronic pain in the absence of appropriate intervention.[46,47] In terms of symptom profile, individuals with a painful TMD are similar to those with headache and back pain with respect to pain intensity, frequency, chronicity, psychosocial distress, and pain-related disability.[48,49] These profiles appear to be similar in individuals with TMDs across cultures; for example, Asian, Swedish, and American populations with TMDs share similar characteristics.[50]

Available evidence indicates that TMDs are most prevalent between the ages of 20 and 40 years, and that prevalence then decreases by age 60, after which it decreases substantially.[51] The lower prevalence of TMDs in older age groups suggests that the disease course in a significant proportion of individuals with TMDs is strongly influenced by situational factors that resolve with aging. TMDs in the community occur at about twice the rate in females vs. males, yet females are eight times more common in the clinic population, compared to males. The reason why women make up the majority of patients presenting for treatment remains unclear. While the natural course of TMDs is poorly understood, gender apparently affects the disease course as well.[52] For example, oral contraceptives and estrogen replacement in women over 40 years of age substantially increases the risk of developing a painful TMD.[53]

Signs and symptoms of masticatory muscle and TMJ dysfunction are also commonly observed in children and adolescents.[54–56] Among adolescents in Sweden between the ages of 12 and 19 years, 4.2% reported TMD pain, and girls reported TMD pain approximately twice more frequently than boys, 6% compared with 2.7%.[57] Surprisingly, a wide variety of painful TMD characteristics observed in adults also occur to largely the same extent in children and adolescents. For example, among a group of 40 children aged 10 to 16 years and presenting with signs and symptoms of a painful TMD, 14 (35%) were diagnosed as having acute reactive depression.[58] Arthrography and computed tomography (CT) were performed on 31 children complaining of TMJ pain and dysfunction: 12 (39%) exhibited disc displacement with reduction, and 17 (55%) exhibited disc displacement without reduction.[59] Among the 29 individuals with internal derangement, causation was attributed to previous injury in 12 individuals. Yet, in a survey of 1000 12-year-old children, only 1% had a maximum mouth opening of less than 40 mm, indicating that the norm for expected opening range is established prior to the final growth phase in adolescents. Despite this extent of abnormal findings, only a small proportion of children presented with clinical findings severe enough to warrant treatment.[60]

Etiology

Etiology of the most common TMDs is unknown. The literature has been dominated by several hypothesized causes: occlusal disharmony, muscle hyperactivity, central pain mechanisms, psychological distress, and trauma.

Occlusal Disharmony

The history of the dental occlusion, as related to TMDs, is long and complex within the dental profession. Managing occlusion is a major task within restorative dentistry and, not surprisingly perhaps, the focus on occlusion has often been at the boundary between clinical lore and scientific evidence. While deviations of the occlusion from the ideal—so-called occlusal disharmony—can be construed in many ways, operational features that clearly distinguish a "good" occlusion from a "bad" occlusion remain missing from the discussions; moreover, the persistent focus on occlusion and TMDs contrasts with the inadequate to poorly designed and executed research used to support that focus. A short history of these concepts will be followed by focusing on some of the major claims regarding the presumed importance of occlusion in relation to TMDs. That this section has been retained, if not expanded, over the past several editions of this book is telling in itself: dentistry is reluctant to abandon the evaluation and treatment of occlusion with regard to TMDs, perhaps to the point that occlusion becomes a cause célèbre.

The relationship of so-called occlusal disharmony and TMD became the center of attention within the profession after Costen reported that a group of patients with multiple complaints associated with the jaws and ears improved after the occlusal–vertical dimension of their dentures was altered.[61] Despite the lack of anatomic support for occlusal–vertical dimension as a mechanism,[62] the occlusal hypothesis was nevertheless expanded to include other occlusal parameters, each believed to be responsible in addition to loss of vertical dimension for causing a TMD,[63,64] yet without evidence. During the 1950s and 1960s, a muscular cause not directly related to occlusion was proposed; the mechanisms were generic for similar pains elsewhere in the body, thereby highlighting the strong plausibility of the model.[65–67] In contrast, because this particular model ignored occlusion as a cause of TMD, the model proved to be very controversial within dentistry, setting the stage for ongoing controversy for any model that did not include occlusion as a cause. In the late 1970s, advances in diagnostic imaging resulted in a better understanding of intracapsular dynamics of the TMJ, and the focus was renewed upon so-called abnormalities of structure, now in the TMJ, as the "cause of TMD" and clearly evident via imaging.[68,69] The lack of a clear understanding with regard to cause, the existence of multiple hypotheses, and strongly held beliefs by some clinicians have resulted in

a wide spectrum of views about what TMD constitutes, regardless of the absence of supporting evidence. This wide spectrum of views continues in the present, such that the transfer of science regarding TMDs to the clinical setting is often compromised, with inappropriate diagnosis and treatment as a consequence.

Clear and convincing evidence for so-called occlusal disharmony as a primary etiology of TMDs does not exist.[70] Research studying discrepancies between centric occlusion and maximal intercuspal position, nonworking side occlusal interferences, posterior crossbite, and Angle's occlusal classification has not established a strong association in patients with myofascial pain compared with controls.[45,71,72] Significant differences in occlusal characteristics are not found between patients with myofascial pain compared with control subjects.[73] Overjet and overbite do not have a strong relationship with joint clicking, crepitus, pain, or limited opening.[74,75] A number of studies have been performed to investigate a possible relationship between orthodontic malocclusions and treatment and the development of TMD, but the results do not support a causal relationship.[76–80]

A mainstay in the clinical lore regarding occlusion and TMDs is centric relation as an index for the position of the mandible relative to the maxilla. Centric relation is a position that has traditionally relied on guiding the condyles into a position to rotate around a stationary axis in the mandibular fossa, and it has served as both a highly idealized and a highly contentious anatomical point. The standard definition is "the maxillomandibular relationship, independent of tooth contact, in which the condyles articulate in the anterosuperior position against the posterior slopes of the articular eminences."[81] This position of condylar rotation about a stationary axis can be reproduced and transferred to an articulator, and while that is useful clinically for restorative dentistry, a biological basis for the manipulated position has not been identified. A mandibular position usefully defined in operational terms for purposes of restorative dentistry should not be confused with necessarily having diagnostic or biological value beyond the operational definition. Evidence for centric relation as a diagnostic test or proxy for TMDs does not exist. Adjusting the maximum intercuspal position to be coincident with centric occlusion (the occlusion that exists when the mandible is at centric relation) has been strongly recommended by some clinicians to treat TMDs, but the biological evidence for this as a standard treatment is absent.[82] In contrast, the available evidence indicates that the "stationary axis" is itself dynamic: for example, restoring a dentition for centric occlusion coincidence with maximum intercuspal position results in the development of a new centric occlusion over time,[83] implying that centric relation is a boundary of a zone used for normal movement. Moreover, such adjustments may actually increase risk for a TMD based on evidence suggesting that a gap in the maximal intercuspal position vs. centric occlusion is protective against TMD onset.[84] The biology associated with centric relation does not appear to support a causal linkage with TMDs.

A particularly contentious topic has been that premature occlusal contacts, such as faulty restorative dentistry, initiate sleep bruxism. This belief stems from research studies that are typically uncritically cited[85,86] but which were completely inadequate for any scientific conclusion. Premature occlusal contacts actually trigger the opposite in healthy individuals: a decrease in the activity of masticatory elevator muscles during sleep.[87] In contrast, the same premature occlusal contact in individuals with a TMD or a prior history of a TMD will cause increased activity of the masticatory elevator muscles during sleep.[88] Importantly, this increased muscle activity in those with a TMD is not evidence of causation. Rather, the impact of such premature occlusal contacts appears to depend on pre-existing trait anxiety and extent of oral parafunctional behaviors.[89]

To date, as summarized elsewhere,[70] TMDs exhibit an association with only a very few attributes of a static occlusion, and the magnitude of the association is relatively small and inconsistent across studies. These associations are based on cross-sectional study designs, not longitudinal designs, and collectively suggest that the specific occlusal features have a complex relationship to TMD pain. The available evidence indicates that that complex relationship, pointedly, does not include a direct causal role. Just as the evidence has not supported occlusal attributes as cause of TMD, the research literature has not supported any efficacy of occlusal treatment for a TMD.[90] Overall, studies examining occlusal characteristics and TMD symptoms have failed to identify a strong association.[91] Returning to the early work of Costen, the loss of occlusal vertical dimension has been (and perhaps continues to be) considered a cause of a TMD, but contemporary evidence for this remains lacking.[92] Finally, the focus on static occlusal features sidesteps the potentially far more important dynamic aspects of the dentition where more force and greater instability occur: during mastication, when the teeth do not actually contact.

Complicating static and dynamic occlusion is where the teeth should be when the teeth do not need to touch and the mandible does not need to function. When the mandible is not functionally active, it adopts a so-called rest position in which the condyle occupies a relatively neutral position in the glenoid fossa with the teeth separated. The rest position is considered to be associated with minimum muscular activity and with the articulating surfaces of the mandibular teeth a few millimeters from the occlusal contact position with the opposing teeth.[93] "Rest position" is, however, somewhat of a misnomer since a wide range of activity in the masticatory muscles is observed, under the presumed

condition of "rest," across individuals as well as within individuals across time; the masticatory muscles seldom exhibit a reliable level of lowest activity, even among those who have no signs or symptoms associated with a TMD. Consequently, the muscle activity as well as mandibular position vary for a number of reasons (for example, head posture, emotion, cognition, pain) and "rest position" is not an exact position.[94] Clinical diagnoses that require an interpretation of rest position must be considered very cautiously.

It may be premature to completely dismiss occlusal attributes for possible causal roles in TMD; a substantial limitation in a majority of studies of occlusion as a putative cause of TMD are that terms such as "disharmony" are used without an adequate operational definition, leading to research that is not reproducible. Inappropriate focus on largely minor occlusal features may have resulted in insufficient attention to the most important attribute of occlusion: stability.[95] Illustrating that perspective, a relationship between tooth loss and osteoarthrosis has been observed in patients with TMD but not in nonpatient populations.[96] In contrast, incisal relationships, condylar position, and joint sounds do not reliably differentiate symptomatic individuals and nonpatient populations.[97–99] Finally, perspectives regarding the importance of occlusion in TMDs typically ignore behavior: premature contacts in one dental segment coupled with balancing interferences on that same side could be due to unilateral guarding behavior in response to the TMD pain. Moreover, a shift in the apex point of the gothic arch can be initiated by masseter pain induced by saline injections, suggesting that pain might be the critical factor in producing the occlusal changes that are sometimes reported by patients with TMD.[100] And, finally, patient reports of changes in their occlusion (either accompanying other signs or symptoms of a TMD, or not), often interpreted by dentists as indicative of a problem in the occlusion that must be addressed through alteration of the occlusion, may represent occlusal dysesthesia.[101] Dysesthesia refers to alteration in sensory perception, which can be induced by a variety of mechanisms such as persistent pain or altered behavior. The occlusal sense—the feeling of the body state regarding how the teeth fit together and as mediated by periodontal proprioceptors and muscle spindles—can be altered such that even a stable occlusion may be perceived as unstable.

Muscle Hyperactivity

Masticatory muscle hyperactivity—muscle activity without functional purpose—has been proposed as a cause of myofascial pain, also using the diagnostic terms in this context *myospasm*, *muscle spasm*, and *reflex splinting*. The combination of muscle hyperactivity and the muscle pain disorder has been characterized as a "vicious cycle" of hyperactivity and pain mutually reinforcing each other.[102] Muscle hyperactivity is usefully separated into sleep bruxism and waking parafunction, corresponding to the respective states. The favored hypothesis for over 50 years was that sleep bruxism is caused by abnormalities of occlusion, but this was based on heavily flawed research mentioned above.[85,86] Currently, evidence strongly supports sleep bruxism as a parasomnia type of sleep disorder; specifically, sleep bruxism events are related to microarousals during sleep.[103,104] While microarousals are a normal part of sleep architecture in everyone, microarousals selectively trigger bruxism events in those individuals with the disorder, and do not do so in individuals without the disorder—for reasons as yet unknown. The evidence to date is circular, and it does not support microarousals as the cause of sleep bruxism; rather, individuals at risk for sleep bruxism may be differentially primed to respond to microarousals with bruxism events.

A variety of studies have linked sleep bruxism to pain.[105–111] The common explanation is that the pain is simply due to overuse of the muscle during sleep, as in postexercise pain. Clinical observations have indicated, however, that severe sleep bruxism, as measured by extensive tooth wear, can occur without symptoms. Moreover, empirical data demonstrate that not only pain but TMJ clicking and masticatory muscle tenderness are unrelated to severe tooth wear from sleep bruxism.[112] These contradictory findings lead to an important paradox: how could the most severe form of a disorder not produce pain while the less severe form presumably does? Polysomnography-based measurement of jaw muscle activity during sleep demonstrates that sleep bruxism may have, at best, a weak relationship to pain on waking the following morning.[113] In other words, individuals with TMD pain may simultaneously have evidence of sleep bruxism and report jaw pain on awakening, but the bruxism may not directly cause the pain.

Parafunction while awake has for more than 50 years also been regarded as a cause of TMD pain, but only recently has any substantial evidence emerged. Waking parafunction has classically been depicted as excessive tooth clenching, but waking parafunction appears to be a much more complex process in terms of a wide range of behaviors (e.g., bracing, pushing, guarding, pressing), a high frequency of occurrence, and generally lower forces than previously assumed. The duration of such behaviors necessary to cause pain appears to vary across individuals. As described previously, muscle activity at so-called rest does not differ between individuals with painful vs. nonpainful jaw-closing muscles,[114] suggesting that jaw behavior is very dynamic across the span of a day.[115] Waking behaviors, such as tooth clenching or muscle guarding, are remarkably concrete and reliable in how they manifest across persons with or without TMD.[116,117] Experimental evidence suggests that tooth clenching at a

relatively low but sustained level might be a source of pain in some individuals.[118] As primary evidence that parafunctional behaviors can cause pain, positive findings on muscle examination are more frequent in individuals who perform tooth-clenching activities.[119] In addition, among individuals who have developed a first lifetime episode of TMD pain, parafunctional behaviors are reported at a much higher rate prior to the development of the painful TMD compared to those who do not develop TMD, demonstrating the potential of these behaviors to contribute to the development of painful TMD.[120] Oral parafunctional behaviors exhibit a substantial association with chronic TMD pain, suggesting that the parafunctional behaviors have both contributed to the persistence of the TMD and become a result of the TMD pain.[121] Increasing frequency of such behaviors is also associated with presence of articular disc disorders;[122] the contribution of parafunction over time to potential worsening of disc displacements remains to be evaluated.

The Pain-Adaptation Model has been proposed as an alternative to the "vicious cycle" hypothesis regarding pain and muscle hyperactivity. The Pain-Adaptation Model is based on observations that EMG activity and force output of the muscle are lower in patients with musculoskeletal pain.[123] The reduction in muscle activity is thought to be protective to prevent further injury, and for acute pain, this model is both sensible and clinically useful. The Pain-Adaptation Model and the vicious cycle hypothesis are not incompatible, however; experimental evidence indicates that persistent parafunctional behaviors occurring at low levels of contractile activity are sufficient to cause pain.[124] Moreover, in chronic pain, the Pain-Adaptation Model fails to have the same relevance in that adaptation and goal-oriented behavior can over-ride the model-specified inhibition in behavior; for example, a person will chew tough textured foods regardless of the pain if the food is desired. In recognition of this clearly observed discrepancy between clinical presentations and the Pain-Adaptation Model, Peck and colleagues provided experimental evidence demonstrating the limits of the Pain-Adaptation Model in understanding pain and behavior.[125] Overall, the available evidence provides strong support for parafunctional behaviors having a strong role in the etiology of TMD as well as a strong role as a contributing factor for persistence of TMD.

Central Pain Mechanisms

In addition to local factors affecting muscle function, the results of a number of experimental studies of myofascial pain support the hypothesis that chronic pain is caused by altered central nervous system (CNS) processing.[126–130] However, these studies have not been able to distinguish whether the findings are a consequence of the pain rather than the cause of the pain. For example, altered CNS processing related to pain amplification occurs in response to having a pain disorder rather than contributing to the etiology of the disorder.[131] Central pain mechanisms are also proposed as the mechanism underlying the increased risk conferred by a pain disorder for developing another pain disorder.[132] As such, comorbidity with widespread musculoskeletal pain is likely to contribute toward the development of a chronic TMD. Individuals with fibromyalgia, a chronic widespread musculoskeletal pain disorder, have a significantly higher frequency of masticatory myofascial pain than the general population.[133,134] In a follow-up study on TMD patients, the group that self-reported the coexistence of fibromyalgia had a higher frequency of chronic TMD symptoms.[135] The presence of pain in other body sites in individuals with a TMD pain diagnosis is high [121,136] and may indicate that a musculoskeletal problem affecting the jaws is part of a more generalized pain disorder, itself a reflection of central mechanisms.

Psychological Distress

The psychological distress hypothesis proposes that TMD evolves as a consequence of pre-existing problems in overall functioning, usually due to the individual's stressful environment coupled with poor coping skills, which leads to distress in the form of depression, anxiety, or both. Two pathways by which the psychological distress leads to TMD have been proposed. The most common pathway in the TMD literature specifies that distress leads to oral parafunctional behaviors (as described above) that then result in muscle pain.[137–139] The second pathway, which is common in the general pain literature, specifies that psychological distress results in an overall increased risk for an individual to experience pain in response to some event (for example, a traumatic yawn). A challenge that is continually faced in the clinic when evaluating patients with chronic pain disorders is determining how much of the psychological distress is a cause or a consequence of chronic pain.[140] The weight of the evidence has suggested that the emotional distress is more likely a consequence than a cause of pain.[141] That evidence has been, however, largely cross-sectional at the time of entry into the clinic, and prior functioning is assessed retrospectively. In contrast, recent evidence from a large-scale prospective longitudinal study indicates that psychological distress, in the form of depression, anxiety, and problems with stress and coping, exerts a long-term effect on the individual with respect to increased risk for subsequent development of a painful TMD and, consistent with the prior cross-sectional evidence, chronic TMD is associated with greater extent of distress.[142,143]

Trauma

The role of trauma as a primary etiology for TMDs varies from self-evident (e.g., pain or mechanical TMJ problem, following

direct blow to the jaw and associated with regional swelling) to purely inferential (e.g., onset of jaw pain 6 months after a motor vehicle collision). While the literature points to some trauma events as having greater likelihood of being a sufficient cause of a TMD and other trauma events as not sufficient on their own to cause a TMD, conflicting conclusions emerge from other studies. The best evidence to date may come from two studies using the same methods and conducted in parallel. In a case-control study, individuals with chronic painful TMD reported a high number of trauma events, compared to individuals with no lifetime history of a TMD.[121] Further results from that study indicate that while reported injury, stemming from various injurious events, is a strong predictor of developing a painful TMD, most such instances of injury are without observable tissue damage and injury does not act alone.[144,145] For example, pain sensitivity, psychological distress, and oral parafunctional behaviors remain important contributors to TMD onset, even when injury has occurred. Regardless of whether trauma has a direct causal role for a TMD, traumatic response to any potential tissue-damaging event appears to be increased once painful TMD is present, and consequently trauma becomes a potent perpetuating factor when pain becomes chronic. Individuals with a TMD and a history of regional trauma may be less responsive to treatment and may consequently require more health care resources.[146,147] Collectively, the research suggests that unless a traumatic event has a self-evident relationship to symptom onset, a simple cause–effect relationship may not adequately describe the potential relationship between such events and TMD symptoms.

Integration of Etiologic Factors

The time period over which potentially etiologic events, from trauma to stress reactivity, occur as well as the latency between event and biological or behavioral consequences make assigning causation very difficult.[51] The lack of a clear single cause of TMD is notable in the majority of individuals, and in such individuals, TMD is increasingly thought to emerge in response to multiple risk determinants: no one factor by itself is sufficient to cause the disorder, whereas multiple factors increase the risk. A final initiating event may even be relatively minor, but if it occurs in conjunction with other already active determinants, then critical thresholds can be exceeded and symptoms emerge. In other words, multiple factors often come together contributing to the initiation, aggravation, and/or perpetuation of the disorder. Given the available evidence, the factors that have supporting evidence and at least some biological plausibility are, from local to systemic, summarized as follows:

- TMJ hypermobility.[148–150]
- Trauma (e.g., dental procedures, oral intubations for general anesthesia, yawning, hyperextension associated with cervical trauma).[145,147,151–156]
- Parafunctional behaviors (e.g., sleep bruxism, tooth clenching, jaw guarding, lip or cheek biting).[120–122,157–159]
- Sleep disturbance.[160,161]
- Comorbidity in the form of other rheumatic, musculoskeletal, or pain disorders. [162,163]
- Emotional distress.[142,143,164,165]
- Poor general health and an unhealthy lifestyle.[166,167]

The factors listed above vary in the strength of both evidence and association with TMD. Each factor can occur, for the most part, along continua defined by magnitude (i.e., weak to strong), frequency (seldom to continuous), and duration (short term to enduring). The actual threshold by which each factor exerts an influence on a given individual likely varies according to their susceptibility to each factor for its potential to cause problems for the organism. Plus, each TMD would appear to have its own profile of risk factors. For example, myofascial pain with arthralgia and myofascial pain alone were associated with trauma, clenching, third molar removal, somatization, and female gender.[168] Emerging research will likely provide much better estimates regarding the relative significance of these and other factors.

Classification

Due to the uncertainty about etiology, the present diagnostic classifications of TMD have been based only on signs and symptoms. Whether this descriptive approach is a particular strength, given the complexity of etiology, or whether this is a weakness, given the emerging data regarding types of pain[169] and pain processing models,[170] remains to be determined. Substantial evidence is now emerging regarding the myriad factors that predict the first lifetime episode of TMD,[171] and collectively the evidence indicates that TMD is a complex disease. A complex disease is one that does not follow simple classical etiologic pathways, whereby a single necessary and sufficient etiologic factor exists; instead, epigenetic factors, phenotypic factors, and environmental factors are dynamic and interact over time. Part of this interaction may also include feedback loops, whereby the activity of a particular factor will facilitate its emergence again; for example, stress experience due to poor coping tends to progress in a downward spiral. This type of complexity requires multidimensional assessment and, correspondingly, multiaxial classification. See Tables 10-1–10-5.

Current perspectives on taxonomy development point to the inadequacy, both scientific and clinical, of classification systems for complex disease developed according to traditional methods. For the future, we envision the merger of genetics, pain medicine, neuroscience, psychology, and bioinformatics as underlying the next major diagnostic system

Table 10-1 Taxonomic classification for temporomandibular disorders.

I. TEMPOROMANDIBULAR JOINT DISORDERS
1. Joint pain
A. Arthralgia
B. Arthritis
2. Joint disorders
A. Disc disorders
1. Disc displacement with reduction
2. Disc displacement with reduction with intermittent locking
3. Disc displacement without reduction with limited opening
4. Disc displacement without reduction without limited opening
B. Hypomobility disorders other than disc disorders
1. Adhesions/Adherence
2. Ankylosis
a. Fibrous
b. Osseous
C. Hypermobility disorder
1. Dislocations
a. Subluxation
b. Luxation
3. Joint diseases
A. Degenerative joint disease
1. Osteoarthrosis
2. Osteoarthritis
B. Systemic arthritides
C. Condylysis/Idiopathic condylar resorption
D. Osteochondritis dissecans
E. Ostronecrosis
F. Neoplasm
G. Synovial Chondromatosis
4. Fractures
5. Congenital/developmental disorders
A. Aplasia
B. Hypoplasia
C. Hyperplasia
II. MASTICATORY MUSCLE DISORDERS
1. Muscle pain
A. Myalgia
1. Local myalgia
2. Myofascial pain
3. Myofascial pain with referral
B. Tendonitis
C. Myositis
D. Spasm
2. Contracture
3. Hypertrophy
4. Neoplasm
5. Movement Disorders
A. Orofacial dyskinesia
B. Oromandibular dystonia
6. Masticatory muscle pain attributed to systemic/central pain disorders
A. Fibromyalgia or widespread pain
III. Headache
1. Headache attributed to TMD
IV. Associated structures
1. Coronoid hyperplasia

for TMD.[172–176] In addition, we envision that diagnostic systems designed for each domain (jaw, head, back, etc.) will be integrated into one system based on a standard set of rules.[177] Yet, it is also likely that the traditional taxonomic approach based on signs and symptoms will continue to be used, despite the limitations inherent in that approach, because the need for identifying the disorder at the local tissue level will continue to have clinical utility. For example, the present validated system for the common TMDs[3] minimizes false positive diagnoses and thereby unnecessary treatment. And this will continue to be a major strength.

In the late 1980s and early 1990s, TMD classification was influenced by several independent developments. The first developments emphasized concise symptom- and sign-based classification systems that were developed for use by the practicing clinician.[178–180] The American Academy of Orofacial Pain (AAOP) published a more far-reaching general classification of disorders that was developed by a broad group of experts who applied available knowledge to the development of an acceptable and useful system for clinical practice,[181] and emphasized multiple diagnoses which reflected clinical reality.[182,183] This classification system was inclusive of all disorders a clinician might encounter but it was not highly reliable (due to its structure) and it was not assessed for validity. These developments, however, did not facilitate research, creating a large hole that was too often filled with poorly done etiologic and treatment studies. The Research Diagnostic Criteria for Temporomandibular Disorders (RDC/TMD) was published as a system "offered to allow standardization and replication of research into the most common forms of muscle and joint-related TMD."[184] This system was based on several core principles with

Table 10-2 Diagnostic criteria for the most common pain-related temporomandibular disorders.

Myalgia (ICD-9 729.1)		
	Description	Pain of muscle origin that is affected by jaw movement, function, or parafunction, and replication of this pain occurs with provocation testing of the masticatory muscles.
Criteria	HISTORY	1) Pain[1] in the jaw, temple, in the ear, or in front of ear; AND 2) Pain modified with jaw movement, function or parafunction.
Criteria	**AND**	
Criteria	EXAM	1) Confirmation[2] of pain location(s) in the temporalis or masseter muscle(s); AND 2) Report of familiar pain[3] in the temporalis or masseter with <u>at least</u> 1 of the following provocation tests: a) Palpation of the temporalis or masseter muscle(s); OR b) Maximum unassisted or assisted opening.
Validity		Sensitivity 0.90; Specificity 0.99
Comments		The pain is not better accounted for by another pain diagnosis. Other masticatory muscles may be examined as dictated by clinical circumstances but the sensitivity and specificity for this diagnosis based on these findings has not been established.
Myofascial Pain with Referral (ICD-9 729.1)		
	Description	Pain of muscle origin as described for myalgia with referral of pain beyond the boundary of the masticatory muscle(s) being examined when using the myofascial examination protocol. Myofascial pain with referral is a subtype of myalgia.
Criteria	HISTORY	1) Pain[1] in the jaw, temple, in the ear, or in front of ear; AND 2) Pain modified with jaw movement, function or parafunction.
Criteria	**AND**	
Criteria	EXAM	1) Confirmation[2] of pain location(s) in the temporalis or masseter muscle(s); AND 2) Report of familiar pain[3] with palpation of the temporalis or masseter muscle(s); AND 3) Report of pain at a site beyond the boundary of the muscle(s) being palpated.
Validity		Sensitivity 0.86; Specificity 0.98
Comments		The pain is not better accounted for by another pain diagnosis. Other masticatory muscles may be examined as dictated by clinical circumstances but the sensitivity and specificity for this diagnosis based on these findings has not been established.
Arthralgia (ICD-9 524.62)		
	Description	Pain of joint origin that is affected by jaw movement, function, or parafunction, and replication of this pain occurs with provocation testing of the TMJ.
Criteria	HISTORY	1) Pain[1] in the jaw, temple, in the ear, or in front of ear; AND 2) Pain modified with jaw movement, function or parafunction.
Criteria	**AND**	
Criteria	EXAM	1) Confirmation[2] of pain location in the area of the TMJ(s); AND 2) Report of familiar pain[3] in the TMJ with <u>at least</u> 1 of the following provocation tests: a) Palpation of the lateral pole or around the lateral pole; OR b) Maximum unassisted or assisted opening, right or left lateral movements, or protrusive movements.
Validity		Sensitivity 0.89; Specificity 0.98
Comments		The pain is not better accounted for by another pain diagnosis.
Headache attributed to TMD (ICD-9 339[4])		
	Description	Headache in the temple area secondary to pain-related TMD* that is affected by jaw movement, function, or parafunction, and replication of this headache occurs with provocation testing of the masticatory system.
Criteria	HISTORY	1) Headache[1] of any type in the temple; AND 2) Headache modified with jaw movement, function or parafunction.
Criteria	**AND**	
Criteria	EXAM	1) Confirmation[2] of headache location in the area of the temporalis muscle(s); AND 2) Report of familiar headache[3] in the temple area with **at least** 1 of the following provocation tests: a) Palpation of the temporalis muscle(s); OR b) Maximum unassisted or assisted opening, right or left lateral movements, or protrusive movements.
Validity		Sensitivity 0.89; Specificity 0.87
Comments		The headache is not better accounted for by another headache diagnosis.
Footnote		*A diagnosis of painful TMD (e.g., myalgia, myofascial pain with referral, or TMJ arthralgia) is derived using valid diagnostic criteria.

[1] The time frame for assessing pain including headache is in "the last 30 days" since the stated sensitivity and specificity of these criteria were established using this time frame. Although the specific time frame can be dependent on the context in which the pain complaint is being assessed, the validity of this diagnosis based on different time frames has not been established.

[2] The examiner must identify with the patient all anatomical locations that they have experienced pain in the last 30 days. For a given diagnosis, the location of pain induced by the specified provocation test(s) must be in an anatomical structure consistent with that diagnosis.

[3] "Familiar pain" or "familiar headache" is based on patient report that the pain induced by the specified provocation test(s) has replicated the pain that the patient has experienced in the time frame of interest, which is usually the last 30 days. "Familiar pain" is pain that is similar or like the patient's pain complaint.

[4] The International Classification of Diseases 9th Edition (ICHD-9) has not established a specific code for *Headache attributed to TMD;* ICD-9 339 is for *"other headache syndromes."* If a primary headache is present (e.g., *tension type headache*) then the headache can be classified according to the primary headache type.

Table 10-3 Diagnostic criteria for the most common intra-articular temporomandibular disorders.

Disc Displacement with Reduction (ICD-9 524.63)		
Description		An intracapsular biomechanical disorder involving the condyle-disc complex. In the closed mouth position the disc is in an anterior position relative to the condylar head and the disc reduces upon opening of the mouth. Medial and lateral displacement of the disc may also be present. Clicking, popping or snapping noises may occur with disc reduction. A history of prior locking in the closed position coupled with interference in mastication precludes this diagnosis.
Criteria	HISTORY	1) In the last 30 days[1] any TMJ noise(s) present with jaw movement or function;
	AND	**OR**
		2) Patient report of any noise present during the exam.
	EXAM	1) Clicking, popping and/or snapping noise detected during both opening and closing, with palpation during at least 1 of 3 repetitions of jaw opening and closing;
		OR
		2) Clicking, popping and/or snapping noise detected with palpation during at least 1 of 3 repetitions of opening or closing; AND
		3) Clicking, popping and/or snapping noise detected with palpation during at least 1 of 3 repetitions of right or left lateral movements, or protrusive movements.
Validity		Without imaging: sensitivity 0.34; specificity 0.92. Imaging is the reference standard for this diagnosis.
Imaging		When this diagnosis needs to be confirmed, then TMJ MRI criteria[2] are positive for <u>both</u> of the following:
		1) In the maximum intercuspal position, the posterior band of the disc is located anterior to the 11:30 position **and** the intermediate zone of the disc is anterior to the condylar head;
		AND
		2) On full opening, the intermediate zone of the disc is located between the condylar head and the articular eminence.
Disc Displacement with Reduction with Intermittent Locking (ICD-9 524.63)		
Description		An intracapsular biomechanical disorder involving the condyle-disc complex. In the closed mouth position the disc is in an anterior position relative to the condylar head, and the disc intermittently reduces with opening of the mouth. When the disc does not reduce with opening of the mouth, intermittent limited mandibular opening occurs. When limited opening occurs, a maneuver may be needed to unlock the TMJ. Medial and lateral displacement of the disc may also be present. Clicking, popping, or snapping noises may occur with disc reduction.
Criteria	HISTORY	1) In the last 30 days,[1] any TMJ noise(s) present with jaw movement or function; OR
	AND	2) Patient report of any noise present during the exam.
		AND
		3) In the last 30 days,[1] jaw locks with limited mouth opening, even for a moment, and then unlocks.
	EXAM	Same as specified for Disc Displacement with Reduction. Although not required, when this disorder is present clinically, examination is positive for inability to open to a normal amount, even momentarily, without the clinician or patient performing a specific manipulative maneuver.
Validity		Without imaging: sensitivity 0.38; specificity 0.98. Imaging is the reference standard for this diagnosis.
Imaging		When this diagnosis needs to be confirmed, then the imaging criteria[2] are the same as for disc displacement with reduction if intermittent locking is not present at the time of imaging. If locking occurs during imaging, then an imaging-based diagnosis of disc displacement without reduction will be rendered and clinical confirmation of reversion to intermittent locking is needed.
Disc Displacement without Reduction with Limited Opening (ICD-9 524.63)		
Description		An intracapsular biomechanical disorder involving the condyle-disc complex. In the closed mouth position the disc is in an anterior position relative to the condylar head, and the disc does not reduce with opening of the mouth. Medial and lateral displacement of the disc may also be present. This disorder is associated with persistent limited mandibular opening that does not resolve with the clinician or patient performing a specific manipulative maneuver. This is also referred to as "closed lock."
Criteria	HISTORY	1) Jaw lock or catch so that the mouth would not open all the way; AND
	AND	2) Limitation in jaw opening severe enough to limit jaw opening and interfere with ability to eat.
	EXAM	Maximum assisted opening (passive stretch) < 40mm including vertical incisal overlap.
Validity		Without imaging: sensitivity 0.80; specificity 0.97. Imaging is the reference standard for this diagnosis.

Imaging		When this diagnosis needs to be confirmed, then TMJ MRI criteria[2] are positive for both of the following: 1) In the maximum intercuspal position, the posterior band of the disc is located anterior to the 11:30 position **and** the intermediate zone of the disc is anterior to the condylar head, **AND** 2) On full opening, the intermediate zone of the disc is located anterior to the condylar head. Note: Maximum assisted opening of < 40mm is determined clinically.
Footnote		Presence of TMJ noise (e.g., click with full opening) does not exclude this diagnosis.
Disc Displacement without Reduction without Limited Opening (ICD-9 524.63)		
Description		An intracapsular biomechanical disorder involving the condyle-disc complex. In the closed mouth position the disc is in an anterior relative the condylar head and the disc does not reduce with opening of the mouth. Medial and lateral displacement of the disc may also be present. This disorder is NOT associated with limited mandibular opening.
Criteria	HISTORY	Same as specified for Disc Displacement without Reduction with Limited Opening.
	AND	
	EXAM	Maximum assisted opening (passive stretch) ≥ 40mm including vertical incisal overlap.
Validity		Without imaging: sensitivity 0.54; specificity 0.79. Imaging is the reference standard for this diagnosis.
Imaging		When this diagnosis needs to be confirmed, then TMJ MRI criteria[2] are the same as for disc displacement without reduction with limited opening. Note: Maximum assisted opening of ≥ 40mm is determined clinically.
Footnote		Presence of TMJ noise (e.g., click with full opening) does not exclude this diagnosis.
Degenerative Joint Disease (ICD-9 715.18)		
Description		A degenerative disorder involving the joint characterized by deterioration of articular tissue with concomitant osseous changes in the condyle and/or articular eminence.
Criteria	HISTORY	1) In the last 30 days[1] any TMJ noise(s) present with jaw movement or function;
	AND	**OR**
		2) Patient report of any noise present during the exam.
	EXAM	At least one of the following must be present: 1. Crepitus detected with palpation during opening, closing, lateral, or protrusive movements.
Validity		Without imaging: sensitivity 0.55; specificity 0.61. Imaging is the reference standard for this diagnosis.
Imaging		When this disorder is present, then TMJ CT criteria[2] are positive for **at least** one of the following: Subchondral cyst(s), erosion(s), generalized sclerosis or osteophyte(s). Note: Flattening and/or cortical sclerosis are considered indeterminant findings for DJD and may represent normal variation, aging, remodeling or a precursor to frank DJD.
Subluxation (ICD-9 830.1)		
Description		A hypermobility disorder involving the disc-condyle complex and the articular eminence: In the open mouth position, the disc-condyle complex is positioned anterior to the articular eminence and is unable to return to a normal closed mouth position without a specific manipulative maneuver. The duration of dislocation may be momentary or prolonged. When prolonged the patient may need the assistance of the clinician to reduce the dislocation and normalize jaw movement; this is referred to as luxation. This disorder is also referred to as "open lock."
12	HISTORY	1) In last 30 days,[1] jaw locking or catching in a wide open mouth position, even for a moment, so could not close from the wide open position; AND
	AND	
		2) Inability to close the mouth without a specific manipulative maneuver
	EXAM	Although no exam findings are required, when this disorder is present clinically, examination is positive for inability to return to a normal closed mouth position without the patient performing a specific manipulative maneuver.
Validity		Without imaging and based only on history: sensitivity 0.98; specificity 1.00.
Imaging		When this disorder is present, then imaging criteria are positive for the condyle positioned beyond the height of the articular eminence.

[1] The time frame for assessing selected biomechanical intra-articular disorders is in "the last 30 days" since the stated sensitivity and specificity of these criteria was established using this time frame. Although the specific time frame can be dependent on the context in which the pain complaint is being assessed, the validity of this diagnosis based on different time frames has not been established.

Table 10-4 Imaging-based diagnosis of soft-tissue and hard-tissue TMJ disorders.

Disorder	Criteria
Disc diagnosis for the TMJ, based on MRI *	
Normal	Disc location is normal on closed and open-mouth images.
Disc displacement with reduction	Disc location is displaced on closed-mouth images but normal on open-mouth images
Disc displacement without reduction	Disc location is displaced on both closed-mouth and open-mouth images.
Indeterminate	Disc location is not clearly normal or displaced in the closed-mouth view
Disc not visible	Neither signal intensity nor outlines make it possible to define a structure as the disc in the closed-mouth and open-mouth views. If the images are of adequate quality in visualizing other structures in the TMJ, then this finding is interpreted to indicate a deterioration of the disc, which is associated with advanced disc pathology.
Osseous diagnoses for the TMJ, based on CT **	
Normal	a) Normal relative size of the condylar head; and b) No subcortical sclerosis or articular surface flattening; and c) No deformation due to subcortical cyst, surface erosion, osteophyte, or generalized sclerosis.
Indeterminate for osteoarthritis	a) Normal relative size of the condylar head; and b) No deformation due to subcortical cyst, surface erosion, osteophyte, or generalized sclerosis; and c) Either of: i) Subcortical sclerosis; or ii) Articular surface flattening
Osteoarthritis	a) Deformation due to subcortical cyst, surface erosion, osteophyte, or generalized sclerosis

Table 10-5 Selected TM disorders and supplemental characteristics.

Disorder	Characteristics
Deviation in form Note: Painless mechanical dysfunction or altered function due to irregularities or aberrations in the form of intracapsular soft and hard articular tissues. Does not require intervention.	• Complaint of faulty or compromised joint mechanics • Reproducible joint noise, usually at the same position during opening and closing • Radiographic evidence of structural bony abnormality or loss of normal shape
Disc displacement with reduction Note: Clinical significance is related to pain associated with the noise, to mechanical locking, or interference in mastication or other functional activities.	• Pain (when present) is directly associated with joint noise during movement • Clinical assessment is often unreliable due to poor stability of the noise • Mandibular deviation during opening or closing coinciding with a click
Disc displacement without reduction	• History of clicking that stopped when the locking began • Pain clearly localized to the TMJ precipitated by function, when acute • Marked limited mandibular opening when acute • Uncorrected deviation to the affected side on opening and marked limited laterotrusion to the contralateral side when acute • Localized pain precipitated by forced mouth opening • Ipsilateral hyperocclusion, when acute
Synovitis or capsulitis Note: Inflammation of the synovial lining or loading of capsular lining. Difficult to clearly differentiate from arthralgia.	• Localized pain at rest exacerbated by function, especially with superior and posterior joint loading • Limited range of motion secondary to pain • T2-weighted MRI may show joint fluid

Table 10-5 (Continued)

Disorder	Characteristics
Osteoarthrosis Note: Degenerative noninflammatory condition of the joint, characterized by structural changes of joint surfaces secondary to excessive strain on the remodeling mechanism. Distinguish from osteoarthritis, which is a secondary inflammatory condition. Both osteoarthrosis and osteoarthritis are subsumed within degenerative joint disease in the DC/TMD.	• Crepitus on examination • Absence of joint pain
Myofascial pain Note: Is a regional disorder, distinguishing it from fibromyalgia. When the pain is local to the area of stimulation, this disorder is termed myalgia in the DC/TMD in order to note the presence of hyperalgesia without spreading, referral, or autonomic reactions. The clinical significance of these additional characteristics is with differential diagnosis; the requirement for specific treatments when referral is present remains untested but anecdotally rich.	• Taut bands and trigger points are hallmark characteristics but exhibit only fair examiner reliability • Reduction in pain with local muscle anesthetic injection or vapocoolant spray, coupled with stretch of the muscle
Protective muscle splinting Note: Restricted or guarded mandibular movement due to co-contraction of muscles as a means of avoiding pain caused by movement of the parts. Should be distinguished from fear-avoidance behavior by ruling out local nociceptive source, either by history or by examination.	• Severe pain with function but not at rest • Marked limited range of motion (generally, pain-free opening and maximal unassisted opening will be similar), and opening is only minimally responsive to attempted passive stretch (maximal assisted opening) initially, and active resistance to further attempts at stretch can be noted
Contracture Note: Chronic resistance of a muscle to passive stretch as a result of fibrosis of the supporting tendon, ligaments, or muscle fibers themselves.	• Limited range of motion • Unyielding firmness on passive stretch • History of trauma or infection

MRI = magnetic resonance imaging; TMJ = temporomandibular joint.

enduring value for the field.[185] The assessment of physical status (Axis I) was described in sufficient detail for standardized data collection, allowing reliable diagnoses and comparison of findings across investigators and clinicians. Because pain transcends a given organ system, the classification system also reflected psychological, behavioral, and social factors considered to be as important as an accurate description of the physical pathology. Consequently, the RDC/TMD classification contained a separate Axis II to assess psychosocial status and pain-related disability. The RDC/TMD was designed for research, and thereby permitted far more reliable diagnoses of the disorders the clinician encounters most often.

The RDC/TMD classification was subsequently assessed in a multicenter study for validation and the findings and subsequent publications improved upon the RDC/TMD while retaining the core features described above.[186] The publications included: Diagnostic Criteria for TMDs (DC/TMD);[3] an overall taxonomy and draft criteria for the less common TMDs;[187] and incorporation of both into the AAOP guidebook.[1,188] In summary, reliable and valid diagnoses of the common TMDs are readily available for clinical and research use. The DC/TMD allows, for each individual, multiple TMD diagnoses: several pain diagnoses and, for each joint, pain, disc displacement, degenerative joint disease, and subluxation diagnoses. The terms used are clearly defined, the clinical examination procedures are completely specified, and the criteria required to meet the diagnosis are specific. The pain diagnoses exhibit excellent sensitivity and specificity. In contrast, the joint disorders, with one exception, exhibit unacceptable sensitivity and specificity based only on clinical assessment. The one exception among the joint disorders is disc displacement without reduction, with limited opening, which does have acceptable sensitivity and specificity from clinical examination procedures.

In clinical practice, it has been generally believed that rigidly adhering to the criteria of a system such as the DC/TMD may not be possible due to the assumption that the common TMDs, for example, exhibit a wide spectrum of signs and symptoms. However, recent evidence indicates that each of the common TMD has reliable characteristics; for the very large majority of patients, the stated criteria clearly define the disorder. The consequence is that the clinician, using the described clinical assessment methods, can reliably and validly provide diagnoses for most individuals with TMD pain. Imaging will be required to establish a disc disorder diagnosis such as "disc displacement without reduction." The clinician should recommend diagnostic imaging as part of the

assessment when the prognosis or choice of treatment might benefit. The reader is referred to the publication by Schiffman and colleagues for a full description of the DC/TMD, to the publication by Peck and colleagues for diagnostic criteria for the less common TMD, to the text by DeLeeuw and Klasser for a comprehensive guidebook to evaluation, diagnosis, and treatment, and to the website of the International Network for Orofacial Pain and Related Disorders Methodologies (INfORM; http://rdc-tmdinternational.org) for clinical examination specifications, training videos, and all patient assessment instruments. Consequently, a system such as the DC/TMD appropriately guides the clinician towards better diagnosis. Yet, despite these developments toward a well-operationalized, reliable, and valid physical examination, it is underutilized and the psychosocial assessment domain is similarly underutilized.[189]

Where sleep bruxism belongs within a TMD classification system was a challenge for the RDC/TMD authors—who omitted it from the classification—and similarly it is not part of the DC/TMD. Is sleep bruxism a disorder, or is it a process?[190] Classification of sleep bruxism remains an ongoing question, as does whether sleep bruxism aggravates or contributes to the persistence of pain symptoms associated with TMD. While the cause of bruxism is not fully understood, the evidence strongly indicates that occlusal abnormalities are not the cause.[191,192] Occlusal appliances may protect the teeth from the effects of bruxism but cannot be expected to prevent or decrease the bruxism activity.[193] When bruxism is considered to be the cause or a factor of TMD symptoms, oral appliance therapy is often effective, but symptoms are likely to return when appliance therapy is withdrawn.[194] In one report, nocturnal aversive biofeedback and splint therapy caused a decrease in the frequency and duration of bruxism, but bruxism activity returned after treatment was withdrawn.[195] Occlusal splints worn during sleep have not been found to stop bruxism but do reduce the signs of bruxing.[196] While oral appliances remain the treatment with the best evidence for sleep bruxism,[197] it is notable that placebo intraoral appliances are equally effective for reducing myofascial pain.[198] The efficacy of the placebo-type oral appliance for bruxism critically questions the nature of the problem that the traditional oral appliance is assumed to address.

The critical question raised by placebo oral appliances is extended when medication treatments are considered. Reports of bruxism and symptoms of facial pain, earache, and headache associated with the use of selective serotonin reuptake inhibitors (SSRIs) have been published.[199] Symptoms of bruxing resolved when the dosage was decreased or when buspirone was added.[200] Buspirone has a postsynaptic dopaminergic effect and may act to partially restore suppressed dopamine levels associated with the use of SSRIs. Tan and Jankovic injected severe bruxers in the masseter muscles with botulinum toxin in an open-label prospective trial and reported significant improvement in symptoms and minimal adverse effects.[201] Botulinum toxin exerts a paralytic effect on the muscle by inhibiting the release of acetylcholine at the neuromuscular junction. The treatment effect lasted approximately 5 months and had to be repeated. The implications of this research, whereby the end organ response of the motor cortex signal is blocked, remain for future investigators.

ASSESSMENT

The most valuable aspect of the diagnostic assessment is a thorough history;[202] pain disorder diagnoses rely predominantly on the history, and the diagnosis of some pain disorders, such as headache, relies exclusively on the history.[203] For some disorders such as headache, the history serves to rule out other forms of pathology; for TMD, the examination is confirmatory for a pain diagnosis but remains only suggestive for most of the joint disorders. An examination for a particular disorder (e.g., the comprehensive examination of TMD, as described),[204] must be supplemented by examination procedures as indicated for a differential diagnosis; for example, ruling out odontogenic causes of regional masticatory system pain. In contrast to the situation 30 years ago when TMD diagnostic tests were not validated or standardized,[180] the clinical tests most needed for the assessment of a person with a TMD are now standardized, reliable, and valid.[3,205] In contrast, diagnostic tests such as ultrasonography of joint sounds, thermography, jaw tracking, and EMG, all of which exhibit high measurement reliability and precision, do not offer the assurance of a more accurate diagnosis or better treatment outcomes.[206] These devices were reviewed for their diagnostic value in assessing patients with temporomandibular complaints, and were judged 30 years ago to not have the necessary sensitivity and specificity for a valid diagnosis.[202] No additional supporting evidence has emerged over the past several decades. Claims that they are adjunctive tests must nevertheless be accompanied by the same evidence as required for any diagnostic test; if an adjunctive test is to be useful, incremental validity must be demonstrated. Incremental validity refers to the ability of an additional test to provide unique information that improves the sensitivity or specificity of the information obtained prior to the additional test. For example, analysis of TMJ synovial fluid is an active area of research but has not yet become a standard procedure in diagnosis or the selection of treatment. These tests require sophisticated instrumentation that would increase health care costs to the patient that, for the present, are not justified.

Consequently, history, clinical examination, and imaging when indicated remain the recommended diagnostic approach for most patients.[4,179] Diagnostic imaging is of value in selected conditions but not as a routine part of a standard assessment. Diagnostic imaging can increase accuracy in the detection of internal derangements[207] and abnormalities of articular bone.[208] The clinical meaningfulness of such tests, however, must be determined prior to ordering the test; a special test should be preceded by a clinical hypothesis (differential diagnosis) that the test will be able to answer, and the clinical hypothesis should be related to a particular course of action. For example, if treatment for what appears to be a painful recurrent mechanical joint problem will proceed in one direction if the problem is a disc displacement, but in another direction if the disc is normal, then imaging would be well-justified. If, on the other hand, both treatments for this stated example would be pursued, each for 4–6 weeks and with no or minimal risk of adverse effects, then the treatment trial without imaging may be more prudent, thereby not unnecessarily expending health care resources and not adding imaging information that may only confuse rather than clarify. A painful clicking joint should be treated, regardless of whether the problem is due to an internal derangement or not.[209] If the choice of treatment depends on a more accurate diagnosis, then imaging would be indicated.

Similarly, other tests should be ordered when the differential diagnosis warrants further diagnostic exploration. Examples follow. Facial pain similar to the pain of a painful TMD may be associated with serious undetected disease. Muscle or joint pain may be a secondary feature of another disease or may mimic a TMD. A diagnosis of a more serious condition may be missed or delayed.[210,211] Severe throbbing temporal pain associated with a palpable nodular temporal artery, increasingly severe headache associated with nausea and vomiting, and documented altered sensation or hearing loss are all indications of serious disease requiring timely diagnosis and management. In short, TMD diagnosis (and management) requires ongoing use of clinical decision-making skills.

History

The most common symptom related to TMD is pain, and it is the overwhelming reason people seek care. Pain may be present at rest, may be continuous or intermittent, and characteristically increases with jaw function such as chewing or opening wide. Other chief complaints in relation to seeking care for a TMD include restricted jaw movement, painful or loud TMJ clicking or crepitus, and jaw locking.

Pain severity or intensity is a subjective measure provided by the patient and can be rated in several ways.[212] A rating scale can be either numeric or verbal. A numeric scale asks the patient to rate pain by identifying a number, typically between 0 and 10, that best reflects pain intensity. Verbal descriptors such as no pain, mild pain, moderate pain, and severe pain can also provide an equally valid assessment. If an estimate with greater precision is needed, a visual analogue scale (VAS) has high sensitivity to change and better independence when using repeated measures. A VAS uses a 10-cm line anchored on the left side with the descriptor of "no pain" and on the right an extreme descriptor such as "the worst pain ever experienced." The patient is asked to mark his or her pain intensity by placing a mark on the line, and the score is obtained by measuring from the left end to the mark.

Because pain intensity associated with TMDs typically varies, including periods of no pain, assessing pain intensity only at one time point—for example, at the clinic consultation—can be misleading. Any of the pain intensity rating scales can be used to assess differing aspects of pain, such as current, minimum and maximum in the past, or average pain ratings. Consideration of time period is important: too short, and meaningful variability may be lost; too long, and memory and relevance become potential problems. For the temporal reference frame regarding whether pain has been present or absent, the DC/TMD (Diagnostic Criteria for Temporomandibular Disorders)[3] explicitly uses the "last 30 days" for two reasons: memory for prior pain is better with shorter time periods, and, in general, the last 30 days appears to be sufficient for an active chief complaint of pain. For assessing pain intensity, the DC/TMD utilizes the pain measurement scales from the Graded Chronic Pain Scale,[213] in order to determine a characteristic pain index, based on current and, over the prior 30 days, average and worst pain.

As defined by the DC/TMD, regional masticatory system pain should be influenced by mandibular function, or an alternative diagnosis should be suspected. Table 10-2 indicates that pain aggravated by function is a criterion for a diagnosis of either myalgia or arthralgia. Mandibular functions shown to reliably increase or trigger myofascial pain include chewing hard or tough food, opening the mouth, or moving the jaw. Table 10-6 lists questions that are useful parts of the history for assessing mandibular function.

A pain drawing that contains the full body is helpful in defining the extent of pain; the recording of other body regions helps identify patients who have multiple sites of pain, which suggests a more systemic or generalized disorder. A pain drawing completed at initial evaluation may also be used to assess treatment progress of the TMD. Following the initial evaluation, a pain diary can be a useful tool for identifying events or times of increased and decreased pain; it may also serve to identify behaviors or situations that are contributing to the persistence of symptoms.[214]

Table 10-6 Assessment of TMD history.*

Where is the pain located? Is there pain in any other areas of the body?
When did the pain first begin? What has been the pattern over time; have there been notable periods of remission, or notable periods of exacerbation, and what were the circumstances?
How often do episodes (or, if pain is continuous: flareups) occur, duration, temporal pattern to the bouts (time of day, day of week), and how managed?
When is pain at its worst (morning [on awakening] or as day progresses [toward evening])?
What aggravates the pain (e.g., when using the jaw such as opening wide, yawning, chewing, speaking, or swallowing; stress or deadlines; postural positions)?
What alleviates the pain (e.g., rest, analgesic, holding the jaw rigid in specific positions)?
[If other pains such as headaches, earaches, neckache, or cheek pain are present] When did the other pain(s) begin, did they worsen when the jaw pain worsened, did they respond to treatment for the jaw pain?
Is there pain or thermal sensitivity in the teeth? Does biting on any teeth cause pain?
Do jaw joint noises (clicking, popping, grinding, or crepitus) occur when moving the jaw or when chewing?
Does the jaw ever hesitate, get stuck, or lock when trying to open or when trying to close from a wide open position?
Does jaw motion feel restricted?
Has the jaw ever been injured?
Has there been an abrupt change in the way the teeth meet or fit together? Does the bite feel "off" or uncomfortable?
What treatments have been provided? What was the outcome? What was the compliance with treatment requirements?

* Miscellaneous symptoms sometimes reported in association with TMD-related include: dizziness; nausea; fullness or ringing in the ears; diminished hearing; facial swelling; redness of the eyes; nasal congestion; altered sensation such as numbness, tingling, or burning; altered vision; and muscle twitching.

Table 10-7 Problem list of domains and specific factors contributing to persistence and symptom amplification in temporomandibular disorders.

Lifestyle	Emotional Factors	Cognitive Factors	Biologic Factors	Social Factors
Diet	Prolonged anger	Negative self-image	Other illnesses	Work stresses
Sleep	Anxiety	Unrealistic expectations	Past trauma	Unemployment
Alcohol	Excessive worry	Inadequate coping	Past jaw surgery	Family stresses
Smoking	Depression			Litigation
Overwork				Financial difficulty

Source: Adapted from Fricton J.[163]

A range of other symptoms sometimes reported in association with a TMD include dizziness, ear symptoms of fullness, ringing, or earache. Altered occlusion and jaw misalignment are also commonly reported.[215] Some patients, especially those with stress related disorders, report additional symptoms such as swelling and numbness, which are functional in nature. Functional symptoms are reported physical abnormalities which are not detected on a careful clinical examination.

Behavioral Assessment

Assessment for psychological distress and pain-related disability is frequently an important component of a TMD evaluation. Some TMDs evolve into a chronic pain disorder, resulting in psychological distress, disruption of interpersonal relationships, and an inability to perform daily activities, including work. Psychosocial factors are considered more important than physical factors in predicting treatment outcome.[216] The lack of a direct relationship between physical pathology and intensity of pain to subsequent disability emphasizes the need to assess the psychological and behavioral effects of the disorder in order to better understand: (1) the reported pain and not assume that as-yet undetected physical pathology is responsible; (2) anticipated barriers to successful treatment; and (3) the potential for relapse.

Table 10-7 lists multiple potential contributing factors, organized by domain, to TMD pain often reported in the pain research literature. No one health care professional can be expected to manage the physical pathology of the temporomandibular structures along with all of the various lifestyle, emotional, cognitive, and social issues that may affect the individual with chronic pain. Chronic TMDs with a significant emotional component are best managed in a multidisciplinary setting.

Cluster models have provided replicable insights into the different constellations of factors important for chronic pain. Rudy et al. classified TMD patients based on psychosocial and behavioral parameters into three unique subgroups: dysfunctional, interpersonally distressed, and adaptive copers.[217] Patients with painful TMD exhibited psychosocial and behavioral profiles similar to those of patients with back pain or with headache.[6] Similarly, Bair et al. also classified individuals with a painful TMD into three unique subgroups: adaptive, pain sensitive, and dysfunctional categories,[218] overall very similar to those identified by Rudy and colleagues. These findings highlight the substantial overlap in important characteristics exhibited by patients with a variety of chronic pain disorders. Clinical evaluation of patients with TMD complaints which do not include consideration of emotional factors often result in incorrect diagnosis, a persistent belief on the part of the patient that a cure is imminent, and unsuccessful treatment.

It is difficult to determine the presence of active oral parafunction, such as bruxism. Direct interview will produce a high rate of false negatives due to the unconscious nature of the behavior. Patients are often unaware of tooth clenching or other behaviors associated with jaw hyperactivity during the waking hours. There are several methods that can improve this assessment. Use of a checklist that describes the common types of parafunctional behaviors appears to trigger intentional access to memory via the patient deciding to "test" each listed behavior in order to determine whether the behavior feels familiar (i.e., I must do this one) or not familiar (i.e., I probably don't do that one). Field monitoring of daytime jaw activity, reports by friends and coworkers of observed behaviors (e.g., clenching with associated observable masseter contraction), and reports by a bedroom partner of tooth-grinding noises during sleep are helpful. Finally, teaching a therapeutic jaw relaxation posture will often uncover the otherwise denied or unknown behaviors via recognition, typically by both patient and clinician, that the target therapeutic behavior is very challenging.

Clinical characteristics that are indicators of the need for expert psychological evaluation of a person with TMD include the following:[219]

1) The persistence of pain beyond the expected healing time and no clear physical explanation is identified.
2) Inconsistent or poor response to usual treatments,
3) Significant psychological distress, as revealed via self-reported instruments and confirmed through clinical interview,
4) Disability greatly exceeds what is expected on the basis of the clinical findings.
5) Excessive or inappropriate use of health care services, encompassing tests and treatments, including prolonged use or reliance on opioids, sedatives, minor tranquilizers antianxiety medications, or alcohol for pain control.

Physical Examination

There is no single pathognomonic physical finding that can establish a TMD diagnosis. Historically, and as described previously for the AAOP Guidelines, a set of possible physical findings was listed for each type of TMD, but in the absence of clear data regarding what constituted a given problem, the diagnostic rubric was based on the presence of any of the findings. By extension, the more such findings occur, either the more severe the disorder or the more certain the diagnosis. For the common TMDs, as initiated by the RDC/TMD and now validly described in the DC/TMD,[3] each disorder is defined by, or constituted by, specific characteristics, and all of them must be present in order for the putative diagnosis to correctly identify the problem. Table 10-8 provides a general overview of the DC/TMD examination procedures. For the uncommon TMDs,[187] each disorder is less strongly defined by the stated characteristics, simply because there are, at present, little data to empirically characterize each of those disorders. Distinguishing clinical decision-making when we have sufficient data versus when we do not is a critical function of being an expert: knowing when—and when not to—use the rules.[220,221] In recognizing that the DC/TMD is not 100% accurate, the clinician must consequently know when exceptions to the rules are optimally invoked. Taking a history prior to the examination has a seminal role: serving as sufficient information by which the clinician has developed clinical hypotheses (i.e., differential diagnoses) and then knows what to look for in the examination. Unexpected findings should be appropriately followed up. A standardized examination routine (as defined by the DC/TMD and available as a full set of specifications[204] from INfORM) and supplemented by a video for examiner training[222] simplifies the task of the examiner: it provides a reference frame emerging from consistent examinations and better identifies unexpected findings. In general, the clinical features that distinguish patients from controls are decreased passive mouth opening,[223] and masticatory muscle pain provoked by maximal mouth opening and palpation.[224] Among all individuals with a TMD, masticatory muscle tenderness on palpation (see Figure 10-10) is the most consistent examination feature.[182] In contrast, the literature has described an uncorrected deviation on maximum mouth opening as characteristic of acute disc displacements without reduction.[39] While that uncorrected deviation is perhaps common in the individual with an acute joint, such deviation is less reliable than assumed; such deviations in chronic conditions are far more variable as a finding. Moreover, uncorrected deviations require a differential diagnosis between disc displacement,

Table 10-8 Physical examination of the masticatory system for TMD.

Examination Component	Observations
Inspection	Facial asymmetry, swelling, and masseter and temporal muscle hypertrophy Opening pattern (corrected and uncorrected deviations, uncoordinated movements, limitations)
General palpation	Parotid and submandibular areas Lymph nodes
Mandibular range of motion (ROM)	Vertical jaw movements: pain-free opening, maximal opening with pain, and maximal assisted opening Horizontal jaw movements: lateral and protrusive movements Pain provocation, location, and replication are assessed with each movement
TMJ noises	Any noise produced by vertical or horizontal movements, as reported by the patient and as identified as to type by the examiner (e.g., click vs. crepitus), any pain and replication with noise, and any locking
Palpation for pain	Masticatory muscles Temporomandibular joints
Additional provocation tests as indicated	Static pain test (no mandibular movement to pressure) Dynamic pain test (active mandibular movement against resistance) Pain in the joints or muscles with tooth clenching or unilateral biting Reproduction of symptoms with chewing (wax, sugarless gum)
Other systems	Cervical ROM Palpation for pain of neck muscles and accessory muscles of mastication Neurologic screening, sensory testing
Intraoral examination	Signs of parafunction: cheek or lip biting, accentuated linea alba, occlusal wear Dental pathology: tooth mobility, percussion, thermal testing, fractures of enamel and restorations General soft tissue: scalloped tongue borders, parotid gland patency

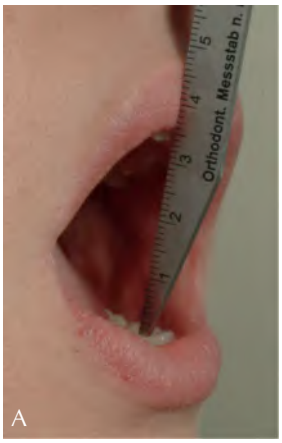
unilateral contractures, and guarding behavior. Components of the physical examination that are discussed in this section are summarized in Table 10-8.

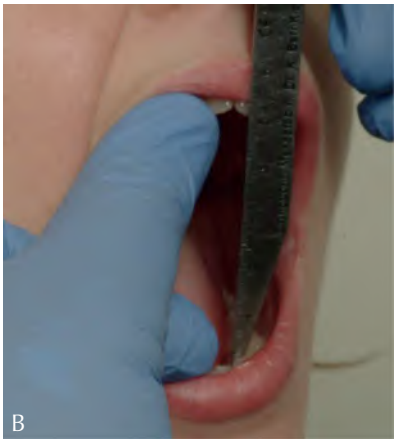
Mandibular Range of Motion

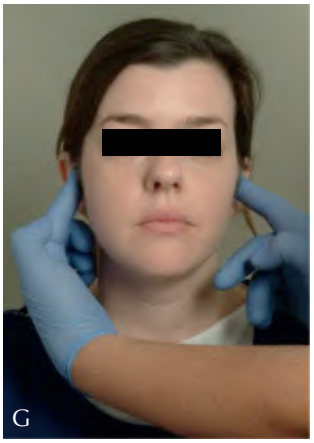
Mandibular range of motion (ROM) comprises three procedures in the vertical plane and three procedures in the horizontal plane. Measurements of vertical ROM are generally far more useful clinically, compared to those of the horizontal ROM. The three vertical ROM procedures include: maximal opening without pain, as wide as possible with pain, and after opening with clinician assistance; each of these is operationalized accordingly. These measures are termed in the DC/TMD pain-free opening, maximal unassisted opening, and maximal assisted opening, respectively. Vertical measurements are made with a ruler between opposing maxillary and mandibular incisal edges; the measurement can be corrected by the extent of vertical overlap of the teeth, if a measure of full mobility is desired. Mouth opening with assistance is accomplished by applying mild to moderate pressure against the upper and lower incisors with the thumb and index finger. All three of these measures exhibit excellent reliability (ICC > 0.90) among trained examiners, and therefore are excellent measures for monitoring status of the disorder over time.

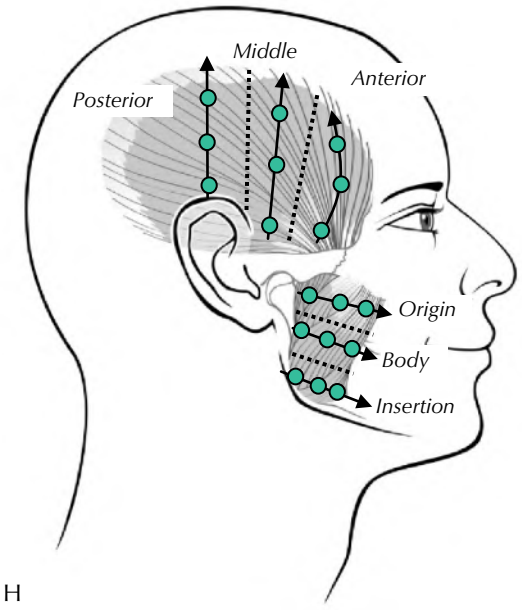
The three horizontal ROM procedures include: right and left lateral, and protrusive movements of the mandible, and all are executed "as far as possible, even if painful" while the teeth are slightly separated. Lateral movement measurements

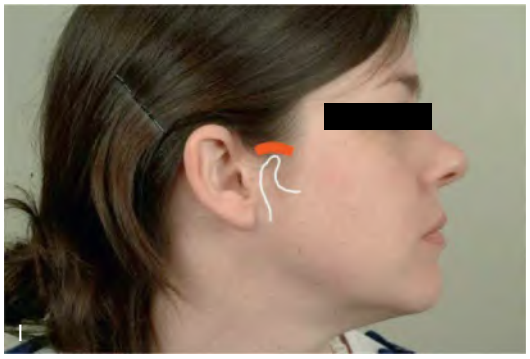
Figure 10-10 The core components of the clinical examination. (a) Measuring pain-free opening and maximal unassisted (active) opening. (b) Measuring maximal assisted (passive) opening. (c) Measuring right lateral movement of the mandible; this is repeated for movement of the mandible to the left, and then in protrusive. (d) Patient points to location of pain, which is asked after each of maximal unassisted and maximal assisted opening, right and left lateral movement, and protrusive. (e) Examiner confirms structure that the patient had pointed to as painful from the range of motion procedure. (f) Position of hands for palpation of single TMJ during range of motion. (g) Position of hands for simultaneous bilateral palpation of the TMJ during range of motion. (h) Location of palpation sites for palpation for pain of the temporalis and masseter muscles. (i) Visualization of lateral pole for palpation for pain of the lateral pole; finger is placed directly on the pole. (j) Visualization of starting finger position (green dot) for circumpolar palpation for pain of the TMJ; the finger rotates around the condyle, as shown by the black arrow. *Source:* Illustrations and photos are adapted from Ohrbach et al., *Diagnostic Criteria for Temporomandibular Disorders (DC/TMD) Clinical Examination Protocol.*[204] See *Protocol* for full set of illustrations and instructions for the clinical examination.

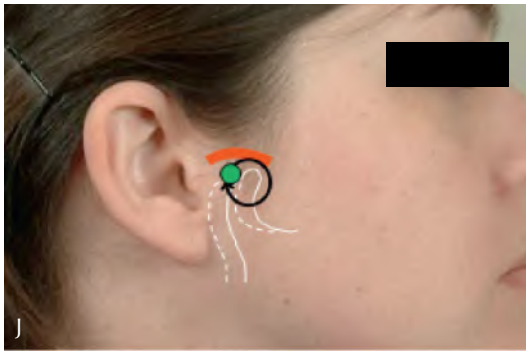












are made with the ruler measuring the displacement of the lower midline from the maxillary midline and adding or subtracting the lower-midline discrepancy. Protrusive movement measurement is made by adding the distance the lower incisors travel beyond the upper incisors to the horizontal distance between the upper and lower central incisors during full closure. All three of these measures exhibit acceptable reliability (ICC > 0.80) among trained examiners; these measures are less useful clinically.

Normal maximum mouth opening is ≥ 40 mm. In a study of 1160 adults, the mean maximum mouth opening was 52.8 mm (with a range of 38.7 to 67.2 mm) for men and 48.3 mm (with a range of 36.7 to 60.4 mm) for women.[225] Normal lateral and protrusive movements are ≥ 7 mm.[226–228] Measures of the mandibular range of movement are similarly performed in children. The mean maximum mouth opening recorded in 75 boys and 75 girls aged 6 years was 44.8 mm.[229] Similar values (a mean maximum opening of 43.9 mm, with a range of 32 to 64 mm) were observed in 189 individuals with a mean age of 10 years.[230] The means of left, right, and protrusive maximal movements were each approximately 8 mm.

ROM assessments have two types of diagnostic significance. The first is that following each of the tests (with the exclusion of pain-free opening), the patient is asked if the movement caused pain, and if so, to point to the area of pain and to indicate whether that pain replicated pain of complaint (see section Palpation for pain for further explanation regarding pain replication). The second is by using maximal assisted opening for distinguishing within the disorder of disc displacement without reduction the subtypes of with vs. without limitation. More generally, observed findings from the three vertical measures, and sometimes the three horizontal measures, are evaluated in relation to the history and other clinical findings: are the ROM measures expected or unexpected?

There are several non criterion-based uses of the ROM measures, particularly when comparing findings across all three procedures. Passive stretching (mouth opening with assistance) is a technique that may assist in differentiating limitation due to a muscle or joint problem, but clinical judgment is needed to interpret. In performing maximal assisted opening, the examiner can evaluate the quality of resistance at the end of the movement. Muscle restrictions are associated with a soft end-feel and should result in an increase > 5 mm beyond the maximal unassisted opening. Joint disorders such as acute nonreducing disc displacements are described as having a hard end-feel and characteristically limit assisted opening to < 5 mm. However, limited movement in response to attempted assisted opening can be due to two other causes: muscle contracture and guarding behavior by the patient. The latter can be especially meaningful when considering other biobehavioral factors, such as fear avoidance or kinesophobia,[231,232] for the direction of treatment. It is difficult to operationalize guarding behavior for reliable assessment.

Noises

Palpation of the TMJs is first performed to detect irregularities during condylar movement, described as clicking or crepitus. The lateral pole of the condyle is most accessible for palpation during mandibular movements. In addition to joint noise, there may be palpable differences in the form of the condyle comparing right with left. A condyle that does not translate may not be palpable during mouth opening and closing. This may be a finding associated with an ADD without reduction. A click that occurs on opening and closing and is eliminated by bringing the mandible into a protrusive position before opening is most often associated with ADD with reduction, but this maneuver for eliminating reciprocal clicks does not assure a diagnosis of ADD with reduction.[205]

Palpation for Pain

The most widely used clinical test for the assessment of a TMD is applying pressure to muscles and joints in order to determine if pain is elicited by the stimulus, known as palpation pain. While this procedure is deemed fully valid and appropriate for the extraoral muscles, intraoral palpation of the lateral pterygoid muscle has been challenged because of its location and inaccessibility (Figure 10-10).[233] In addition to poor reliability associated with its examination, the examination procedure is likely to cause discomfort in individuals without a TMD, diminishing the value of lateral pterygoid palpation as a diagnostic test.[234] The fibers of the deep masseter muscle are intimately related to the lateral wall of the joint capsule, which may explain the frequent localization by patients of the pain complaint to the preauricular area broadly. This anatomic characteristic makes differentiating muscle and joint pain in this area difficult.[235,236]

While pain is reported in response to ROM procedures among individuals with a TMD, pain is elicited much more frequently from palpation of the masticatory muscles and TMJs. Because palpation is a discrete stimulus, the response can be separated into reported pain local to the area of stimulation, pain spreading beyond the area of stimulation, and pain perceived in a different area (i.e., referred pain to another structure). These categories of pain response are particularly relevant for muscle tissue, but spreading and referral also occur, albeit less frequently, in response to palpation of the TMJs. A critical aspect of the DC/TMD examination is to inquire if provoked pain (whether from ROM or palpation procedures) is "familiar" to the person's usual pain (i.e., the examination procedure has provoked replication of the pain of complaint); this specific finding is part

of the criteria for the pain-related diagnoses. Another level of pain replication from palpation (but not ROM) is whether spreading or referral response is also familiar. While familiar spreading or referral are not, at this time, part of the criterion for the respective subtypes of myalgia, inquiring of the patient, with respect to whether any elicited referral patterns typically occur, during the palpation examination, is recommended. Differential diagnosis (e.g., TMD vs. odontogenic pain) sometimes depends critically on elicitation of referral response, its replication of the pain of the complaint, and the specificity in identifying the target tissue of the referral.

Many methods for palpation are advocated, and parameters that affect palpation, as a procedure, include amount of loading to the tissue, surface area of the loading, duration of loading, and where the loading is applied. The DC/TMD guidelines recommend 1.0 kg of loading for the muscles and 0.5 kg for lateral pole loading and 1.0 kg circumpolar loading of each TMJ, as based on population and clinical samples,[184,205] and an extensive range of research has generally supported these parameters. In recognition that fingertips used for palpation vary considerably in surface area, the indicated loadings will ultimately vary in terms of pressure to the peripheral receptors in the patient's tissue, and thereby introduce error in the palpation procedures. Hence, the DC/TMD specified that loading should be "at least" to the stated criterion. The alternative, for better standardization, is to use a simple algometer that will provide consistent pressure (loading/square area); one example is the Palpeter which is easy to use and has excellent reliability.[237] There appears to be sufficient empirical support for the stated magnitudes of palpation in terms of maximizing true positives and negatives, and minimizing false positives and negatives. During loading, the muscles should be in a noncontracted state. As further explained below, muscles may be placed on a stretch prior to palpation.

As an alternative to standardized loading, some clinicians have recommended that palpation loading be normalized to the individual's pain threshold: establish a baseline (to serve as a general guide or reference) by squeezing a muscle between the index finger and thumb or by loading the center of the forehead or thumbnail to gauge the minimum extent that becomes painful. While perhaps intuitively sensible, this approach has two problems: circularity, through the assumption that the individually tailored threshold for painful loading is "normal" for that person (and thereby sidestepping the considerable problem of widespread body tenderness as either a comorbid condition or simply as a reflection of central sensitization);[238] and likely poor reliability in applying the individually-tailored loading (which will vary from patient to patient) during the examination.

In contrast to palpation loading, duration of palpation is more nebulous in terms of empirical support. Patients report that fast palpation (e.g., loading of the tissue for less than 1 second) is too quick to feel confident about the response (e.g., painful yes or no?), whereas a stimulus that is at least 2 seconds in duration (including ramp up and down) appears to be sufficient to respond to. Referred pain phenomena, in contrast, seldom occur in relation to a stimulus as short as 2 seconds; the minimum duration to elicit referral is unknown, and a stimulus at least 10 seconds in duration has been recommended.[239] The DC/TMD attempts to provide a starting point for further research by requiring the stimulus to be at least 5 seconds in duration if referral is of interest; this stimulus duration is sufficient for at least a reliable diagnosis of referred pain. Clinically, if referral phenomena are suspected and are important for, say, differential diagnosis, then extending the palpation duration to 10 (or more) seconds would be justified, as based on reported observations; in addition, as Travell and Simons indicate, placing the muscle on a stretch prior to the palpation can reportedly facilitate elicitation of referral.[239] Whether increasing the magnitude of the loading is as important as the duration of the loading (in order to trigger temporal summation) is unknown, but anecdotal evidence points to increasing the duration of the loading for elicitation of referred pain. The necessary stimulus duration for elicitation of spreading phenomena is unknown, but because the mechanism is likely similar to that underlying referral, the same 5 seconds duration is recommended at this time.

The location of palpation is another parameter with much clinical lore. For simple myalgia, it seems that a sampling approach (e.g., divide the temporalis and masseter muscles into three zones each, and distribute three palpation sites across each zone) to the underlying tissue is sufficient. Critically, this method is reliable.[240] For eliciting referral phenomena, in contrast, the finding of "bands" and "trigger point nodules" is advocated, yet this method is only marginally reliable and then only with extensive training.[241] One problem affecting reliability in the examination of trigger points is that their location is not stable across relatively short periods of time.[242] Abnormalities such as trigger points and taut bands in muscle have not been sufficiently characterized in the masticatory muscles to enable the clinician to reliably distinguish these sites anatomically from normal muscle. If there is a particular clinical question (e.g., differential diagnosis) that needs to be answered with regard to presence of referred pain, then the most reliable method of detection is probably to sample the muscle in a systematic manner: divide the muscle into enough zones and each zone into enough palpation sites, such that the areas of stimulation via the fingertip are sufficiently small. If subtyping myalgia into local myalgia, spreading, or referral is important

primarily for adequate capture of the stated symptom descriptions, then the standard sampling method of the DC/TMD will likely be sufficient: palpate temporalis and masseter muscles at 1 kg loading, for 5 seconds at each of 9 palpation sites within each muscle.

Related to where to palpate each muscle is which muscle to palpate. The muscles of mastication include not only the temporalis and masseter, as the muscles most commonly associated with location of pain complaints, but also additional muscles of the lateral and medial pterygoids, the hyoids, and digastrics on each side. Yet, in terms of incremental validity, little is often gained by palpating these additional muscles versus the information gained from initially examining the temporalis and masseter muscles. The lateral pterygoid is in a position that does not allow access for adequate palpation examination, even though there are examination protocols and descriptions for palpating this muscle.[243] Hence, the DC/TMD requires palpation of temporalis and masseter, and palpation of the other muscles is optional and should be determined by the nature of the chief complaint.

The location in which to palpate the TMJ for pain, and its interpretation, has a range of perspectives. Traditionally, palpating the lateral pole and through the ear canal was believed to be sufficient to provoke pain associated with the capsular ligament. However, the Validation Project determined that lateral pole palpation alone was insufficient, and that the false negative rate of arthralgia diagnosis was too high. Consequently, a circumpolar dynamic palpation, with loading at a minimum of 1.0 kg, was recommended; the full circle around the lateral pole should take approximately 5 secs. The clinical literature states that pain elicited in one part of the joint is indicative of a posterior capsulitis, while pain from another part of the joint is indicative of a synovitis, etc.; while such differentiations may be possible in principle, the available empirical data only identify arthralgia as a reliable diagnosis.

The severity of the pain provoked from palpation can be assessed (e.g., using a 4-point verbal scale of none, mild, moderate, or severe; or by using a 0–10 numeric rating scale) but this type of discriminatory response has not, in the research literature, been shown to be more useful than the simple binary report of pain yes versus no with respect to disorder classification or overall severity of the condition. For monitoring pain sensitivity of a single muscle, the severity ratings could help. The report of pain is followed by the question of whether the provoked pain is familiar—whether it replicates the pain of complaint. Because pain sensitivity varies across individuals, some patients even after treatment may well report that palpation still induces pain, but if the patient no longer has pain, then the pain replication question will be negative, which would be essential for assessing treatment progress.

Provocation Tests

Provocation tests are designed to elicit the pain complaint. Assessing jaw ROM and palpation for pain are types of provocation tests. Since pain is often aggravated by jaw use according to the patient's history, an appropriate clinical test would assess function; a positive response adds support for a TMD diagnosis even though functional tests such as clenching the teeth (i.e., involving sustained muscle contraction) did not provide additional information that improved sensitivity and specificity for a TMD compared to a nonpain control.[205] In contrast, functional tests improved diagnostic validity of a painful TMD versus a comparison pain condition of odontogenic pain.[244] Consequently, including functional testing when the history or findings from the standardized clinical examination yield an ambiguous diagnostic outcome is very sensible and represents good practice. Four types of functional tests have been recommended and continue to be sensible at least in terms of face validity. These tests include static muscle contraction test, and dynamic muscle contraction test, bilateral loading via clench, and unilateral loading via clench.

The static pain test involves having the mandible slightly open and remaining in one position while the patient resists the slowly increasing manual force applied by the examiner in each of right lateral, left lateral, upward, and downward directions. If the mandible remains in a static position during the test, the muscles will be subjected to activation, and any pain should be specific to muscle. In the dynamic test, the mandible slowly moves against resistance, in each of the same directions as for the static test; any provoked pain should be specific to the joint. As for the static test, however, the specificity of response in muscle versus joint does not seem to accord with the putative principle. Nevertheless, dynamic and static tests exhibited excellent specificity: 84% of dental pain cases were negative for these tests.[244] Neither of the static or dynamic tests added incremental validity to the provocation tests of ROM and palpation procedures for a myalgia diagnosis.[205]

Clenching the teeth, biting on a unilateral separator between the teeth, or chewing wax or gum is expected to load the joints and muscles. According to one study, approximately 50% of TMD patients who chewed half of a leaf of 28-gauge casting wax for 3 minutes reported increased pain, but 30% reported decreased pain and 20% reported no change.[245] This is not surprising, given the report by many patients who participate in examiner reliability studies that despite the considerable provocation of painful muscles by palpation across four examiners, the repeated maximal opening and other jaw movements become therapeutic for some of the subjects. In the clinic, some patients will clearly report that chewing gum improves their pain (and they are seeking consultation primarily to rule out a more complex

disorder, and if so, with the plan to use gum more frequently). Biting on unilateral cotton roll or tongue blade has been recommended for many years as an important diagnostic test; however, the ability of this test to discriminate between muscle and joint pain is poor.[246] In summary, many adjunctive tests are available, but in the end their diagnostic utility must be rigorously assessed in order to determine if the test is useful, and in what circumstance.

Assessment of Consequences or Correlates of Parafunctional Behaviors

Each of tooth wear, soft tissue changes (evidence of lip or cheek chewing, an accentuated occlusal line, and scalloped tongue borders), and hypertrophic jaw-closing muscles has been suggested as an objective means of assessing for parafunctional behaviors (or muscle hyperactivity). The face validity, with regard to pathophysiology or cause-effect with parafunction, varies across these different types of findings, with tooth wear and muscle hypertrophy seemingly high and scalloped tongue borders seemingly lower. However, the interexaminer reliability of assessing tooth wear is fair at best,[247] and the other assessments also exhibit poor reliability, thereby decreasing the clinical utility of these procedures.

Cervical Region: ROM and Palpation of Muscles

Patients with TMDs often have musculoskeletal problems in other regions, particularly the neck.[248,249] The upper cervical somatosensory nerves send branches that synapse in the spinal trigeminal nucleus, which is one proposed mechanism to explain referral of pain from the neck to the orofacial region. The sternocleidomastoid and trapezius muscles are often part of cervical muscle disorders and may refer pain to the face and head. The cervical area and the masticatory area, therefore, share several linkages: mechanical, motor control, and afferent input.

Consequently, the cervical region warrants at least a screening examination. Mobility is assessed during flexion, extension, rotation, and side-bend of the neck. Using an observational method, the head should, in general, flex to the extent that the chin can touch the sternum, extend until the face is parallel to the ceiling, rotate 90° to either direction, and side-bend 45° to either direction. Methods, including ruler or goniometry, can be used for quantitative assessment, but utility of higher precision should be considered if the goal is screening. For palpation, the trapezius, levator scapula, and suboccipital muscle groups seem adequate for screening; other cervical muscle groups of SCM, splenius capitus, and semispinalis capitus can be included. The inclusion of examination and treatment of the cervical area, in relation to a TMD, is strongly advocated in the clinical literature, but there is little data at this time to draw on for evidence-based guidance. One substantially limiting factor is that research has been largely nonreplicable due to no universally held evaluation and diagnostic standard for the common forms of cervical pain (e.g., a hypothetical RDC/Cervical). A potential standard appears to be emerging for basic cervical diagnostic classification from the perspective of chronic pain.[250] One cervical parameter that seems to have sufficient agreement regarding assessment method is forward head posture; there is, however, no reliable relationship between static head posture and TMD.[251] Some type of RDC for cervical musculoskeletal pain problems is urgently needed in order to gain a better basic classification, from which science can move forward and clinical evaluation and treatment can have a better basis.

Diagnostic Imaging

The TMJs can be imaged using primarily noninvasive modalities; however, relatively invasive modalities are also used.[252] Noninvasive imaging includes conventional radiography (e.g., panoramic radiographs and transcranial radiographs), tomography (TMJ open and close), ultrasonography, computed tomography (CT), cone beam CT (CBCT), and magnetic resonance imaging (MRI). Relatively invasive imaging methods include arthrography, bone scintigraphy, and radioisotope scanning.

Imaging should be part of the assessment whenever any of the following characteristics are present: history or clinical findings suggesting a progressive pathologic condition of the TMJs; recent injury with progressive or worsening symptoms; sensory or motor abnormality; severe restriction in mandibular motion; nonresponse to usual treatment for a joint condition; differential diagnosis dictating change in treatment direction; or acute alterations of the occlusion. The most frequent abnormalities that are imaged in TMD patients are disc displacements and degenerative changes of the articular bones, both of which require imaging for a confirmed diagnosis.[3]

For the majority of TMDs, however, the information from diagnostic imaging has not proven to be important for directing treatment, predicting treatment outcome, and determining long-term prognosis. For example, a study was carried out comparing CBCT findings of bony changes in TMJ for symptomatic and asymptomatic patients with TMD. Bony changes were notably similar in both symptomatic (90%) and asymptomatic (86.7%) patients.[253] Consequently, imaging should be ordered only when a clinical hypothesis can be answered by incorporating such information. For example, imaging for confirming a diagnosis of disc displacement should be requested only if diagnostic confirmation will affect treatment direction or outcome.

Conventional and tomography plain film radiographs are largely used to evaluate normal anatomy (Figure 10-11A) and osseous changes in condyles (Figure 10-12), including advanced degenerative changes and asymmetry. A large variation exists in closed mandible condylar position as observed in plain-film radiographic and tomographic studies, making the closed condyle–fossa relationship of little value in the diagnosis or treatment of TMD.[254] No differences were found in joint-space narrowing in the centric occlusion position in symptomatic and asymptomatic patients by transcranial plain-film radiography and tomography.[255,256] Consequently, using plain films (such as transcranial radiography) to determine condylar position or using the condylar position on these films to infer disc position is not recommended.[256,257] Panoramic radiographs have limitations due to the presence of skull base and zygomatic arch superimpositions on captured images.

More emphasis is being placed on the use of three-dimensional and high-resolution imaging in the diagnosis of

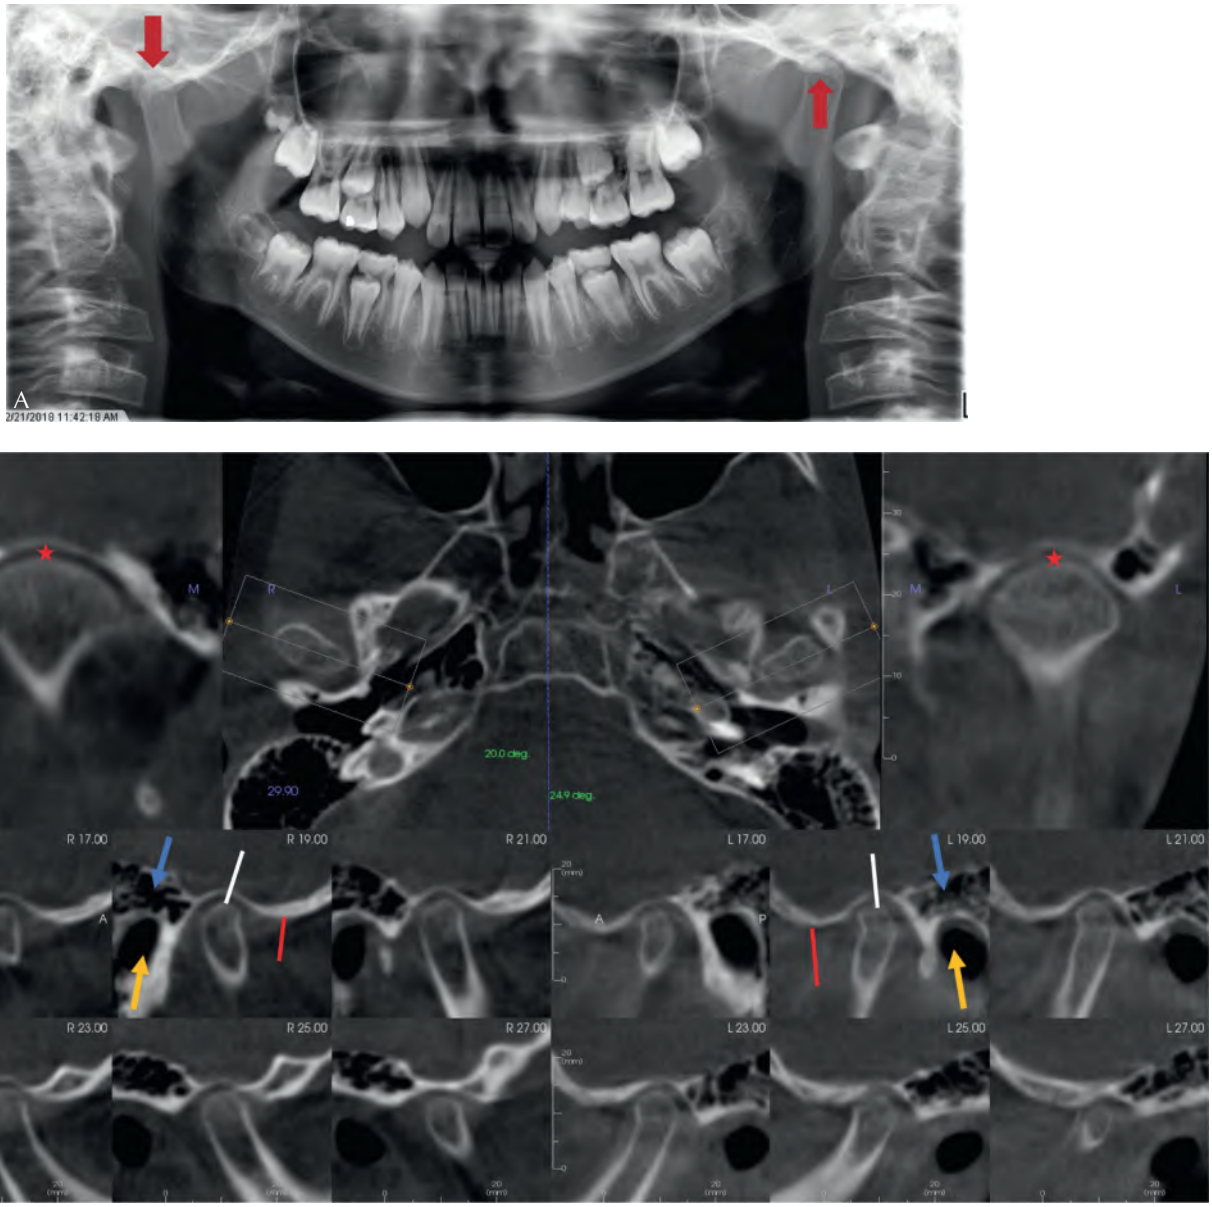


Figure 10-11 (A) Panoramic radiograph of a 12-year-old male patient showing the smoothly contoured normal anatomy of the right and left condyles. Note the superimposition of the zygomatic process on the articular eminence bilaterally (red arrows). (B) CBCT multiplanar representation of the temporomandibular joint of the same patient in Figure 10-11A showing the thin cortical outline of the condyles (white line) and articular eminences (red line). Note the mastoid air cells (blue arrow) and external auditory meatus (yellow arrow). The right and left articular spaces (red star) are within the limits of normal. *Source:* Courtesy Dr. Adeyinka Dayo. Oral radiology Penn Dental Medicine.

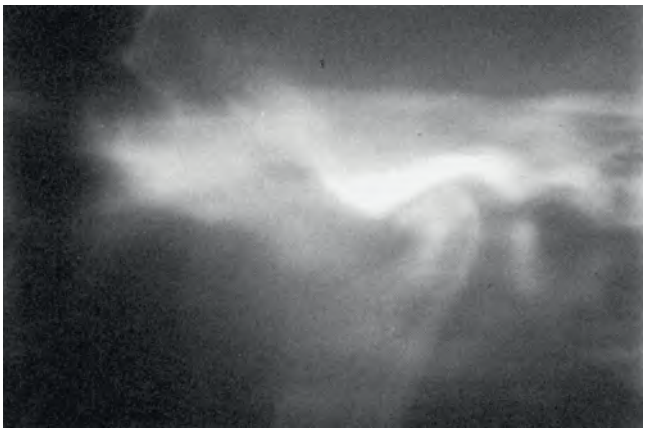

Figure 10-12 Temporomandibular joint tomogram displaying flattening of the condylar head in degenerative joint disease.

temporomandibular disorders, as there is better visualization of anatomic landmarks and no superimposition. Computed tomography—both multidetector computed tomography (MDCT) and cone-beam computed tomography (CBCT)—is the imaging method of choice (Figures 10-11B, 10-13A and 10-13B). CT provides detail for bony abnormalities and is an appropriate study when considering ankylosis, fractures, tumors of bone, and DJD (Figure 10-14). CBCT has an advantage of comparable low cost and low dose of radiation exposure.[258,259]

MRI remains the reference standard for TMJ soft tissue imaging, including articular disc and TMJ ligaments, and for muscles of mastication.[260] MRI effectively documents alterations in articular disc form and position in closed and open mouth positions. The value of MRI for TMJ soft tissue requires careful interpretation. MRI studies in asymptomatic volunteers have shown disc position abnormalities in approximately one-third of subjects,[261] and consequently abnormal disc position alone should not be considered a disorder. With the use of T2-weighted MR, a correlation between joint pain and joint effusion has been suggested, but the results are conflicting.[262–264] TMJ effusion is associated with an elevated concentration of synovial fluid proteins, including proinflammatory cytokines, but the ability to confirm the presence or absence of synovitis in the joint has not been established.[265] It is still not possible to predict the presence of pain based on MRI findings. Individual features on MRI of internal derangement, osteoarthrosis, effusion, and bone marrow edema are not predictive of TMJ pain, but when these features occur together, an increased risk of TMJ pain has been observed.[266]

Arthrography involves the fluoroscopic guided injection of contrast dye into the TMJ, followed by CT imaging. While this imaging modality provides perhaps the most dynamic depiction of joint and disc mechanics, the modality is not popular due to its invasive nature and risk of allergic reaction to contrast dye.

Radioisotope scanning for detecting increase in metabolic activity has been used to detect condylar hyperplasia. Bone scanning is a sensitive indicator of metabolic bone activity and will show similar activity in a joint that is undergoing physiologic remodeling as well. Scintigraphy is a sensitive test but is not specific for TMJ disease. Bone scintigraphy in combination with other imaging and clinical findings (including findings on periodic examinations) is usually effective in diagnosing continued condylar change due to hyperplasia.

Diagnostic Local Anesthetic Nerve Blocks

Injections of anesthetics into the TMJ or selected masticatory muscles may help confirm a differential diagnosis. Immediate elimination of or a significant decrease in pain and improved jaw motion should be considered a positive test result. In situations in which a joint procedure (such as surgical intervention) is being considered, local anesthetic injection of the joint may confirm the joint as the source of nociception. Injecting trigger points or tender areas of muscle should eliminate pain localized to that site and should also eliminate referred pain associated with the injected trigger point.[239] These tests, like all others, require interpretation in the context of all the diagnostic information since a positive result does not ensure a specific diagnosis. Injecting medication such as corticosteroids may be part of therapy.

Injection Sites

Kopp has described a technique for TMJ injection.[267] The site of injection should be anterior to the tragus to minimize the risk of intravascular injection of the external carotid artery or the accompanying vein. Because the auriculotemporal nerve enters the capsule from the medial aspect, injections (normally given from the lateral aspect) may not completely anesthetize the joint.[268] Fernandes and colleagues found the auriculotemporal nerve to be 10 to 13 mm inferior to the superior surface of the condyle and 1 to 2 mm posterior to the neck of the condyle.[269]

Occlusion

The purpose of evaluating the occlusion is to identify clear loss of normal stability as a result of acute occlusal change, which occurs as a consequence of a TMD. Occlusal changes of interest include the sudden onset, typically unilateral, of posterior open bite (associated with atypical disc displacement or synovial chondromatosis) or the gradual onset of bilateral anterior open bite (associated with progressive condylar erosion occurring, for example, in aggressive

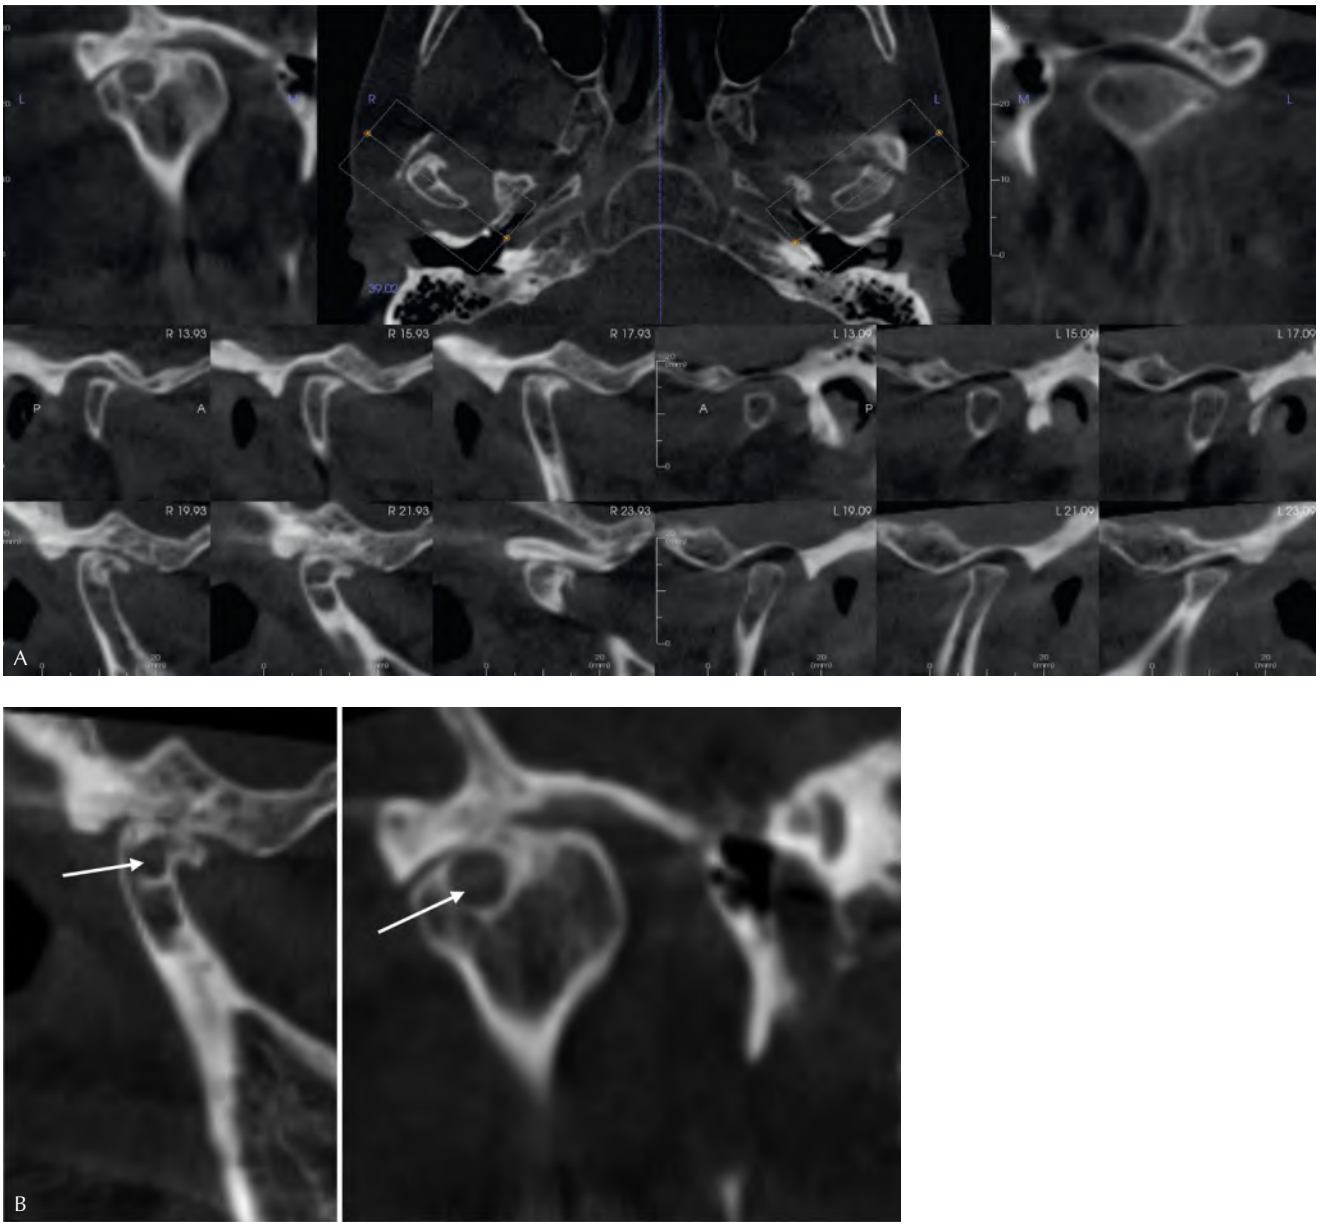

Figure 10-13 (A) CBCT multiplanar representation of the temporomandibular joint of a 68-year-old female with 2 mm slice interval of the sagittal view. There is subchondral sclerosis and flattening of the right condyle with osteophyte formation on the anterior pole of the right condylar head. Note the large subchondral cyst within the right condyle. The right articular eminence and glenoid fossa exhibit subchondral sclerosis and flattening with thinning of the right articular space. The radiographic features are consistent with moderate degenerative joint disease of the right temporomandibular joint. *Source:* Courtesy Dr. Adeyinka Dayo. Oral radiology Penn Dental Medicine. (B) Cone beam CT. (Left) parasagittal view of the right TMJ and (Right) coronal view in the same patient.

degenerative joint disease of the TMJs). The loss of normal stability is first suspected during the patient history, in which the patient will describe a sudden inability to firmly place the posterior teeth together in the usual way, or a gradual loss of ability to incise food. The patient description is the primary determinant for evaluating the occlusion for loss of stability with respect to what is normal for that individual. The intercuspal position is achieved when maximum intercuspation of opposing teeth occurs.[270] From this position, the occlusion is evaluated grossly for acute change versus being a functional occlusion. A functional occlusion does not have to be ideal; rather, a functional occlusion exhibits stability. The patient's perception of a minor change in maximal occlusal contract, such as often occurs in response to a masticatory muscle disorder, must be distinguished from the patient report of (typically intermittent) inability to fully

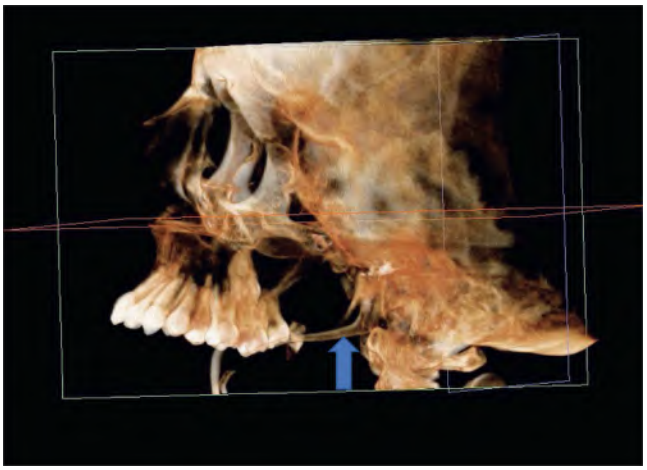

Figure 10-14 Sagittal view (CBCT) of a patient with First arch syndrome (Treacher Collins and Pierre Robin syndrome) and aplasia of the mandible. Arrow points to attempted fibular graft to replace the missing mandible.

close the posterior teeth or the gradually increasing space between anterior teeth and loss of incision. Detailed analysis of the patterns of occlusal contact during full closure, excursive movements, or with the mandible in some manipulated so-called reference position has neither etiologic nor diagnostic value. Recall that a very large volume of research has as yet failed to find associations between those occlusal attributes and a TMD. For example, a reduced number of contacting teeth in the intercuspal position and loss of posterior teeth have been hypothesized to be risk factors for the subsequent development of a TMD,[271] but at present no longitudinal evidence exists for this hypothesized relationship. The clinician must think dynamically about time and longitudinal change when considering the impact of a TMD on the occlusion.

MANAGEMENT: GENERAL GUIDELINES

Prediction of Chronicity

Whereas a majority of individuals with a TMD respond, at least in part, to nonsurgical management that can be provided or coordinated by a dentist, a substantial number of individuals with TMD evolve into a chronic musculoskeletal pain disorder that results in significant disability. Patient histories suggest that most individuals with acute TMD do not immediately seek care; instead, they wait for weeks or perhaps months in order for it to resolve on its own, much as one might with a flu, the common cold, or a joint sprain. Consequently, in clinical settings, most patients with a TMD have most likely already either begun the transition to having chronic pain, or already have chronic pain, increasing the importance of utilizing comprehensive assessment and treatment models routinely for all patients with a presumed TMD.

Chronic pain has been traditionally defined in three different ways: pain that persists beyond the time of usual healing; pain that does not respond to usual treatment; or pain that extends beyond a certain period. The first two definitions of chronic pain are very sensible and useful for patient discussions regarding treatment recommendations. However, both of those definitions include ambiguous reference points: what is the usual period for healing of this problem in this person, and how can the adequacy of treatment provided to date be judged for sufficiency? Consequently, the dominant definition for chronic pain revolves around time since onset and for many decades, a period of 6 months was selected,[272] but more recently the definition has been refined to "pain that occurs on at least half of the days for 6 months or more."[273] The rationales for using time include the commonly recognized behavioral or social changes that accompany persisting pain and which have their own latency period; and time is easy to measure.

Perhaps more important than chronicity is the impact of the pain. Some changes, such as worry, appear early, while financial and work-related problems tend to occur later. Whether depression is a cause of chronic pain or a consequence has been rigorously debated for many years; current evidence from the OPPERA project indicate that it is probably both: depression appears to be a significant risk factor for developing chronicity, and once pain becomes chronic, the CNS burden of ongoing pain leads to alterations at multiple levels in the CNS, and the state of depression is one manifestation, in terms of behavior and mood, of the CNS changes. Plus persisting depression only further exacerbates persistent pain; two obvious direct mechanisms for how depression worsens pain include dampening of descending modulatory systems and the impact on motivation and intentional behavior necessary for adherence to any treatment that involves the development and use of self-regulatory skills. This type of recursive involvement of a factor, such as depression, readily illustrates the complex disease character of TMD. Individuals vary, of course, in the degree of impact by which chronic pain affects their functioning, and it is very useful to distinguish those who have less severe chronic pain from those who experience substantial disruption.[274] High-impact chronic pain is persistent pain with "substantial restriction of participation in work, social, and self-care activities for 6 months or more."[275] Among those with chronic painful TMD, 33% have high-impact pain, which is comparable to 35% among those with headache.[136] Similar to other chronic pain disorders, with high-impact chronic painful TMD comes substantial psychological distress, disruption of normal daily activities, and ongoing pursuit of health care resources.

Predicting which individual is likely to become chronic is important in order to provide alternative or additional interventions earlier in the scope of treatment. Early treatment that addresses biobehavioral factors appears to decrease the likelihood of acute pain becoming chronic.[276] Among the potential risk factors for the transition from acute to chronic which may be assessed, as based on the DC/TMD framework, the primary predictor of the transition from acute pain to chronic pain is pain: reported pain intensity (as measured by the Graded Chronic Pain Scale) and pain-free opening of the jaw, pain with movement of the jaw, and pain from palpation of the muscles and TMJ, as assessed by the clinical examination.[46] Similarly, a combination of high pain intensity (as measured by the Graded Chronic Pain Scale) and a myofascial pain diagnosis was predictive of persisting TMD symptoms.[276] From a clinical perspective, any patient who comes for a consultation should be considered for chronicity. Overall, chronicity is a function of multiple factors, and focusing primarily on seemingly obvious ones, such as trauma (with a presumed biological impact), to the exclusion of other, more abstract ones, such as depression, anxiety, or pain-related disability, is to contribute to the patient's pain chronicity.

Principles of Treatment

The most important feature of TMD is, in general, pain; and consequently pain is the most important patient reported outcome (PRO) with regard to whether a treatment was helpful. Other common and important features that can serve as a target for a PRO include inability to eat hard-to-chew foods, restricted range of mandibular movement, and mechanical joint problems that interfere with function. Chronic TMD pain (like all chronic pain) results in psychological, behavioral, and social disturbances, and while these characteristics may be a dominant part of the overall symptom presentation, they seem to be less often regarded as important by the patient with TMD or by the provider. However, patient education into how biobehavioral factors are linked to their pain can make such variables more relevant as indicators for specific treatment types as well as important PRO measures.[277,278]

Treatment goals for TMDs can be divided into two levels, both of which are equally relevant. The first level includes: control pain, improve mandibular motion, and restore function as close to normal as possible. The second level concerns: impact to the person by the pain, methods to restore general functioning, and strategies for relapse prevention. The relative importance and timing of implementing each level is determined by many patient-specific factors as well as available health care expertise. Explanatory models[279] held by each of patient and clinician will affect how treatments oriented to each of the two levels will proceed; when pain is the dominant symptom (as it typically is at the first consultation), addressing the pain directly is generally the first priority, and success in reducing or better controlling the pain helps patients incorporate other treatment recommendations that may exist outside their explanatory model of illness. Unless an obvious and clearly causal source of nociception is identified for the TMD pain which warrants invasive therapy (e.g., chronic pulpitis presenting as myalgia), initial treatment should focus on noninvasive therapies which also have desirable nonspecific effects and which readily permit the integration of therapies across the two levels described here.

Clinical case studies and a variety of randomized controlled trials suggest that the majority of individuals with TMD respond to conservative noninvasive therapy, making the use of invasive procedures unwarranted as initial therapy. No one treatment has emerged as superior, although many of the treatments studied have shown beneficial effect.[280] The symptoms of painful TMDs tend to be intermittent, fluctuate over time, and are often self-limiting.[281–283] A 5-year follow-up indicated that TMD patients could be allocated roughly into thirds: remission, recurring symptoms, or persisting symptoms.[284] The process of deciding whether to treat and how aggressively to treat should take into account the course of symptoms. Patients who are improving at the time of assessment may require a minimum of care and follow-up compared with the individual whose symptoms are becoming progressively more severe and disabling.

The variations in types of treatment recommended by dentists have been explained by the gap between published information in the medical and dental literature and individual dentist's beliefs and attitudes.[285,286] Yet, because the different types of TMD treatment appear to have more or less equivalent efficacy, the treatment effect may be nonspecific and related more to the therapeutic relationship established between therapist and patient than to the specific attributes of the treatment.[287] These factors further support the use noninvasive reversible therapies for managing TMD.

Management, not cure, is the guiding principle for selecting and deciding when, if at all, to escalate treatment of TMD. Widely known and generally accepted clinical observations are highly informative. Patients with irreversible anatomic abnormalities, such as disc disorders, are nevertheless able to regain pain-free jaw function.[288,289] Decreased pain and improved physical findings are not directly related.[216,290] The presence of joint noises and deviations from the ideal in occlusion, in maxillomandibular relationships, and in the morphology of bony structures such as the condyle are relatively common in the general population. Evidence supporting prophylactic treatment of these anatomic abnormalities when no pain, impairment of function, or disability exists is lacking. Rather, treatment should be

based on the severity of pain and disability and should be directed toward those factors that are considered important in initiating, aggravating, or perpetuating the disorder.

Episodes of pain and dysfunction may recur even after successful symptom control. Reinjury or factors that contributed to earlier episodes of symptoms may be responsible. Recurrence should not be considered a treatment failure, and therefore regarded as justification to escalate treatment; rather it is more prudent to first consider the initiation of previous treatment that was successful. Myogenous disorders appear to relapse more often and therefore require retreatment more frequently than do articular disorders.[291]

For the smaller group of patients in whom TMD progresses to a chronic pain disorder, treatment becomes more complex. These patients may still benefit from local therapies; however, it is essential for the provider to more carefully consider the need for more comprehensive management in order to address the emotional and behavioral disabilities that result from chronic pain. Drug therapy of chronic pain is becoming increasingly complex, requiring knowledge and experience that are not common in general dental practice. These patients are often at risk for unnecessary investigations or treatments that may be harmful (such as longer term opiate use) that may further complicate their problems.[292–294] Persistence of pain does not necessarily indicate progressive disease; one task for the clinician is to monitor for possible disease progression (and thereby reassure the patient), while simultaneously holding the reins on a management treatment model that focuses on successful adherence to self-management treatments and improving function.

A National Institutes of Health conference on TMD therapy, while now somewhat dated, produced the following conclusions which remain worth considering: [295]

1) Significant problems exist with present diagnostic classifications because these classifications are based on signs and symptoms rather than etiology.
2) No consensus has been developed regarding which TMD problems should be treated and when and how they should be treated.
3) The preponderance of the data does not support the superiority of any method for initial management, and the superiority of such methods to placebo controls or to no treatment controls remains undetermined.
4) Because most individuals will experience the improvement or relief of symptoms with conservative treatment, the vast majority of TMD patients should be initially managed with noninvasive and reversible therapies.
5) The efficacy of most treatment approaches for TMD is unknown because most have not been adequately evaluated in long-term studies and because virtually none have been studied in randomized controlled group trials.
6) Therapies that permanently alter the patient's occlusion cannot be recommended on the basis of current data.
7) Surgical intervention should be considered for the small percentage of patients with persistent and significant pain and dysfunction who show evidence of pathology or evidence that an internal derangement of the TMJ is the source of their pain and dysfunction and for whom more conservative treatment has failed.
8) Relaxation and cognitive–behavioral therapies (CBTs) are effective approaches to managing chronic pain.

Referral to a Pain Specialist

Many patients with TMD respond to usual treatments oriented towards symptom reduction, improvement of jaw mobility, and restoration of normal jaw function. Such treatment is appropriately managed by dental professionals. More severe myofascial pain or presence of comorbid cervical problems warrants the inclusion of physiotherapists or physiatrists. Presence of other comorbid pain disorders warrants the inclusion of providers specialized in pain management. For patients who have depression, anxiety, comorbid pain disorders, multiple nonspecific physical symptoms, or pain-related disability, psychologists or psychiatrists are helpful. Other health care professionals become important for conditions such as neuropathic pain or nonresponsive headache (neurologist), or for multiple joint pains (rheumatologist). Some patients may be more appropriately managed by a pain specialist within a setting of a multidisciplinary pain clinic. This may be indicated when: (1) the disability greatly exceeds what is expected on the basis of physical findings; (2) the patient makes excessive demands for tests and treatments that are not indicated based on existing evaluations and no subsequent symptom change; (3) the patient displays significant psychological distress (e.g., depression); (4) the patient displays aberrant behavior, such as continual nonadherence to treatment; or (5) the patient is unable to sufficiently control significant contributing environmental factors, such as family reaction to the patient's illness or persistent problems in illness behavior.

SPECIFIC DISORDERS AND THEIR MANAGEMENT

The majority of patients likely to present in a dental practice with a complaint of temporomandibular pain and dysfunction can be broadly categorized into muscle disorders, articular disc disorders, and disorders affecting the articular bones. The most common muscle disorder is myalgia (as per the DC/TMD; also commonly referred to as myofascial pain that remains localized to the hyperalgesic tissue upon

provocation). This pain is not associated with an identifiable anatomic muscle abnormality.

Intracapsular disorders affecting the TMJ are divided into two broad categories: articular disc disorders and degenerative joint disease. Either may be present without causing symptoms or impairment. It is important for the clinician treating patients with a TMD to distinguish clinically significant disorders that require therapy from incidental findings in a patient with facial pain from other causes. TMJ abnormalities are often discovered on routine examination and may not require treatment. The need for treatment is largely based on the level of pain and dysfunction and the progression of symptoms. The discovery of an anatomic abnormality such as a longstanding joint noise that is otherwise asymptomatic and consistent with a disc displacement is usually not treated given what is presently known about the longitudinal course of such disorders as well as the presently available treatments.

Myalgia and Myofascial Pain of the Masticatory Muscles

Description

The diagnostic terms *myalgia* and *myofascial pain* are used for muscle pain disorders that are characterized primarily by pain, limitation, and absence of progressive disease. The DC/TMD considers myalgia as the general disorder for muscle pain, and local myalgia and myofascial pain are subtypes of myalgia. Local myalgia refers to pain that remains local to the provoked muscle, and it contrasts with *myofascial pain* which can be associated with either spreading or radiating of the pain within the muscle or referral to a different structure when the muscle is stimulated during palpation.[3,187] Understanding the pathophysiology associated with muscle pain is still a challenge for further research. Since treatment cannot yet be designed to address a particular cause, multiple therapies for controlling symptoms and restoring range of movement and jaw function are usually combined in a management plan.[188] The general belief is that these therapies are more effective when used together than when used alone. Given the complex disease character of TMD, the multimodal approaches to treatment currently used for any pain condition may still be the primary form of treatment for TMD even when etiology is better understood.

Most of the research on the natural course of this disorder suggests that for most individuals, symptoms are intermittent and usually do not progress to chronic pain and disability. A comprehensive history and examination should be provided, leading to a differential diagnosis; management of these patients then logically follows. The principles of treatment provided here are based on a generally favorable prognosis and an appreciation that only a small number of clinically controlled trials exist indicating the superiority, predictability, and safety of the respective treatments. The literature suggests that many treatments have some beneficial effect; moreover, the literature suggests that the treatment effect may be nonspecific and not directly related to the particular treatment. Surgery for a chronic muscle pain disorder has no value. The principle of "do no harm" has particular salience for these disorders: aggressive treatments should be avoided, and adaptive biological responses should be supported.

Priority should be given to treatments that have the following characteristics: relatively accessible, acceptable cost, safe, and reversible. Treatments with these characteristics can be divided into two types. The first is based on self-management and includes education and acquisition of self-care skills. The second is based on provision of specialist treatments such as physical therapy, intraoral appliances, pharmacotherapy, and relaxation techniques (Table 10-9). Evidence suggests that combining treatments produces a better outcome.[296] Despite evidence clearly to the contrary, occlusal therapy continues to be recommended by some clinicians as an initial treatment or as a requirement to prevent recurrent symptoms. It bears repeating that research does not support occlusal abnormalities as a significant etiologic factor and the research does not support the use of occlusal treatment (e.g., occlusal adjustment) for TMDs.[297–299] The evaluation of occlusion and correction of occlusal abnormalities are not part of standard treatment for TMDs.

Self-Management

Self-management consists of patient education and a range of skills or activities that are synergistic in their effectiveness. The core activities include self-exercise, use of thermal modalities, avoidance of strain or overuse while chewing or yawning, reestablishing normal chewing patterns, self-massage, and parafunctional behavior control.[300] While the evidence is strong for efficacy of self-management in other diseases (e.g., arthritis),[301] the evidence is weak at present for these approaches for TMDs; yet, the principle of do no harm and the absence of progression of the painful TMDs points to the importance of using these approaches. Because the available evidence has consistently indicated that across pain conditions, psychosocial factors have been better predictors of treatment outcome compared to physical findings, diagnosis, or how much treatment was pursued,[302] treatments better aligned with the implications of psychosocial factors are more justified.

The key principles underlying self-management are as follows:[303–306]

- the activities do not require professional intervention (other than teaching and monitoring) but are entirely self-directed;

Table 10-9 Major treatment components for myofascial pain.

Treatment Component	Description
Self-management	Explanation regarding diagnosis, treatment, prognosis, and patient's and doctor's roles in therapy Information, skills training, and adherence monitoring for patient to be competent with self-exercise, thermal modalities, self-massage, diet and nutrition, bilateral chewing, yawn control, and parafunctional behavior control
Physiotherapy	Education regarding biomechanics of jaw, neck, and head posture and integrated movement patterns Passive modalities (heat and cold therapy, ultrasound, laser, and TENS) for pain Passive stretching and range of motion exercises Posture therapy sufficient to regain a neutral zone General exercise and conditioning program
Intraoral appliances	Cover all the teeth on the arch the appliance is seated on Adjust to achieve simultaneous contact against opposing teeth Adjust to a stable comfortable mandibular posture Does not alter mandibular position Use during sleep and rely on behavioral methods for waking hours
Pharmacotherapy	NSAIDs, acetaminophen, muscle relaxants, antianxiety agents, tricyclic antidepressants
Relaxation techniques & behavioral therapy	Relaxation therapy Hypnosis Biofeedback Cognitive–behavioral therapy

NSAIDs = nonsteroidal anti-inflammatory drugs; TENS = transcutaneous electrical nerve stimulation.

- acquiring skills and implementing them strategically takes time;
- adherence is essential but everyone adopts adherence at their own pace;
- therapeutic effects are cumulative over weeks to months, and adherence despite limited initial therapeutic benefit is often a challenge and benefits from provider assistance;
- symptom flareups are common but do not indicate either progression of a disorder or the need to escalate treatment;
- integration of skills with lifestyle and symptom patterns is the desired endpoint in skills acquisition; and
- control and knowing that one can manage flareups is empowering, and self-management skills acquired for a TMD have heuristic value for further self-development.

Education and Information

A source of great anxiety for patients with complaints of pain and limitation in the jaw is the possibility that their condition is progressive and degenerative and will thereby lead to greater pain and disability in the future. Patients may have sought prior consultations from other physicians and dentists who were not able to establish a diagnosis or explain the nature of the problem. This often leads to fears of a more catastrophic problem, such as a brain tumor or other life-threatening disease. Explaining the nature of pain, its distinction from nociception as an indicator of tissue damage, and the varied nature of the symptoms across time and linked to function and behavior has multiple important effects. Understanding one's disorder is the basis for the self-care activities that patients must perform for immediate symptom control as well as for longer-term rehabilitation and maintenance. Being better informed generally reduces anxiety, and that in turn decreases pain amplification and disability. Successful patient education requires enough time in an unhurried environment for the clinician to provide the necessary information and to allow the patient to express any concerns and ask questions. This interaction is the basis for the therapeutic relationship. Education and information provide the patient with an understanding of the condition and the ability to perform activities and make choices that have a direct effect on the symptoms. The patient has to participate in developing strategies to avoid stresses that aggravate symptoms or interfere with the ability to manage therapy.

Self-exercise Therapies

The most common self-exercise is simple stretching of the masticatory elevator muscles; face validity for this exercise is very high, given the pain accompanying restriction in opening the mouth as perhaps the most frequent symptom of the common TMDs. Muscle stretching, for most patients, should be performed 2–3 times each day; about 10 repetitions, each held for about 5 seconds, seem sufficient. Stretching should be performed within the limits of pain threshold; that is, in a comfort zone; excessive stretching elicits a protective

response which causes simultaneous activation of alpha-motor neurons, undermining the efficacy of the stretching. The mouth-opening and mouth-closing phases of stretching should be monitored in order to ensure that the jaw moves in a straight line at a steady rate. Monitoring is best achieved by the patient using a mirror (as an inexpensive form of biofeedback) and watching the movement of the jaw. An alternative form of this variant on stretching is to maintain the tongue in contact with the palate in order to control mouth-opening in terms of both encouraging primarily rotational movement of the TMJ as well as limiting the overall opening extent; both aspects are sometimes strategically implemented when painful popping is interfering with full stretching. A 3-month period of treatment consisting of education only or education plus a home physical therapy program found that education plus home physical therapy was more effective.[307] Other self-exercises, such as resisted opening, are used for TMD pain, but they tend to be used in a more idiosyncratic manner and any unique therapeutic effects beyond the basic muscle stretch have not been established.

Thermal Modalities

Thermal agents consist of the application of moist heat to the affected areas for 15 to 20 minutes twice daily, as well as ice packs for about 10 minutes.[307] Ice has traditionally been considered to be primarily for acute problems, especially joint injury, but clinical experience has shown that ice seems to be more effective than heat for not all but certainly a larger number of patients with chronic problems than generally thought. Ice is particularly effective when applied to very tender or irritable areas of muscle or joint prior to stretching. When given the opportunity to try each of heat and ice, the patient will discover which works better for them. For some individuals, the use of both (for example, ice first, then heat after stretching; or the reverse) is good. Thermal modalities can be used as often as needed to manage pain.

Self-massage

Manual physical therapy has a long tradition for TMDs, and recent clinical studies support the benefit of soft-tissue manipulation.[308] Similarly, the patient can engage in self-massage; this is particularly true for the masseter muscle, using either cross-fiber technique or stroking the fibers along their length. Patients report nearly as much pain relief from self-massage as they do for thermal modalities.[309] Self-massage may also stimulate large-diameter afferent fibers and thereby facilitate inhibition of nociception at the trigeminal nucleus caudalis.[310] Self-massage also has a real-time educational value: patients can feel muscle tightness and local soreness, helping to integrate body state with perception. Finally, self-massage simply feels good, and that typically has motivational aspects for patients to continue with other self-care methods.

Diet and Nutrition

A common treatment recommendation for TMDs is to eat only softer foods; the rationale is that avoidance of tougher or harder foods will facilitate recovery. Resting a painful body part is a traditional and intuitively understood action, especially for instances of acute tissue damage. However, as clearly shown for bouts of back pain,[311] too much "rest" leads to atrophy and, therefore, via a negative feedback loop emphasized in the pain/fear avoidance model,[231] to further restrictions in activities. Similarly, when extending indefinitely the restriction to only eat soft foods, muscle atrophy and occlusal changes occur, as well as increasing fatigue such as with ordinary speech. Persistent avoidance of normal function decreases the pain threshold and increases the tendency for the patient to believe that trying to function normally will lead to further deterioration of the jaw. In contrast, emphasizing resumption of normal function, such as via usual textured foods, facilitates recovery rather than blocks it.[312] Nutritional needs for those with chronic pain have been largely neglected, though recent attention highlights how little is really understood regarding pain and nutrition.[313–315]

Bilateral Chewing

Unilateral chewing may originate with a missing tooth or a pulpitis; the unilateral chewing pattern tends to persist even after the dental problem is resolved. As part of avoidance behavior, many patients with a TMD will start to chew on only one side, and unilateral chewing is one of the very few local factors associated with TMD.[99] Before resuming a normally textured diet, the patient who chews unilaterally should retrain in order to chew bilaterally; this is best facilitated by judicious use of a mechanical soft diet for perhaps 2 weeks at most, and then gradually resuming more normally textured foods. Hard or brittle food should still be avoided until symptoms substantially improve. Normal chewing restores strength, which balances muscle tone between elevator and depressor muscles, and aids muscle relaxation.

Yawn Control

Yawning is a ballistic movement, leading to rapid translation of the TMJ and rapid stretch of the masticatory elevator muscles; for an individual with a painful TMJ or a myalgia of the masticatory muscles, yawning is painful. Patients instinctively learn to suppress the yawn by co-contraction of the elevator muscles—which opposes the action of the jaw opening muscles under yawn reflex control. The result is that the mandible is torqued during the yawn, and such

suppression is not so effective. A better method of control is to use the lightly formed fist of one hand, applying counter-pressure from beneath the chin. The evidence for controlling yawns in this manner is purely anecdotal.

Parafunctional Behavior Control

Attention to jaw activities that are unrelated to function (such as tooth clenching, jaw-posturing habits, jaw-muscle tensing, and leaning on the jaw) is a critical beginning. Those parafunctional behaviors associated with clinically relevant hyperactivity need to be replaced with restful (neutral) jaw postures, and this should be part of any initial therapy. Parafunctional behavior control is simultaneously the same thing as fully resting or relaxing the jaw, which allows the jaw to assume a neutral position. Parafunction control is helpful in reducing pain in myofascial pain patients.[316] In order to have the skills to appropriately monitor and control their parafunctional behaviors, patients need education, training, support, and reinforcement from their provider.

Implementation of Self-management

Structured provider skills are necessary to strategically implement appropriate escalation of skills, titrate their frequency of use, and evaluate the relative contribution of such behaviors to the aggravation or persistence of symptoms. Table 10-10 illustrates a sample patient instruction sheet.

Clinician Management

Physiotherapy

Appropriate goals of PT are to restore normal muscle tone and resilience, improve joint movement, reduce pain, and improve function. Both passive and active treatments are

Table 10-10 Self-management for TMDs.

Use thermal agents to control pain.
Apply moist heat to the sides of the face and to the temple areas for 10 to 20 min twice daily.
Apply ice packs to targeted areas for 10 mins.
Can alternate ice with heat, and use before and after stretching; discover what works best for you.
Self-massage
Jaw muscles on sides of face can be stretched along their length by pulling the muscles in that direction, or by pulling the fibers to the sides.
Apply gentle massage to the skin overlying the sore areas.
Diet and nutrition
During initial phase of self-management, select foods that do not aggravate your pain or cut your usual foods into smaller pieces. Avoid foods that require wide opening of the mouth or considerable force with the front teeth. Maintain this for about 2 weeks, then gradually resume more normal food textures.
As possible, chew food on both sides of the mouth, alternating sides or splitting food into two parts, one part for each side.
Avoid chewing gum, and the most difficult to chew foods such as hard nuts, tough foods.
Avoid certain postures or movements.
During yawning, support the jaw by providing mild counter-pressure underneath the chin with the thumb and index finger or with the back of the hand.
Avoid the following: lean on or cup the chin when performing desk work or at the dining table; testing the jaw by opening wide or moving the jaw around excessively to assess pain or motion; maneuvering the jaw into positions to assess its comfort or range; habitually clicking the jaw if a click is present.
Do not sleep on the stomach or in postures that place stress on the jaw.
Avoid elective dental treatment while symptoms of pain and limited opening are present.
Be aware of and control oral parafunctional behaviors.
Teeth should only contact during chewing and swallowing.
Monitor jaw at regular intervals through the day for any clenching, grinding, touching, or tapping of teeth or any tensing or rigid holding of the jaw muscles.
Monitor jaw for parafunctional behaviors during specific situations such as while driving, studying, using computer, reading, engaging in athletic activities, when at work, or in social situations, and when experiencing overwork, fatigue, or stress.
Practice neutral jaw posture: Place the tip of the tongue (optimally) behind the top teeth (by saying "N" and retaining the tip of the tongue in that location) or in the floor of the mouth (if the patient cannot manage the tongue in the superior position), separate the teeth slightly, and allow the jaw to "hang" in this position; maintain this position when the jaw is not being used for functions such as speaking and chewing.

commonly included as part of therapy. Although randomized trials necessary to confirm the effectiveness of physiotherapy are generally lacking, the clinical literature suggests that physiotherapy is a reasonable and effective therapy.[308,317] Evidence supporting one type of physical therapy in favor of another has not been demonstrated.[318] Posture therapy has been recommended to avoid forward head positions that are thought to adversely affect mandibular posture and masticatory muscle activity; research evidence, however, suggests that forward head posture, by itself, is not strongly associated with having TMD.[251] This leads to a conundrum in how to best use evidence to guide treatment: clinical practice of physical therapy, when done in a manner that reliably helps symptoms, typically includes many elements, most of which either have not been adequately researched or, as in the case of forward head posture, have disconfirming data. Explanatory models for how physical therapy works are plentiful but critical data are absent; this situation, however, is rapidly changing and better quality evidence will begin to emerge.

Passive modalities such as ultrasound, cold laser, and transcutaneous electrical nerve stimulation (TENS) are typically used initially to reduce pain. Passive modalities are often used as a prelude to active treatments of joint mobilization and soft tissue stretching in order to reduce discomfort associated with the active treatments. Ultrasound relies on high-frequency oscillations that are produced and converted to heat as they are transmitted through tissue; it is a method of producing deep heat more effectively than the patient could achieve by using surface warming. Ultrasound is generally regarded as effective; however, whether it is effective alone is questionable.[319] Cold laser is heavily promoted for its role in effecting cellular metabolism,[320] and it appears to be effective for at least some types of pain;[321,322] its use in chronic pain has, so far, not been supported by strong evidence.[323] TENS uses a low-voltage biphasic current of varied frequency and is designed for sensory counterstimulation for the control of pain. It is thought to increase the action of the modulation that occurs in pain processing at the dorsal horn of the spinal cord and (in the case of the face) the trigeminal subnucleus caudalis of the brainstem. The general principle in the use of TENS is to consider it for therapeutic trial, recognizing that long-term efficacy is highly idiosyncratic. Physical therapists will commonly add more jaw exercises such as active stretching to increase the range of jaw motion, and isotonic and isometric exercises to facilitate strength and coordinated movement. Providing too many exercises too quickly can lead to poor compliance; the addition of exercises to the self-management program should be titrated based on performance and adherence.

Some physiotherapists apply mobilization techniques to increase mandibular motion. These are done passively under the control of the physiotherapist and will usually include distraction and some combination of lateral and protrusive gliding movements. The choice and timing of treatment are individual considerations since the literature is not developed enough to provide specific guidelines.

In addition to the benefits of the therapeutic relationship between the dentist and patient, a physiotherapist trained in managing temporomandibular disorders is likely to interact with the patient regularly for review and coaching regarding physical self-management, education regarding the disorder, and further provision of physical therapy. A physiotherapist can reinforce management from a biopsychosocial approach contributing to a successful treatment outcome.

Intraoral Appliances

Intraoral appliances (variously termed splints, orthotics, orthopedic appliances, bite guards, nightguards, or bruxing guards) are used in TMD treatment. When carefully used, an intraoral appliance is considered to be a reversible form of therapy; however, appliances also have adverse effects as well. A number of studies on splint therapy have demonstrated a treatment effect, although researchers disagree as to the reason for the effect.[282,296,324,325] In an early review of the literature on splint therapy, Clark found that patients reported a 70–90% improvement with splint therapy.[326] Qualitative, quantitative, and systematic reviews have carefully considered the question of appliance treatment, concluding in general that the use of appliances in TMD treatment is beneficial, though whether better than a placebo appliance remains an open question; available high-quality evidence as well as a plausible mechanism of action is still lacking.[90,198,295,327–330] Notably, oral appliances appear to be more effective when TMD is the sole pain disorder; when fibromyalgia, for example, is comorbid with a painful TMD, the efficacy of the oral appliance diminishes considerably.[331]

A decrease in masticatory muscle activity has been associated with splint therapy and might be the reason for the effects of splint therapy.[107] Alternatively, a nonspecific treatment effect has been proposed.[332] Other explanations for the effects of splint therapy include occlusal disengagement, altered vertical dimension, realigned maxillomandibular relationship, mandibular condyle repositioning, and cognitive awareness of mandibular posturing and habits.[333] The nature of treatment effects of appliance therapy will require further research. For the present, however, intraoral appliance therapy is considered to be a reversible treatment. When to include an intraoral appliance differs considerably across practice settings; some practices start treatment with an appliance, while more behaviorally-oriented practices will include an appliance only after specific goals have been met with regard to self-care and behavioral treatments. Early

use of an appliance can facilitate treatment response,[334] but early use can also diminish the value and adherence to the other self-care treatments. Excessive reliance on appliances typically leads to poor treatment outcomes of TMD.

The choice of material for the construction of an appliance remains one of individual preference. In comparing hard versus soft material appliances, a 3-month trial found no difference in outcome when either the hard or the soft appliance was used,[335] and a 12-month trial had the same findings.[336] In contrast to the equivocal study results, a survey of dentists and dental specialists reported that a flat-plane splint made of hard acrylic was used more frequently than any other design or material.[337] Reasons for this preference of hard appliance include adherence to occlusion models and the belief that appliances should replicate an occlusal scheme, belief that dental proprioception facilitated by the hard appliance is beneficial to muscle retraining, greater longevity, and reports by patients that soft appliances often feel bulky or provoke clenching that was not previously present.

The most common purposes advocated for appliance therapy are to provide joint stabilization, protect the teeth, redistribute forces, relax elevator muscles, and decrease or control the effects of bruxism.[333] The appliance most commonly used for these purposes is described as a stabilization appliance or muscle relaxation splint (Figure 10-15). Such appliances are designed to cover a full arch and are adjusted to avoid altering jaw position or placing orthodontic forces on the teeth. Long-term continuous wearing of an occlusal appliance is a risk for a permanent change in the occlusion.[338] This is a greater concern with appliances that provide only partial coverage or that occlude only on selected opposing teeth.[339] Not because of occlusal theory related to TMD, but rather because appliance treatment should not cause teeth to move, the appliance should be adjusted to provide bilateral even contact with the opposing teeth on closure and in a comfortable mandibular posture. Anterior guidance during excursive movements is often preferred and can be achieved with an appropriate acrylic contour; however, anterior guidance patterns do not improve appliance efficacy.[340]

During the period of treatment as symptoms improve, the appliance should be re-examined periodically and readjusted as necessary to accommodate changes in mandibular posture or muscle function that may affect the opposing tooth contacts on the appliance. At the beginning of appliance therapy, a combination of appliance use during sleep and for periods during the waking hours is used by some providers; however, better behavioral management during the waking hours should preclude the need to rely on an appliance except during sleep. Each patient has his or her own needs and characteristics, and these should be monitored to determine the most effective schedule for appliance use. Factors such as tooth clenching when driving or exercising may be managed by increasing splint use during these times, or perhaps such symptom-related events serve as a gateway for referral for stress management. Pain symptoms that tend to increase as the day progresses generally indicate pervasive parafunctional behaviors; the appliance can be used at various times during the day in response to such pain patterns, or behavioral management can be emphasized. Overall, to avoid the possibility of occlusal change, the appliance should certainly not be worn continuously (i.e., 24 hours per day) over prolonged periods, which suggests that behavioral management must remain the primary method for waking parafunction. Full-coverage appliance therapy during sleep is a common practice to reduce the effects of bruxing and is not usually associated with occlusal change. In addition, appliances seem to retain more efficacy if used for shorter periods (e.g., only during sleep) by relying upon behavioral methods for parafunction management during the waking hours.

Figure 10-15 Maxillary acrylic full-coverage stabilization splint.

The choice of inserting a stabilizing appliance on the upper or lower arch is a clinical judgment related to how the appliance is to be used and the clinical findings regarding the dentition. Placing the appliance on the arch with missing teeth allows for an increase in occlusal contact position. For patients who are likely to benefit from daytime wear, a lower appliance is usually less visible and does not interfere with speech as much as an upper appliance. When an appliance is to be used only at night, most clinicians choose the upper arch, but this choice seems to be more a function of tradition. There is no evidence that indicates one arch is the better home for an appliance in the treatment of a TMD.

Splints that reposition the mandible anteriorly have been used effectively in treating disc displacements,[341] but they increase the risk of permanently altering the occlusion and should be used with caution if at all.[342] These splints have been made for the upper or lower arch, although the maxillary appliance is better able to maintain a forward mandibular posture by using a ramp extending from the anterior segment that guides the mandible forward during closure. These appliances were used with greater frequency in the past to putatively correct disc position as a step toward more permanently altering mandibular position through permanent changes in the occlusion. This approach was associated with great technical difficulties, and the treatment failed to correct disc displacement in a significant percentage of patients. Evidence supporting the need for such treatment remains lacking. In contrast, repositioning appliances used intermittently for short periods can be useful in controlling symptoms arising from the mechanical instability associated with a problematic disc displacement, such as transient episodes of jaw locking due to disc displacement and accompanied by pain and dysfunction.

In summary, a stabilizing oral appliance that fully covers one arch and does not reposition the mandible or alter the occlusion has been considered a standard part of therapy of TMD. Continuous appliance wear, appliances that only provide partial coverage, and appliances that reposition the mandible and alter the occlusion have a greater chance of adverse effects. The relative importance of an oral appliance for treating a TMD is increasingly questioned in light of the advantages of a purely self-management treatment approach.

Pharmacotherapy

Mild analgesics, nonsteroidal anti-inflammatory analgesic drugs (NSAIDs), antianxiety agents, tricyclic antidepressants, and muscle relaxants are used for treatment of TMD pain. The use of any of these agents, along with the other components of initial therapy, may contribute to improved and more rapid symptom control.[343] The use of medications for TMD management should follow the general principles of analgesic therapy and be used on a fixed dose schedule according to time rather than as needed for pain. Drug therapy requires a thoughtful assessment of the potential risks relative to the benefits, including the clinician's own professional ability and confidence in using the particular drug or drugs. Because of the adverse effects of all of these drugs, short-term or intermittent use is preferred, but a smaller percentage of patients who evolve into a chronic musculoskeletal pain disorder are usually taking combinations of medications long term. The use of multiple drugs and their management as a part of a complex chronic pain disorder is beyond the scope of this chapter. Medication management of pain, particularly chronic pain, is a continually evolving area within the dental profession.

NSAIDs are probably the most commonly prescribed medication for pain control in TMD therapy. The promise of the COX-2 inhibitors (e.g., rofecoxib) as safer alternatives to other NSAIDs has proven unfulfilled due to the association of cardiovascular incidents. There is modest evidence for efficacy of NSAIDs in TMD therapy.[294] For example, ibuprofen 2400 mg daily for 4 weeks did not demonstrate a clear analgesic effect due to the drug,[344] whereas naproxen 500 mg twice daily in a 6-week trial was more effective than placebo or celecoxib.[345] The outcomes of such studies are seldom fully replicated; consequently, successive trials of several systemic NSAIDs in order to identify which one works best for a given patient is a reasonable part of initial therapy. NSAIDs for most TMDs should be short term to supplement the other nondrug therapies that should reduce the need for long-term NSAID therapy. A mild analgesic such as acetaminophen might be a first choice for analgesic drug treatment since it is much less likely to cause adverse side effects when taken in the appropriate dose for short periods; this is particularly so when the pain is regarded as nociceptive rather than inflammatory.[169] A combination of ibuprofen and acetaminophen is commonly regarded as more effective than either medication alone for certain pains—perhaps reflective of a combination of both nociceptive and inflammatory mechanisms—but the data are inconclusive.[346,347]

Topical NSAIDs have demonstrated significant pain-reducing effects in acute and chronic musculoskeletal injuries. NSAIDs can be incorporated in transdermal creams for application on the skin over the painful joint or muscle. Ketoprofen, felbinac, ibuprofen, diclofenac, and piroxicam have significant efficacy. This efficacy holds true for chronic conditions such as arthritis. The incidence of local and systemic adverse events is low and no different from placebo.[348] Capsaicin cream, originally found to be of value in treating postherpetic neuralgia, is a substance-p depleter, a neurotransmitter responsible for increased nerve sensitization. Capsaicin has not been studied for TMD therapy but it has

been recommended as a topical analgesic (0.025% and 0.075%) when applied to the skin over a sore joint or muscle four times daily for at least 2 weeks. Capsaicin therapy is limited due to its burning quality on application, which frequently causes the patient to abandon treatment; careful titration to tolerance of the capsaicin concentration can improve adherence.

Whereas the long-acting benzodiazepine clonazepam was effective in a pilot study of TMD treatment,[349] 10 mg cyclobenzaprine, a muscle relaxant, taken at bedtime was found to be superior to clonazepam at managing jaw pain on awakening.[350] Muscle relaxants are a class of drugs that act in the central nervous system, inhibiting interneurons and depressing motor activity. These medications are used before sleep due to their sedative effects. Some patients taking 10 mg of cyclobenzaprine at bedtime experience continued sedation into the day, but they are able to tolerate a lower dose by splitting the tablet into two or four sections and taking less than the full pill. The sedative effects of cyclobenzaprine may contribute to their efficacy and, in addition, be of value in promoting sleep, which is often also compromised in individuals with pain. Sleep disorders may also require the use of hypnotics or other drug combinations to increase restorative sleep, but behavioral approaches for improving sleep should be considered the primary therapy due to better efficacy.[351–353]

Tricyclic antidepressants, particularly amitriptyline, have proven to be effective in managing chronic orofacial pain. Amitriptyline is analgesic at low doses, has sedative effects, and promotes restful sleep; all of these effects can be helpful in treatment. It is the anticholinergic effects of the drug (dry mouth, weight gain, sedation, and dysphoria) that often make it intolerable. An effective dose can be as low as 10 mg at night but can be increased gradually to 75 to 100 mg, depending on the patient's tolerance of the side effects. Two clinical studies demonstrated a positive treatment effect using low-dose amitriptyline for TMD treatment.[354,355] Depression commonly accompanies chronic pain; referral for depression-relevant dosages of antidepressant medications should be considered.

Opioids were previously considered appropriate for complex chronic pain disorders or briefly for acute injuries to the TMJs or muscles where moderate to severe pain is present. The use of opioids for chronic pain has always been a controversial issue, driven by differing views of pain and suffering as well as owing to the unfortunate practice by some patients of medication diversion. Due to serious adverse events associated with the use of opioid medication for nonmalignant pain, opioid use for chronic pain is now considered inappropriate. A related issue is pseudo-addiction, which is the reliance on adequate dosages of medication (often opioid, but it could be any type) to control a symptom but which is then viewed as "addiction." Knowing one's patient is essential, but careful prescribing is also essential.

Relaxation Techniques and Behavioral Therapy

Integrating relaxation techniques and behavioral therapy in chronic pain management is effective.[356] In some cases, self-management skills, including awareness and attempted control of parafunctional behaviors, may not be sufficient to change behavioral patterns that are contributing to symptoms. A more structured program supervised by a clinician who is competent in behavioral therapy offers a greater chance of addressing issues that are contributing factors. There is general agreement in the literature that behavioral and educational therapies are effective in the management of chronic pain disorders, although the existing research is not sufficient to conclude that any one technique is superior. Relaxation techniques, biofeedback, hypnosis, and CBT have all been used to reduce symptoms in patients with TMD.[357] The mechanism of action of these techniques is likely complex.

Relaxation techniques generally decrease sympathetic activity and (possibly) arousal. Methods include autogenic training, meditation, and progressive muscle relaxation.[356] These techniques are aimed at producing comforting body sensations, calming the mind, and reducing muscle tone. Brief methods for relaxation use self-controlled relaxation, paced breathing, and deep breathing. Hypnosis produces a state of selective or diffuse focus in order to induce relaxation. The technique includes pre- and post-suggestion and is used to introduce specific goals. Individuals vary greatly in their susceptibility to hypnosis and suggestion. Hypnosis does not affect endorphin production, and its effect on catecholamine production is not known.

CBT, which often includes relaxation techniques, is primarily focused on changing patterns of negative thoughts. Hypnosis and CBT have been hypothesized to block pain from entering consciousness by activating the frontal limbic attention system to inhibit pain impulse transmission from the thalamic to the cortical structures.[356] Functional imaging data clearly demonstrate that CNS activity quickly changes in response to changes in thought patterns. A six-session CBT intervention enhanced the treatment effect of usual TMD treatment.[358]

Biofeedback is a treatment method that provides continuous feedback, usually by monitoring the electrical activity of muscle with surface electrodes or by monitoring peripheral temperature. The monitoring instruments provide patients with physiologic information that allows them to reliably change physiologic functions in order to produce a targeted system response similar to that produced by relaxation therapies. The patient develops strategies that are aimed at either lowering the electrical activity of the muscle or raising

peripheral temperature, respectively. Repetitive practice using the biofeedback instrumentation provides the training for the patient to develop better motor control and more accurate proprioception of the targeted muscle(s), with the goal of ultimately achieving a more relaxed state in the targeted muscle(s); central to the success of biofeedback, in terms of generalizing treatment effects from the clinic to the environment, is developing a greater sensitivity to the environmental stimuli that have adverse effects on the individual. A primary limitation to biofeedback treatment is the cost associated with the number of supervised treatment sessions; instrumentation for home use has become much more available, which can help reduce clinician costs and enhance generalized training. However, such instrumentation for home use is primarily oriented towards a general relaxation response rather than muscle activity.

Barriers to integrating behavioral and relaxation therapy exist in standard medical and dental care. The biomedical model of disease is emphasized in medical and dental education. The biomedical model emphasizes the anatomic and pathophysiologic aspects of disease and does not emphasize psychosocial issues, the importance of the patient's experience of disease, or the fundamental importance of self-regulation. In addition, behavioral therapies can be time-intensive and may also not be supported by insurance companies; moreover, clinicians trained for behavioral management of pain can be difficult to identify for referral. Consequently, this is yet one more reason why there is increased emphasis on self-management approaches.

For the patient who does not respond to initial treatment and who continues to have significant pain and disability, additional therapies beyond those described above are usually required. These patients are characterized more as having a chronic pain disorder than as having an anatomic abnormality that is unique to the masticatory system. Treatments used in the management of chronic pain are indicated for this group. A greater focus on behavioral therapies and coping strategies may provide additional benefits. Multidisciplinary pain clinic management may be required. The use of chronic pain medications, including the drugs described as adjuvant analgesics (tricyclic antidepressants, anticonvulsants, membrane stabilizers, and sympatholytics), may be part of a long-term management plan. Chronic pain disorders cause psychosocial changes that require comprehensive management in order to reduce the associated disability.

Trigger Point Therapy

Trigger point therapy has traditionally used two modalities: cooling of skin over the involved muscle followed by stretching, and direct injection of local anesthetic into the muscle. More recently, botulinum toxin injections are being used for trigger points.

"Spray and stretch" therapy is performed by cooling the skin with a refrigerant spray (e.g., fluoromethane) and stretching the involved muscle. Cooling allows for stretching without pain that causes a reactive contraction or strain. Travell and Simons described this technique in detail, introducing the method for the treatment of myofascial pain.[239] Patients who respond to this therapy can use a variation at home by first warming the muscle, then briefly icing it, and then gently stretching the jaw passively. Anecdotal evidence suggests that simply icing the muscle, without preceding heat, and then stretching, can also be effective.

Intramuscular trigger point injections have been performed by injecting local anesthetic, saline, or sterile water or by dry needling without depositing a drug or solution. The choice of solution for injection exists because of the lack of established benefits of any one method.[359] Injection of sterile water was associated with greater injection pain than was injection of saline.[360] In a study in which patients with myofascial pain were treated with injection of lidocaine or with dry needling, both groups reported decreased pain immediately after injection, but the group that received dry needling experienced greater soreness 48 hours after the procedure.[361] Procaine diluted to 0.5% with saline has been classically recommended because of its low toxicity to the muscle,[362] but 1% lidocaine is an alternative.

There are no tested protocols for trigger point injection therapy. A set of three to five weekly sessions has been recommended, and this may be continued with modification of the intervals between injections, depending on the response.[363] Injections can be given to a muscle group in a series of five weekly or biweekly treatments. If there is no response to the initial series of injections, the classic recommendation was that trigger-point injection treatment should be abandoned. Hopwood and Abram analyzed treatment outcomes for 193 patients who received trigger point injection therapy for myofascial pain.[364] They found that: (1) unemployment due to pain increased the odds of treatment failure threefold; (2) a longer duration of pain and greater change in social activity increased the risk of failure twofold; and (3) constant pain (versus intermittent pain) increased the likelihood of treatment failure by 80%. These results emphasize that chronic pain is a multidimensional and complex problem and that a variety of factors will influence treatment outcome.

Nevertheless, treatment failure from traditional injection therapy is now followed by, or is often substituted at the beginning by, use of botulinum toxin injections. Botulinum toxin has been advocated for the treatment of TMDs,[365] but randomized clinical trials question the true efficacy of this treatment for pain beyond that of decreasing muscle tone.[366–368] Moreover, botulinum toxin is not necessarily more effective than the traditional injection approaches for myofascial pain.[369,370] As Travell and Simons established decades ago,

behavioral factors promoting the persistence of chronic myofascial pain must be the primary focus of treatment, for which augmentation by injection therapies can be additionally helpful.[239] Most treatment studies of myofascial pain utilizing injection therapies tend to be standalone injection therapy, and consequently the value of comprehensive treatment remains largely untested.

Other TMD Treatments

The above sections highlight only the most common treatment methods and have not addressed many treatments that have been recommended for the management of TMDs. Acupuncture has been shown to be an effective part of the management of chronic pain. Acupressure, different forms of injection therapy using natural substances, massage therapy, naturopathic and homeopathic remedies, and herbal remedies are just a few of the treatments patients may pursue.[371] The Internet has produced treatment programs that allow patients to evaluate their problem to determine whether the advertised treatment will be of benefit. There is a critical need (which will increase in the future) for dentists to help patients evaluate the treatments and products that are promoted for TMD therapy. Many of these treatments lack publication in the scientific literature that is even descriptive. The large variety of treatments promoted, coupled with the lack of clarity in the scientific research about cause, makes the need to establish a trusting doctor–patient relationship critical.

Restorative Dental Procedures in Individuals with TMDs

Patients who require elective dental treatment should defer such procedures until the TMD symptoms have resolved or are under reasonable control. Patients who develop active dental disease requiring treatment while they report active and problematic TMD pain or mechanical TMJ problem are likely to have increased pain and dysfunction after dental procedures. The dentist should attempt to minimize the effect of a procedure on myalgia or joint strain by using a variety of procedures, as outlined in Table 10-11. One clinically proven method of minimizing symptom aggravation from dental treatment visits is the use of a mechanical support device for the mandible; both pain and fatigue are reduced, and focus groups report that its use by the dentist also minimizes jaw over-extension during dental procedures.[372]

Table 10-11 Managing TMD patients requiring dental procedures.

Prior to the procedure
Use hot compresses to masseter and temporalis areas 10 to 20 minutes two to three times daily for 2 days.
Use a minor tranquilizer or skeletal muscle relaxant (e.g., lorazepam, 1 mg; cyclobenzaprine, 10 mg) on the night and day of the procedure (patient must be accompanied by an adult).
Start a nonsteroidal anti-inflammatory analgesic the day of the procedure.
During the procedure
Use a child-sized surgical rubber mouth prop to support the patient's comfortable opening; remove periodically to reduce joint stiffness. Alternatively, an extraoral device that supports the jaw can be used.
Consider intravenous sedation and/or inhalation analgesia.
Provide frequent rest periods to avoid prolonged opening.
Apply moist heat to masticatory muscles during rest breaks.
Gently massage masticatory muscles during rest breaks.
Perform the procedure in the morning, when reserve is likely to be greatest.
After the procedure
Extend the use of muscle relaxant and NSAID medication as necessary.
Apply cold compresses to the TMJ and muscle areas during the 24 hours after the procedure.

NSAID = nonsteroidal anti-inflammatory drug; TMJ = temporomandibular joint.

Articular Disc Disorders

Description

The TMJ, like other joints, is susceptible to internal derangements of the intracapsular soft tissue. The most common form of internal derangements affecting the TMJ is the disc displacement, an abnormal relationship between disc, condyle, and eminence. Among disc displacements, the evidence is largely limited to those that are oriented in the sagittal plane, and, consequently, the classification of disc displacements reflects the sagittal plane orientation. The most common and by far best studied is the anterior disc displacement (ADD). In an ADD, some part of the disc is displaced anteriorly relative to the normal position on the condyle as described previously. The extent of disc displacement in the closed position of the condyle ranges from minor, such as an elongation of the disc with the anterior band no longer in contact with the condyle in the fully closed position, to complete, where the posterior band is anterior to the condyle. During the opening phase, the disc may return to its normal position, defined as the anterior band and intermediate zone being in the expected functional position on the anterior–superior aspect of the condyle. If the disc returns, the problem is classified as anterior disc displacement with reduction (ADDwR). During the opening phase, the disc may not return to its normal position, and the problem is classified as anterior disc displacement without reduction (ADDwoR). Reduction is an orthopedic term, referring to a return to normal anatomical confirmation. "Locking" of the jaw joint is a commonly used colloquial term indicating a state of nonreduction, and locking can occur acutely with

disc displacements (the acute ADDwoR) and with wide opening of the mandible (subluxation or dislocation).

ADD, during normal jaw opening, may result in abnormal joint sounds, limitation and deviation of mandibular motion, and pain. The majority of individuals with an ADD, with or without reduction and whether in one or both TMJs, have no pain or limitation in functioning; MR studies have demonstrated that ADD is present in 25 to 35% of the normal asymptomatic adult population.[373,374] This is comparable to the finding of asymptomatic clinically insignificant internal derangements that are well documented in the knee and spine.[375,376] Although clinical signs of internal derangement are seen in children,[377] some have reported that ADD of the TMJ does not appear to affect children below the age of 5 years in significant numbers.[378]

A specific etiology in the majority of cases of disc displacement is poorly understood. Some cases result from direct trauma to the joint, such as from a blow to the mandible. With respect to trauma, the particular events and presumed pathophysiology that may result in ADD are often unknown. Clinicians have theorized that indirect trauma from cervical flexion extension injuries (whiplash associated disorders: WAD) may predispose an individual to disc displacement. There is some support that WAD can affect the jaw in adverse ways,[379] but the evidence is weak based on insufficient study designs for assessing causation. It is generally believed that chronic low-grade microtrauma resulting from long-term bruxism or clenching of the teeth or certain types of malocclusion could be a cause of ADD. Arthroscopic examination of the TMJ has demonstrated an association between oral parafunction broadly and intracapsular disorders,[380] but this evidence is insufficient to support direct causation. There is evidence that a generalized laxity of joints is associated with ADD;[381] this is of particular concern for major connective tissue disorders such as Ehlers–Danlos syndrome, but the evidence is presently only anecdotal. Alternations in craniofacial morphology, such as those with an increase in middle anterior facial height and a decrease in the posterior cranial base vertical height, may also play a role in ADD.[382]

The angle or steepness of the mandibular fossa has been considered a contributing factor in the development or aggravation of intracapsular disorders. However, the steep, vertical form of the fossa has been inconsistently associated with disc displacements across studies. Osseous changes appear to occur in response to the disc displacement suggesting that the steepness of the eminence may be a consequence of disc displacement rather than a cause.[383] Differing levels of muscle activity across individuals, as one possible contributing variable, for example, may explain disparate findings regarding the role of the eminence angle on disc position.[384] Collectively, these varied findings regarding joint function and disc displacements highlight the uncertain roles of disc attachment, fossa morphology, bony adaptation, muscle function, and their potentially complex interaction.

One of the most common disc displacements is classically described as anterior and medial to the condyle.[385] The attachment of the superior head of the lateral pterygoid muscle to the TMJ capsule and the direction of pull by that muscle aligns with this classic description of the ADD. Consequently, dysfunction of the lateral pterygoid muscle mediated via its attachment to the capsule is theorized to cause disc displacements. More specifically, the theory suggests that differential hyperactivity of the superior head of the lateral pterygoid is capable of pulling the disc forward from its normal position over the mandibular condyle.[386] While the muscle fibers that do insert into the disc are located primarily at the medial portion, not all such fibers insert directly into the disc but rather only insert into the capsule.[30] Moreover, research on cadaver specimens has indicated that muscle fibers inserting into the disc or the condyle are not adequately differentiated into inferior and superior heads.[30,387] Carpentier and colleagues postulated that the two heads did not have distinct independent actions and concluded that the lateral pterygoid was not likely a significant cause of disc displacement.[30] The inferior lamina of the posterior attachment is considered to be the primary restraint preventing the disc from moving forward. Injury to this ligament has been proposed as the cause of disc displacements,[388] based on evidence in a cadaver model that suggested a superficial injury to the inferior section of the posterior attachment resulted in ADD.

The anterior disc displacement may reflect a shift in location purely in the sagittal plane, or it may, as stated previously, also include some medial aspect (antero–medial displacement) such that the disc is rotated medially as well as well as displaced. Displacements of the disc may also be antero–lateral. Displacements may also occur solely within the coronal plane, such that the intermediate zone of the disc is either medial or lateral to the anatomically normal position, but these are not well-described in the literature.[389] Finally, posterior disc displacement (when a portion of the disc is found posterior to the top of the condyle) is rare but has been reported in the literature.[390]

Based on available evidence and considering the many intersecting proposed mechanisms for articular disc disorders, it is less likely that any particular event causes an internal derangement, and, consistent with TMD as a complex disease, it is more likely that a combination of mechanisms related to the anatomy of the joint and the facial skeleton, connective tissue composition, generalized joint laxity, acute or chronic trauma, and chronic loading of the joint increases the susceptibility of certain individuals to a disturbance of the restraining ligaments and displacement of the disc.

Clinical Manifestations

Disc displacement is divided into stages based on signs and symptoms combined with the results of diagnostic imaging. A variety of staging systems have been proposed (e.g., Wilkes criteria),[391] but a sufficient and simple classification system divides ADD into: (1) anterior disc displacement with reduction (clicking joint); (2) anterior disc displacement with intermittent locking; and (3) anterior disc displacement without reduction (closed lock).[392]

Anterior Disc Displacement with Reduction (ADDwR)

Some part of the articular disc has been displaced anteriorly from its position on top of the condyle due to some combination of elongation of the restraining ligaments, alteration in the form or shape of the disc, or thinning of the posterior band presumably allowing the disc to migrate anteriorly over time. A reducing disc displacement ADDwR is common in the general population, and a clicking or popping joint is of little clinical significance unless it is accompanied by pain, loss of function, and/or intermittent locking. An individual may seek professional advice regarding treatment of an audible click that is not accompanied by pain but that may be socially embarrassing.[209]

Palpation or auscultation of the TMJ may reveal a clicking or popping sound during either opening and closing mandibular movements; if a sound occurs during both opening and closing, it is called a reciprocal click. Any clicking or popping sound due to ADDwR may occur during opening, closing, lateral movements, protrusive movement, or any combination of these movements. The clicking sound of an ADD occurs due to relative movement of the disc while the condyle translates. Clinicians examining patients with ADD may observe a deflection of the mandible early in the opening cycle prior to the click with correction to the midline after the click, but this is a variable finding and deflection due to muscle guarding must be distinguished. Diagnostic sensitivity and specificity of clinical tests for ADD are fair to poor, because joints without ADD may click and joints with ADD may not click. Pain from palpation of the TMJ may be present when ADD is accompanied by capsulitis or synovitis, as seen in some patients, yet the reason the majority of patients with ADD remain asymptomatic across the lifespan is not completely understood.[393,394] The implication for caution regarding necessity of any treatment for this condition is self-evident: an ADD should be left alone in the absence of clear symptoms localized to the joint.

Anterior Disc Displacement with Reduction, with Intermittent Locking

An ADD may be stable over time, or it may, either occasionally or progressively, shift into an intermittent lock, lasting seconds to minutes and which resolves on its own. This limited mandibular opening occurs due to disc interference with the normal translation of the condyle. Specific behaviors, such as opening the mouth during mastication, yawning, or certain speech movements or nonverbal expression, may suddenly result in the inability to fully open the mouth (i.e., fully translate the affected condyle). The sudden restriction may or may not be accompanied by pain. The resolution of the locking episode may occur spontaneously or may occur as a result of the individual moving the mandible in such a manner as to overcome the locking disc.

Anterior Disc Displacement without Reduction (ADDwoR; also termed Closed Lock)

ADD without reduction is often referred to as a (persistent) closed lock and occurs in three variants: acute closed lock that is persistent (i.e., does not resolve in the absence of treatment); chronic closed lock as the extension of an acute lock over time and characterized by continued limitation in jaw range of motion; and the chronic closed lock that exhibits some or complete resolution of the limitation in range of motion. A patient with an acute closed lock will often have a history of a long-standing TMJ click; that click may have also previously occurred with intermittent locking, or that click may have never previously been associated with an intermittent lock but rather abruptly disappeared followed by a sudden initial restriction in mandibular opening. The first-time occurrence of a persistent acute closed lock is typically accompanied by pain localized to the joint and exacerbated during mandibular opening (especially at maximum opening), limited lateral movement to the side contralateral to the affected joint, and deviation of the mandible to the affected side during maximum mouth opening. Collectively, these findings point to the condyle on the affected side which does not translate normally. In addition, the affected condyle will not be as palpable on examination. In chronic closed lock, the symptoms associated with the acute stage typically remit but opening is initially restricted to about the same extent, and over time the disc will deform and maximum mouth opening will gradually improve. The displacement of the disc exposes the posterior attachment to compression by the condyle. The posterior attachment has been shown to react to the change by depositing hyaline in the connective tissue[395] and has been called a "pseudomeniscus" or "pseudodisc."[396,397]

An important caveat to an acute closed lock that is associated with disc displacement without reduction was proposed by Nitzan and Etsion.[398] They suggested that adhesion of the disc in the fossa might cause acute closed lock,[398] which can occur with both normal discs as well as displaced discs. Adhesion occurs when hyaluronic acid and associated phospholipids are degraded. Support for this hypothesis is the immediate and generally stable improvement of

mouth opening after arthrocentesis,[398] a procedure in which saline is injected into the inferior and superior joint spaces in order to temporarily expand the spaces and break any adhesions. In fact, this procedure can probably be an effective treatment for a significant number of patients, but the specific clinical characteristics of those for whom it would be effective remain poorly defined. The phenomenon of adhesions between disc and adjacent bone may have a greater role beyond the acute closed lock, as based on the variability of how the fundamental "types" of disc displacements actually present in patient histories, but this has not been systematically studied. The clinician, however, should consider that while anterior disc displacements are commonly classified as with versus without reduction, a spectrum may be more likely.

Posterior Disc Displacement

Posterior disc displacement has been described as the condyle slipping over the anterior rim of the disc during opening, with the disc being caught and brought backward in an abnormal relationship to the condyle when the mouth is closed. The disc is folded in the dorsal part of the joint space, preventing full mouth closure.[399] The clinical features are: (1) a sudden inability to bring the upper and lower teeth together in maximal occlusion; (2) pain in the affected joint when trying to bring the teeth firmly together; (3) displacement anteriorly of the mandible on the affected side; (4) restricted lateral movement to the affected side; and (5) no restriction of mouth opening.[399]

Coronal Disc Displacement

There is little information regarding coronal plane disc displacements other than as part of an anterior disc displacement (e.g., rotated disc). The little information available suggests that coronal displacements are not associated with any identified characteristics, such as pain complaint, palpation pain, or limitation in mandibular movement. Consequently, coronal plane displacements may have little to no clinical relevance.[389]

Subluxation Associated Disc Displacement

Another type of intracapsular disorder involving the disc occurs when the condyle moves beyond its normal maximal boundary in the open jaw position (subluxation or dislocation of the condyle). Subluxation/dislocation of the condyle often coexists with a disc displacement. The form and steepness of the fossa has been considered a contributing factor in the frequent coexistence of subluxation with disc displacement and highlights the dynamic functional character of the intracapsular disorders. In contrast, Bell[400] pointed to the intrinsic role of muscle tone; he suggested that subluxation (or dislocation) occurs due to a combination of fossa steepness and increased activity of the masticatory elevator muscles preventing the condyle from translating posteriorly around the eminence during the closing phase of mandibular movement.

Management

The clinician must distinguish the patient with myofascial pain and coincidental TMJ clicking from the patient whose pain is directly related to disc displacement. In making this distinction, the clinician will be able to formulate an appropriate treatment selection.

Longitudinal studies demonstrate that most symptoms associated with ADD resolve over time either with no treatment or with minimal conservative therapy.[401] One study of patients with symptomatic anterior disc displacement without reduction experienced resolution without treatment in 75% of cases after 2.5 years.[402] A 30-year outcome study of natural course demonstrated similar findings.[403] Since symptoms associated with anterior disc displacement with and without reduction tend to decrease with time, painful clicking or locking should initially be treated with conservative therapies aimed at reducing symptoms and allowing the body to respond adaptively. Similarly, the clinician should not treat asymptomatic clicking on the assumption that such clicking will inevitably progress to painful clicking or locking.

Recommended treatments for symptomatic ADD include, as a starting point, self-management strategies: patient education, regular use of thermal agents, pain-free chewing, yawn control, simple joint mobility, and reducing parafunctional behaviors. In addition to these core methods, the following can be added based on indication: splint therapy, physical therapy including manual manipulation, and anti-inflammatory drugs. Finally, for more advanced problems involving ADD that have failed conservative therapy, arthrocentesis, and arthroscopic lysis and lavage, arthroplasty, and vertical ramus osteotomy may be considered. Although most of these nonsurgical and surgical techniques are effective in decreasing pain and in increasing the range of mandibular motion, the abnormal position of the disc is not usually corrected.[207]

Anterior Disc Displacement with Reduction

Patients with TMJ clicking or popping that is not accompanied by pain or locking ***do not require*** therapy. Both flat-plane stabilization splints that do not change mandibular position and anterior repositioning splints have been used to treat painful clicking. Anterior repositioning splints maintain the mandible in an anterior position with the disc in a reduced position, preventing the condyle from closing posterior to the disc. One meta-analysis concluded that repositioning splints were more effective than stabilization splints in eliminating both clicking and pain in patients with

ADD.[404] However, it also appears that appliances may only reduce symptoms quicker, with noted outcomes being the same at 3 months regardless of whether an appliance was added to the self-management treatments or not.[405] Clinicians must weigh the potential benefits of using repositioning splints against the potential adverse effects that include tooth movement and open bite. Clinicians have advocated techniques that are designed to "recapture" the disc to its normal position, but splint therapy, arthrocentesis, or arthroscopy rarely correct disc position and function.[406]

Anterior Disc Displacement without Reduction

Some patients with closed lock may present with little or no pain, whereas others have severe pain during mandibular movement. Treatment options should depend on the degree of pain and limitation associated with the ADD. Management of a locked TMJ may be nonsurgical or surgical. The goals of successful therapy are to eliminate pain, restore function, and increase the range of mandibular motion. Correcting the disc position is not necessary to achieve these goals.

Patients who present with restricted movement but minimal pain frequently benefit from manual manipulation and an exercise program designed to increase mandibular motion. A flat-plane occlusal stabilization appliance to decrease the adverse effects of sleep bruxism on the affected joint is appropriate. There is no evidence to suggest that repositioning the mandible using oral appliance therapy is indicated as a treatment for ADD without reduction. Sato and colleagues reported that a combination of a flat-plane stabilization splint and anti-inflammatory drugs was successful in reducing pain and increasing the range of motion in over 75% of patients.[401] The success of this therapy was attributed to decreased inflammation and to the gradual elongation of the posterior attachment, permitting increased translation of the condyle. In a multigroup RCT, Schiffman and colleagues[407] randomized individuals with severe closed lock to medical management, rehabilitation, arthroscopic surgery, or arthroplasty; each of the surgical treatments included post-operative rehabilitation. At 5 years, all treatments resulted in equal improvement as based on symptoms and examination findings, and no treatment was superior, indicating that medical management or rehabilitation should be regarded as sufficient treatments.

Patients with severe pain on mandibular movement may benefit from either arthrocentesis or arthroscopy. Flushing the joint and deposition of intra-articular corticosteroids to decrease inflammation or sodium hyaluronate to increase joint lubrication and decrease adhesions have been reported to decrease pain associated with nonreducing disc displacements.[408,409] A significant reduction in the range of movement preprocedurally was considered a risk factor for delay in postprocedural improvement.[410]

Kurita and colleagues reported on a 2.5-year follow-up on patients with ADD without reduction. During the observation period, approximately 40% of patients became asymptomatic, 33% continued to have symptoms but at a decreased level, and 25% had no improvement. An association was noted between continued TMD symptoms and radiographically detectable degenerative changes.[411]

Subluxation Associated Disc Displacement

Surgical treatments that modify the steepness or flatten the eminence have been recommended, but controlled outcomes do not yet exist for any treatment approach.

Temporomandibular Joint Arthritis

Osteoarthritis (Degenerative Joint Disease, DJD)

Description

Degenerative joint disease (DJD), is primarily a disorder of articular cartilage and subchondral bone, with secondary minimal inflammation of the synovial membrane. It is a localized joint disease without systemic manifestations. The process begins in loaded articular cartilage that thins, clefts (fibrillation), and then fragments leading to sclerosis of underlying bone, subchondral cysts, and osteophyte formation.[412] The articular changes are essentially a response of the joint to chronic microtrauma or pressure. Microtrauma may be in the form of continuous abrasion of the articular surfaces as in natural wear associated with age or due to increased loading related to chronic parafunctional activity. The fibrous tissue covering in patients with degenerative disease is preserved.[413] This may be a factor in remodeling and the recovery that is usually expected in osteoarthrosis and osteoarthritis of the TMJs.[414]

The relationship between internal derangements and DJD has been, until recently, unclear. A higher frequency of radiographic signs of DJD was observed in cross-sectional studies of subjects with disc displacement without reduction[413], and similarly a significant association was observed between an anterior displaced disc and osteoarthritis of the TMJ.[415] Yet, longitudinal observation (8 years) utilizing reliable imaging interpretation indicates that the majority of both disc displacement and DJD diagnoses (76%, and 71%, respectively) remain stable, that approximately equal proportions worsen and improve diagnostically across time, and that change in soft tissue and hard tissue are unrelated.[416] Consequently, DJD of the TMJ remains best considered a disease of aging in which genetic factors play an important role. By the age of 40 a majority of individuals have radiographic evidence of DJD of the TMJ. Secondary DJD results from a known underlying cause, such as trauma, congenital dysplasia, or metabolic disease.

Risk factors for symptomatic DJD include gender, diet, genetics, and psychological stress. Epidemiologic studies suggest a female predisposition to TMDs overall, including osteoarthritis.[52] The possibility that a diet of excessively hard or chewy foods might cause increased loads on the joints and lead to degenerative changes has been proposed. Psychological stress leading to parafunctional activities such as tooth clenching or bruxism has been proposed as a factor which increases loading at the TMJ. The present disease model for DJD of the TMJ suggests that excessive mechanical loading on the joints produces a cascade of events leading to the failure of the lubrication system and destruction of the articular surfaces. These events include the generation of free radicals, the release of proinflammatory neuropeptides, signaling by cytokines, and the activation of enzymes capable of matrix degradation.[417]

Clinical Manifestations

DJD of the TMJ begins early in life and has been observed in over 20% of the TM joints in individuals older than 20 years.[418] A study of patients younger than 30 years old presenting to a TMD clinic demonstrated that two-thirds of the patients had degenerative changes detected on tomograms.[419] The incidence of degenerative changes increases with age. Degenerative changes are found in over 40% of patients older than 40 years. Many patients with mild to moderate DJD of the TMJ have no symptoms, although arthritic changes are observed on radiographs.

Degenerative changes of the TMJ detected on radiographic examination may be incidental and may not be responsible for facial pain symptoms or TMJ dysfunction; however, some degenerative changes may be underdiagnosed by conventional radiography because the defects are confined to the articular soft tissue. These soft tissues changes are better visualized with MRI,[420] but whether such improvement in detection is reflected in a better outcome by more targeted treatment provided earlier has not been evaluated.

Patients with symptomatic DJD of the TMJ experience pain directly over the affected condyle, limitation of mandibular opening, crepitus, and a feeling of stiffness after a period of inactivity. Examination reveals tenderness and crepitus on intra-auricular and pre-auricular palpation. Deviation of the mandible to the painful side is a characteristic finding. Radiographic findings in DJD may include narrowing of the joint space, irregular joint space, flattening of the articular surfaces, osteophyte formation, anterior lipping of the condyle, and the presence of subchondral cysts. These changes may be seen best on CT scans (see Figures 10-13A and 10-13B). The presence of joint effusion is most accurately detected in T2-weighted MRIs; while interexaminer reliability for detection of effusions is overall acceptable (kappa = 0.64),[421] smaller effusions are more difficult to reliably identify. Whether MR-depicted effusion in the TMJ is important clinically has not yet been determined.[264]

Management

DJD of the TMJ can usually be managed by conservative treatment with an emphasis on physical therapy and NSAIDS that control both pain and inflammation. In osteoarthritis, significant improvement is noted in many patients after 9 months, and a "burning out" of many cases occurs after 1 year.[422] Nonsurgical management may consist of jaw self-management, including behavior modification, heat application, soft diet, physical therapy including jaw exercises, and NSAIDS. Occlusal appliances may be helpful when sleep bruxism is an etiologic factor. When nonsurgical management is not effective in reducing either pain or dysfunction, a more invasive method may be indicated, such as a corticosteroid injection.[423]

Arthrocentesis is a relatively conservative joint procedure if intra-articular steroid injection is ineffective.[424] Arthroscopy, arthroplasty, and arthrotomy and joint replacement are surgical procedures that may be indicated in a small percentage of cases depending on the response to more conservative treatment and the severity of pain and disability.[425] It seems prudent to manage a patient with conservative treatment for at least several months before considering surgery unless severe pain or dysfunction persists after an adequate trial of nonsurgical therapy. Only when there is significant TMJ pain or disabling limitation of mandibular movement is surgery indicated.

Rheumatoid Arthritis

Description

Rheumatoid arthritis (RA) is an inflammatory, autoimmune disease primarily affecting periarticular tissue and secondarily bone. The disease process starts as a vasculitis of the synovial membrane. It progresses to chronic inflammation marked by an intense round cell infiltrate and subsequent formation of granulation tissue. The cellular infiltrate spreads from the articular surfaces eventually to cause an erosion of the underlying bone. The percentage of RA patients with TMJ involvement ranges from 40% to 80%, depending on the group studied and the imaging technique used.[420,426] Studies using conventional radiography and tomography find fewer abnormalities than changes detectable on CT.[420] TMJ changes on CT were found in 88% of RA patients, but changes were also detected in more than 50% of controls.[426] Moreover, changes detected using conventional CT do not correlate well with clinical complaints. Yet, using high-resolution CT, condylar changes are detected in approximately 80% of RA patients.[427] It should be noted that many patients with radiographic TMJ changes do not report pain

and have few other symptoms or clinical signs, so a diagnosis of a clinically significant TMD requiring treatment should not be based on imaging alone.

Radiographic changes in the TMJ associated with RA may include a narrow joint space, destructive lesions of the condyle, and limited condylar movement. There is little evidence of marginal proliferation or other reparative activity in RA in contrast to the radiographic changes often observed in DJD. High-resolution CT of the TMJs in RA patients shows erosions of the condyle and glenoid fossa that are not detected on conventional radiography.[420]

Clinical Manifestations

The TMJs in RA are usually involved bilaterally. Pain is usually associated with the early acute phase of the disease but is not a common complaint in later stages. Other symptoms often noted include morning stiffness, joint sounds, and tenderness and swelling directly over the joint.[428] The symptoms are usually transient in nature, and only a small percentage of patients with RA of the TMJs experience permanent clinically significant disability. The most consistent clinical findings include pain on joint palpation, limited mouth opening, and crepitus. Micrognathia and an anterior open bite are commonly seen in patients with juvenile idiopathic arthritis. Ankylosis of the TMJ related to RA is rare.

If RA is suspected after a history and physical exam, laboratory tests including rheumatoid factor, antinuclear antibody, ESR, and C reactive protein should be ordered. Patients with positive laboratory results should be referred to a rheumatologist or their family physician.

Seronegative Spondyloarthropathies

Several arthropathies are distinct from RA and are not associated with positive serology (rheumatoid factor). These disorders, characterized by arthritis, are known as the seronegative spondyloarthropathies and include ankylosing spondylitis (AS), psoriatic arthritis (PA), and reactive arthritis (Reiter's syndrome). The TMJs can be involved in these arthropathies. The clinical manifestations are joint pain with function, limited mouth opening, and erosion of the superior surface of the condyle on radiography. There are no specific findings that are pathognomonic of involvement of the TMJs.

AS primarily involves the spine, although other joints are often involved. It causes inflammation that can lead to new bone formation, causing the spine to fuse, reducing mobility and producing a forward, stooped posture. The disease usually involves the sacroiliac joints where the spine joins the pelvis. TMJ involvement has been reported in AS, but the prevalence has not been established. TMJ involvement has been estimated at about 15–20% of patients with AS.[429] Significantly decreased mouth opening, TMJ pain, crepitus, and muscle pain are frequent clinical findings.[430]

PA is a chronic disease characterized by psoriasis and inflammation of the joints. Approximately 10% of patients who have psoriasis develop joint inflammation. The skin lesions may precede the joint involvement by several years. PA commonly involves the fingers and spine and pitting of the nails is common.

The masticatory system is affected in about 50% of patients with PA.[431] The symptoms of PA of the TMJ are similar to those noted in RA, except that the signs and symptoms are likely to be unilateral. TMJ pain with chewing is a common finding,[431] and limitation of mouth opening may occur.[432] The most common radiographic finding is erosion of cortical outline of the mandibular condyle.

Reactive arthritis, also called Reiter's syndrome, is a nonpurulent joint inflammation triggered by infection elsewhere in the body, such as a gastrointestinal Salmonella infection or a chlamydial genital infection. The symptoms include polyarthritis, conjunctivitis, and superficial oral ulcers. The arthritis is characteristically unilateral and most frequently involves the joints of the lower extremity.[433] A clinical and radiographic study of patients with reactive arthritis demonstrated that approximately 10% had temporomandibular joint involvement.[434]

Connective Tissue Disease

Connective tissue diseases that affect the TMJ include systemic lupus, systemic sclerosis (scleroderma), undifferentiated connective tissue disease, and mixed connective tissue disease. These disorders are addressed in Chapter 19 "Immunological Diseases." When the TMJ is involved, the clinical presentation is similar to other disorders causing inflammation and subsequent degenerative changes. The history will usually be positive for involvement of other joints. A clinical examination of the masticatory system supplemented with diagnostic imaging, as indicated based on the history of other joint involvement, is usually adequate to confirm involvement of the TMJ.

Diseases Associated with Crystal Deposits in Joints

Gout is a disease that includes hyperuricemia, recurrent arthritides, renal disease, and urolithiaisis. The disease primarily affects men. Acute pain in a single joint is the characteristic clinical presentation. The TMJ is rarely involved. Calcium pyrophosphate deposition is also known as pseudogout. Deposits of microcrystals in affected joints are responsible for the clinical manifestations. Examination of aspirated synovial fluid from the involved joint by polarized light and detection of monosodium urate crystals confirms the diagnosis.

Treatment includes colchicine, NSAIDs, and intra-articular steroid injection. Pseudogout affecting the TMJ has been treated with colchicine and arthrocentesis.[435]

Synovial Chondromatosis

Synovial chondromatosis (SC) is an uncommon benign disorder characterized by the presence of multiple cartilaginous nodules of the synovial membrane that break off resulting in clusters of free-floating loose calcified bodies in the joint. It is theorized that SC originates from embryonic mesenchymal remnants of the subintimal layer of the synovium that become metaplastic, calcify, and break off into the joint space.[436] SC most commonly involves one joint, but cases of multi-articular SC have been reported.[437] Some cases appear to be triggered by trauma, whereas others are of unknown etiology. The knee and elbow are the most commonly involved joints.

More sophisticated imaging techniques, such as CT and arthroscopy, have revealed cases of SC that previously would have received other diagnoses, causing authors of recent publications to suspect that SC is more common than previously believed.[438] Extension of SC from the TMJ to surrounding tissues (including the parotid gland, middle ear, or middle cranial fossa) may occur.[439]

Slow progressive swelling in the preauricular region, pain, and limitation of mandibular movement are the most common presenting features. TMJ clicking, locking, crepitus, and occlusal changes may also be present. The extension of the lesion from the joint capsule and involvement of surrounding tissues may make diagnosis difficult, causing SC to be confused with parotid, middle ear, or intracranial tumors. Cases of SC that were mistaken for a chondrosarcoma have been reported. Intracranial extension may lead to neurologic deficits such as facial nerve paralysis. Panoramic radiographs may not lead to the diagnosis due to superimposition of cranial bones that may obscure the calcified loose bodies.[440] A CT scan or an MRI should be obtained if SC is suspected after clinical evaluation. The lesion may appear as a single mass or as many small loose bodies.[441]

Treatment should be conservative and consist of removal of the mass of loose bodies. This may be done arthroscopically when only a small lesion is present, but arthrotomy is often required for larger lesions.[442,443] The synovium and articular disc should be removed when they are involved. Lesions that extend beyond the joint space may require extensive resection.

Septic Arthritis

Septic arthritis of the TMJ most commonly occurs in patients with previously existing joint disease, such as RA or underlying medical disorders—particularly diabetes. Patients receiving immunosuppressive drugs or long-term corticosteroids also have an increased incidence of septic arthritis. The infection of the TMJ may result from blood-borne bacterial infection or by extension of infection from adjacent sites, such as the middle ear, tonsils, maxillary molars, and parotid gland.[444] Gonococci are the primary blood-borne agents causing septic arthritis in a previously normal TMJ, whereas *Staphylococcus aureus* is the most common organism involved in previously arthritic joints.[445]

Symptoms of septic arthritis of the TMJ include trismus, deviation of the mandible to the affected side, severe pain on movement, and an inability to occlude the teeth owing to the presence of inflammation in the joint space. Examination reveals redness and swelling over the involved joint. In some cases, the swelling may be fluctuant and extend beyond the region of the joint.[446] Large tender cervical lymph nodes are frequently observed on the side of the infection. Diagnosis is made by detection of bacteria on Gram's stain and culture of aspirated joint fluid.

Serious sequelae of septic arthritis include osteomyelitis of the temporal bone, brain abscess, and ankylosis. Facial asymmetry may accompany septic arthritis of the TMJ, especially in children. Diagnosis is aided by MRI, CT, and synovial fluid analysis.

Evaluation of patients with suspected septic arthritis must include a review of signs and symptoms of gonorrhea, such as purulent urethral discharge or dysuria. The affected TMJ should be aspirated and the fluid obtained tested by Gram's stain and cultured for *Neisseria gonorrhoeae*.

Treatment of septic arthritis of the TMJ consists of surgical drainage, joint irrigation, and 4–6 weeks of antibiotics.

OTHER DISORDERS

An additional set of less common disorders is described below for purpose of differential diagnosis and contrast with the more common conditions, above.

Myositis

In addition to the far more prevalent myalgia and myofascial pain, the masticatory muscles may be occasionally affected by inflammation. The inflammation may be local as well as systemic in nature. Localized inflammation, known as myositis, has been reported as a result of direct trauma to the muscle, infections such as a submasseteric abscess or pericoronitis, and procedures such as third molar extraction or routine dentistry.[447,448] When calcifications result from the inflammation of the muscle, the condition is referred to as myositis ossificans. These calcifications can be detected on

either CT or MRI. Inflammation of the masticatory muscles can also result from diseases such as polymyositis or dermatomyositis (see Chapter 19 "Immunological Diseases").

The patients characteristically have a history of unilateral jaw pain and decreased mandibular range of motion. Examination findings include erythema, tenderness, and swelling over the affected muscle, usually the masseter, and a restricted range of mandibular movement. The tenderness to palpation is usually severe when injury is the cause of the myositis, such that only very light palpation will be permitted by the patient and the pain is classified as allodynia. Laboratory tests will show elevated white blood cells in patients with acute infection and elevated serum muscle enzymes in patients with an inflammatory myopathy such as dermatomyositis and polymyositis.

Treatment of myositis resulting from infection includes use of antibiotics and surgical drainage when necessary. For myositis not resulting from infection, NSAIDS and rest have been reported as helpful in the initial phase, supplemented by mobility exercises and physical therapy after the initial allodynia has subsided.

Contracture

Contracture of the muscles of mastication can result from fibrosis of muscle, ligament, and tendon tissue related to trauma, infection, or head and neck radiation therapy. Contracture also occurs in response to persistent limitation in muscle range of movement, such as a myalgia that is inadequately treated with mobilization to regain normal muscle length. The limited mandibular range of motion may be mistaken for articular disc displacement or muscle guarding, although contracture does not directly result in pain or tenderness of the muscle or joint.[187,449] The differential diagnosis of limited movement can be particularly difficult when anterior disc displacement without reduction results in limited jaw opening and the nonreducing disc does not respond over time to permit normal condylar movement; the masseter muscle can undergo contracture due to the limited mobility of the condyle. Long-term, it is both the nonreducing disc and the masseter contracture that may restrict movement.

Examination will reveal a decreased maximum mandibular opening with a reproducible firm stop, deviation of the jaw to the affected side with an absence of tenderness.

Treatment of contracture is slow and difficult; with increasing chronicity, the outcome is increasingly unpredictable with respect to expected therapeutic gains. While stretching alone may help, typically manual mobilization of the soft tissue is required. Identifying an end-point for such treatment is important, with maintenance of the restricted mobility becoming the more realistic therapeutic goal.

Trismus

Trismus is a CNS-driven activation of the motor neurons resulting in muscle contraction as a protective behavior. Trismus, myositis, and contracture exhibit similar restriction in mobility, but they are distinguished by history and examination: trismus is a noninflammatory secondary response to injury (e.g., needle injection during mandibular block) or nociception (cancer pain) to a tissue different from the source of the restriction.

In order to minimize trismus resulting from head and neck radiation, a range of motion exercises should be instituted as early as possible. Management of trismus interfering with function includes instruction in home exercises and treatment by a physical therapist when necessary (see Chapter 8).

Developmental Disturbances

Developmental disturbances involving the TMJ may result in anomalies in the size and shape of the condyle. Local factors, such as trauma or infection, can initiate condylar growth disturbances, such as hyperplasia, hypoplasia, agenesis, and the formation of a bifid condyle, all of which may be evident on radiographic examination of the joint. True condylar hyperplasia usually occurs after puberty and is completed by 18 to 25 years of age. Limitation and deviation of mouth opening and facial asymmetry may be observed.

Facial asymmetry often results from disturbances in condylar growth because the condyle is a site for compensatory growth and adaptive remodeling. The facial deformities associated with condylar hyperplasia involve the formation of a convex ramus on the affected side and a concave shape on the normal side. If the condylar hyperplasia is detected and surgically corrected at an early stage, the facial deformities may be prevented. Bone scintigraphy is recommended as part of a presurgical evaluation to identify activity in the joint.[450]

Condylar aplasia is a congenital condition where the condyles did not develop before birth, while hypoplasia can occur as a result of a congenital or acquired anomaly. When congenital, it is usually associated with syndromes such as Treacher Collins Syndrome, Pierre Robins syndrome, or other syndromes affecting the first and second branchial arches (Figure 10-14). Deviation of the mandible to the affected side and resultant facial deformities are associated with unilateral agenesis and hypoplasia of the condyle. Rib grafts have been used to replace the missing condyle to minimize the facial asymmetry in agenesis. In cases of hypoplasia, there is a short wide ramus, shortening of the body of the mandible, and antegonial notching on the affected side, with elongation of the mandibular body and flatness of the

face on the opposite side. Early surgical intervention is again emphasized to limit facial deformity.

Hyperplasia of the coronoid process is an uncommon cause of restricted mouth opening but may be missed in the differential diagnosis of restricted mouth opening. One study estimated that 5% of 163 patients had restricted mouth opening due to elongation of the coronoid process.[451] Careful clinical examination can include coronoid hyperplasia into the differential diagnosis, readily confirmed by plain or CT imaging.

The bifid condyle is a rare condition affecting less than 1% of the population and can occur unilaterally or bilaterally. It is seen as a groove or depression midline of the condylar head. Even though this is usually an incidental finding on radiographs, some patients with bifid condyle present with limited range of motion and/or arthralgia.

Fractures

Fractures of the condylar head and neck often result from a blow to the chin (see Figure 10-16). The patient with a condylar fracture usually presents with pain and edema over the joint area and limitation and deviation of the mandible to the injured side on opening. Bilateral condylar fractures may result in an anterior open bite. The diagnosis of a condylar fracture is confirmed by diagnostic imaging. Intracapsular nondisplaced fractures of the condylar head are usually not treated surgically. Early mobilization of the mandible is emphasized to prevent fibrous or bony ankylosis.

Figure 10-16 Fractured and medially displaced condyle.

Dislocation

In dislocation of the mandible, the condyle is positioned anterior to the articular eminence and cannot return to its normal position without extrinsic manipulation. This disorder contrasts with subluxation, in which the condyle moves anterior to the eminence during wide opening but is able to return to the resting position without extrinsic manipulation. Notably, subluxation is a variation of normal function and the normal range of motion of the condyle is not limited to the fossa but does extend anterior to the height of the eminence.

Dislocation of the mandible can occur from both traumatic and atraumatic causes. Traumatic causes include procedures such as endotracheal intubation or any other procedure that involves oral access to internal organs. Atraumatic mandibular dislocation usually results from muscular incoordination in wide opening during eating, yawning, or laughing. Mandibular dislocation may be unilateral or bilateral. The typical complaints of the patient with dislocation are an inability to close the widely open jaws and pain related to muscle spasm. On clinical examination during dislocation, a deep depression of the skin may be observed in the preauricular region corresponding to the condyle being positioned anterior to the eminence.

The condyle can usually be repositioned without the use of muscle relaxants or sedation. If muscle spasms are severe and reduction is difficult, the use of intravenous diazepam (approximately 10 mg) can be beneficial. The practitioner who is repositioning the mandible should stand in front of the seated patient and place his or her thumbs lateral to the mandibular molars on the buccal shelf of bone; the remaining fingers of each hand should be placed under the chin. The condyle is repositioned by a downward and backward movement. This is achieved by simultaneously pressing down on the posterior part of the mandible while raising the chin. As the condyle reaches the height of the eminence, it can usually be guided posteriorly to its normal position.

Postreduction recommendations consist of limiting mandibular movement and the use of NSAIDs to lessen inflammation. The patient should be cautioned not to open wide when eating or yawning because recurrence is common, especially during the period initially after repositioning. Long periods of immobilization are not advised due to the risk of fibrous ankylosis.

Chronic recurring dislocations have been treated with surgical and nonsurgical approaches. Injections of sclerosing solutions have been used but are no longer frequently utilized because of difficulty in controlling the extent of fibrosis and condylar limitation. Various surgical procedures have been advocated for treating recurrent dislocations of the mandible; these include bone grafting to the eminence, lateral pterygoid myotomy, eminence reduction, eminence augmentation with implants, shortening the temporalis ten-

don by intraoral scarification, plication of the joint capsule, and repositioning of the zygomatic arch.

Ankylosis

True bony ankylosis of the TMJ involves fusion of the head of the condyle to the temporal bone. Trauma to the chin is the most common cause of TMJ ankylosis, although infections also may be involved.[446] The primary sources of these infections were the middle ear, teeth, and the hematologic spread of gonorrhea. Children are more prone to ankylosis because of greater osteogenic potential and an incompletely formed disc. Ankylosis frequently results from prolonged immobilization following condylar fracture. Limited mandibular movement, deviation of the mandible to the affected side on opening, and facial asymmetry may be observed in TMJ ankylosis. Osseous deposition may be seen on radiographs. Ankylosis has been treated by several surgical procedures. Gap arthroplasty using interpositional materials between the cut segments is the technique most commonly performed.

INTRODUCTION

Pain is a multifaceted experience involving physiological, cognitive, and emotional aspects. Reflecting this complexity, pain is defined as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage."[1]

Acute pain resulting from injury or a painful stimulus generally results in a withdrawal reaction, ensuring minimal or no damage to the organism. If tissue damage occurs, a local inflammatory response is initiated causing increased sensitivity in peripheral nociceptors (peripheral sensitization) and in dorsal horn neurons associated with pain transmission (central sensitization). Usually, the injured area becomes sensitive to light touch (allodynia) and hypersensitive to painful stimuli (hyperalgesia). The injured area is painful during the healing phase, in most cases the pain is resolved with no residual disability following healing.

Chronic pain, on the other hand, is not directly associated with injury; it continues beyond healing and has no value for the organism's survival. It may be associated with primary or reactive changes in the nervous system that perpetuate the sensation of pain even in the absence of an active injury. Chronic pain is often not a symptom but a disease in itself that inflicts severe physical and emotional suffering on the individual. Chronic orofacial pain may be subdivided into three main symptomatic classes: musculoskeletal, neurovascular, and neuropathic.[2]

This chapter focuses on neuropathic orofacial pain (NOP); that is, painful neuropathies affecting oral and facial structures.

NEUROPATHIC PAIN

Neuropathic pain (NP) is defined as "pain arising as a direct consequence of any lesion or disease affecting the somatosensory system,"[3,4] which induces chronic pain that may originate from a peripheral nerve, a ganglion, the dorsal root, or from the central nervous system (central NP).

Burket's Oral Medicine, Thirteenth Edition. Edited by Michael Glick, Martin S. Greenberg, Peter B. Lockhart, and Stephen J. Challacombe.

The best estimate of NP prevalence is between 6.9–10% of population.[5] The exact prevalence is unclear, in part due to inconsistent definitions and clinical criteria. The prevalence of syndromes involving NP is expected to increase together with life expectancy and disease survival rates. The relatively limited existing treatment options for NP, largely pharmacologic, may lead to impaired quality of life and extensive usage of health care facilities.[6,7]

The International Headache Society's (IHS's) classification and the International Classification of Headache Disorders (ICHD) can serve as the basis for the definitions and descriptions of the clinical NOP syndromes described in this chapter.[8] We review all the painful orofacial neuropathies except for the rarer pain conditions, such as optic neuritis, ischemic ocular motor nerve palsy, Tolosa–Hunt syndrome, paratrigeminal oculosympathetic (Raeder's) syndrome, and recurrent painful opthalamoplegic neuropathy.

The quality of pain across many NPs is often described as burning, sharp, or electric. The pain may be evoked (stimulus-dependent; e.g., mechanical, thermal) or spontaneous (stimulus-independent)[9] with hyperalgesia, allodynia (e.g., positive sensory sign) and/or numbness (e.g., negative sensory signs).[10] Quantitative Sensory Testing (QST) can be used to evaluate the patients. In the absence of advanced QST tools, sensory function can be assessed using a simple pin, a blunt instrument, warmed and cooled implements, or cotton wool.[11]

Neuropathic Orofacial Pain

Neuropathic orofacial pain (NOP), sometimes termed as trigeminal neuropathic pain is an umbrella term that includes conditions related to painful lesions of the cranial nerves.[12] The most common clinical entities are trigeminal neuralgia, painful post-traumatic trigeminal neuropathies, and burning mouth syndrome.

NOP may be generally classified as peripheral or central, or based on the symptomology as episodic and continuous. Episodic neuropathies are characterized by short, sharp, or electrical like paroxysmal pain similar to trigeminal neuralgia, while post-traumatic neuropathy or inflammation in nerve structures (neuritis) are commonly characterized by continuous burning pain.

NOP shares mechanisms and features with spinal neuropathic pain, yet it demonstrates inimitable characteristics. Conditions such as burning mouth syndrome or trigeminal neuralgia occur solely in this region, while other conditions such as painful diabetic neuropathy, one of the most common neuropathic conditions, rarely affects the orofacial region. This may be explained in part by trigeminal nerve injury studies that show divergent responses to physical and inflammatory insults compared to spinal nerves injury.[13,14]

There is no single, common, easy method to diagnose NOP. The diagnosis is based on self-reports, symptoms, as well as physiological and behavioral methods. Occurrence of NOP may be spontaneous (stimulus-independent) or touch-evoked (stimulus-dependent); these episodes may also be superimposed as a result of constant pain.

Some sensory signs and symptoms, particularly thermal or mechanical allodynia, are frequently associated with NOP. Evaluation of sensory changes is best performed by Quantitative Sensory Testing (QST), a method that utilizes noninvasive assessment and quantification of normal and abnormal responses of the nervous system to various stimuli.[15] Typically, mechanical or thermal stimuli selectively activate different sensory nerve fibers (e.g., heat activates C-fibers, cold stimuli and punctuate mechanical stimuli activate Aδ-fibers and light touch activates Aβ fibers). Sensory evaluation can be performed using sophisticated equipment or using simple pin, blunt instruments, warmed and cooled implements, and cotton wool. Data obtained from QST can support treatment decisions; for example, when the pathology is mainly peripheral microsurgical repair or topical, treatment should be considered, while in cases where the pain has a strong central nervous system component, centrally acting drugs should be the treatment of choice.

Painful Trigeminal Neuropathies

The term "painful trigeminal neuropathy" (PTN) is an umbrella term bringing together a number of facial pains in the distribution(s) of one or more branches of the trigeminal nerve caused by a disorder associated with the trigeminal neuralgias and indicative of neural damage.[8]

The primary pain in PTN is continuous, and commonly described as burning, squeezing, or as pins and needles. Superimposed brief pain paroxysms can be present, but not as the main type of pain. Sensory changes within the trigeminal distribution—such as mechanical allodynia, cold hyperalgesia, and numbness—are prevalent findings in PTNs. Allodynic areas are different from trigeminal neuralgia's trigger zones; they are generally much larger than the punctate trigger zones, and allodynic areas lack both the "latency" and "refractory period" associated with trigeminal neuralgia triggers.

Painful Trigeminal Neuropathy Attributed to Acute Herpes Zoster

Acute herpes zoster (HZ) or shingles is a reactivation of latent varicella virus infection that may occur even decades after the primary infection. The exact mechanisms leading to viral reactivation and the subsequent appearance of acute HZ are unknown. Clinical presentation of HZ includes a dermatomal vesicular eruption. The symptoms are more severe in immunocompromised patients and

include a prolonged course, recurrent lesions mimicking a typical zoster infection, and involvement of multiple dermatomes.[16]

Diagnosis of HZ is based on the clinical presentation and laboratory testing.[17] The clinical features important to the diagnosis include a painful prodrome, a unilateral dermatomal distribution, a vesicular or papular eruption, a history of a rash in the same distribution, and pain.[16] Identification of viral DNA in vesicular or cerebrospinal (CSF) fluid provides a more definitive diagnosis.1[8] Additionally, identification of HZ DNA in saliva has been suggested as a possible and less invasive diagnostic test.[18]

HZ Etiology and Pathophysiology

Peripherally, viral replication induces epithelial cell degeneration and ballooning, followed by invasion of giant cells. In rare cases, necrosis and bleeding are observed. The vesicles rupture and release infectious contents.

Activation of varicella zoster virus at the spinal root or cranial nerve neurons results in an inflammatory response that may also include the leptomeninges. Nerve damage following inflammation around the nerve trunk with lymphocytic infiltration of the nerve root contributes to pain in HZ. The ongoing inflammation may induce neuronal loss, fibrosis, and focal necrosis of nerve cells and satellite cell bodies.[19] Infected DRG cells demonstrate cell degeneration and accumulation of glia cells. The distribution of sensory changes and development of hyperalgesia are associated with the spread within the spinal cord.

HZ Epidemiology

HZ does not generally appear in epidemics and does not follow a seasonal pattern. The annual incidence of HZ has been reduced significantly since the introduction of the first varicella vaccination in 1995.[20]

HZ incidence increases with age, approximately 0.3% of the population will develop HZ.[20] More than 50% of patients over the age of 80 are at risk to develop HZ, and the overall lifetime risk to develop HZ is estimated as 30%.[20] HZ is not common among young patients, and it remains to be determined when the presence of HZ in young patients should be interpreted as sign of underlying immunosuppressive disease.

Clinical Features of Acute HZ

Acute HZ is characterized by a unilateral, dermatomal, red macopapular rash that matures into vesicular eruptions over 3–5 days. The vesicles dry within another 7–10 days, but complete healing may take a month. HZ virus most commonly affects the thoracic nerves, followed by the lumbar region. The trigeminal nerves are affected in 8–28% of cases. Among the trigeminal cases, the ophthalmic branch involvement is most common, occurring in 80% of cases. Ophthalmic nerve involvement can result in keratitis, a vision-threatening condition. When the maxillary or mandibular branches are affected, the vesicles may appear intraorally. Cervical nerves are affected in 13–23% of cases.

Pain in HZ is constant with superimposed piercing attacks. Evoked pain may be the prominent feature in some patients. The pain quality varies: burning (26%), stabbing (15%), shooting (15%), tingling (10%), and aching (9%) are common descriptors used.[21] Its intensity is moderate to severe (VAS 6.2 average), but up to 25% of patients have no pain.[22] High pain severity correlates with an increased incidence of Post Herpetic Neuralgia (PHN).[22] In three-quarters of the patients, acute HZ presents with prodromal pain, headache, itching, malaise, and fever.[16,23–25] The pain develops 2–3 days (< 7) prior to acute HZ and may last with varying intensity up to 3–6 months after healing.[24] Acute HZ patients may have mechanical allodynia and altered sensory thresholds that can spread to adjacent dermatomes, but is rarely bilaterally. Motor weakness may occur, but is usually transient.

Dermatomal pain with no rash, termed "*zoster sine herpete*," is very rare and its diagnosis requires evidence of concurrent viral reactivation.[26]

HZ Management

Acute HZ treatment is focused on pain control, reducing the risk of complications such as spreading and local secondary infection, post herpetic neuralgia (PHN), as well as efforts to accelerate healing.[24] Early initiation of antiviral treatment (less than 72 hours following rash onset), mainly in patients older than 50 years, shortens the rash duration and reduces pain severity and frequency.[22,27] Meta-analyses, however, did not find significant reductions in PHN incidence following oral acyclovir therapy[28]

Antiviral Medications The antiviral medications used to treat acute HZ include valacyclovir (1000 mg x 3/d), acyclovir (800 mg x 5/d), and famciclovir (500 mg x 3/day). Valacyclovir is more efficacious than acyclovir in terms of pain resolution. Famciclovir is well-tolerated therapy that has the advantage of reduced frequency of dosing.[17] Brivudin is an antiviral medication that is available in some countries for the early treatment of HZ, mainly in immunocompetent adults. Overall, brivudin (125 mg daily) is superior to acyclovir (800 mg x 5/d), however it has a mixed efficacy profile.[29] Brivudin and famciclovir (250 mg x 3/d) are comparable in effectiveness on pain and rash with similar tolerability. Severe drug interactions have been reported between brivudin and 5- fluorouracil (FU) and other 5-fluoropyrimidines; therefore, brivudin should not be used along with 5-FU or its derivatives, capecitabine, floxuridine, or flucytosine.[29] Newer anti-HZ drugs, such as the bicyclic nucleoside

analogue FV-100, the helicase-primase inhibitor ASP2151, and valomaciclovir, have been evaluated in clinical trials and offer promising improved efficacy, reduced daily doses, and side effects.[30]

Systemic administration of corticosteroids in combination with antiviral medication offers clinically significant benefits for acute pain and quality of life outcomes when administered systemically within 72 hours of rash onset.[29]

Pain medications Analgesics such as paracetamol or nonsteroidal anti-inflammatory drugs (NSAIDs) should be used to control fever and pain. Stronger pain may require analgesic/NSAID combinations or short-term opioid treatment, mainly for nonresponsive pain. Amitriptyline and gabapentin are centrally acting analgesics that can also provide some pain relief. Amitriptyline may be associated with cardiovascular effects, which limit its use in the elderly and medically complex patients.

Trigeminal Post-Herpetic Neuralgia (PHN)

Post-Herpetic Neuralgia (PHN) is a complication of acute HZ (shingles). It is a neuropathic pain syndrome that develops following herpes virus-induced nerve injury. Affected nerve fibers induce burning pain that lasts long after the rash and blisters disappear.

Multiple risk factors contribute to the development of PHN, including age and severe symptoms such as pain and rash.[25,31] Advanced age (> 50 years old) and intense pain independently predict PHN at 3 months after the acute infection.[31,32] It is not clear when acute HZ transitions into PHN.[33,34] HZ-associated pain may be best classified into three phases: acute HZ (lasting less than 30 days); subacute HZ (more than 30 days but less than 120 days); and PHN (more than 120 days).[16] This classification is in line with evidence suggesting that acute HZ and PHN have distinct pathophysiologies.[35]

Varicella vaccine may offer an effective method of preventing HZ and PHN in individuals at risk. The live attenuated zoster vaccine was shown to be effective in reducing the incidence of PHN among older adults[36] as well as reducing the duration and severity of the acute disease.[37] The vaccine has been shown to be 70% efficacious, safe, and effective. The efficacy of the vaccine appears to decrease with age; however, this can be overcome by vaccine modifications.[30] Zoster vaccines are approved and recommended for individuals over the age of 50.[38] The recombinant version was approved in the United States in 2017 and is safe and effective.[39] A recent metanalysis concluded that the adjuvant recombinant subunit vaccine might be more effective[39] at preventing herpes zoster than the live attenuated vaccine, but the recombinant vaccine also has a higher risk of local adverse events.

Varicella vaccine is contraindicated in immunosuppressed individuals, a group that is at high risk of infection. Instead, passive immunity with an immune globulin preparation should be considered for these patients following exposure to varicella.[17,30]

PHN Etiology and Pathogenesis

Some of the characteristics commonly found in PHN patients include scarring of sensory ganglia and peripheral nerve damage (often bilateral) with loss of large myelinated nerve fibers.[19] Both peripherally and centrally generated mechanisms are involved in PHN and the extent to which each of the processes contributes to PHN will affect the clinical presentation.[40] Patients with the least residual epidermal neurites following acute HZ more often develop PHN, suggesting mechanisms secondary to nerve damage.[19] In trigeminal PHN patients, neurophysiological abnormalities in the A-delta and C fibers were associated with the intensity of the constant burning pain, while dysfunctions of A-beta fibers were associated with paroxysmal pain.[41,42]

PHN patients do not usually present with an active viral infection. PHN patients develop spinal dorsal horn atrophy, which does not exist in acute HZ patients that do not progress to PHN.[19] Postmortem examination has revealed bilateral, severe, peripheral nerve pathology in an ophthalmic PHN patient;[43] while the trigeminal ganglion and trigeminal root were unaffected, suggesting that PHN progresses from peripheral to central structures. It is assumed that ongoing activity in peripheral nociceptors plays an important role in the early PHN stages (< 1 yr) while central mechanisms have more prominent role in later stages.[44]

PHN Epidemiology

The specific incidence of PHN in the trigeminal region is not known; however, the overall PHN incidence is estimated at 3.9–42.0/100,000 person per year.[5] The frequency of persistent pain 3 months following acute HZ increases with age, ranging from 0.3% in patients under 44 years old to 9% in those 75 and older.[19] Between 5–40% of acute HZ patients will report pain 6 months following initial onset,[16,36] and it has been estimated that after 1 year, 5–10% of the patients will report persistent pain.[16,36] There is some variability in the reported durations of pain following acute HZ.

PHN Clinical Features

The ophthalmic division of the trigeminal nerve is most commonly involved in trigeminal PHN.[45] The quality of pain associated has been described as burning, throbbing, stabbing, sharp, or shooting. Most PHN patients will report a constant, deep, burning or aching pain. However, variable temporal patterns of pain have been reported, with some

PHN patients presenting with constant pain and others with paroxysmal pain as the leading symptom.[41]

Between 30–50% of PHN patients report itching of the affected area, termed post-herpetic itch (PHI).[46] Although PHI is usually mild to moderate, in some cases it may be extremely bothersome and is often subjectively graded as worse than pain.[19] PHI may be accompanied by anesthesia and may result in self-injury from persistent scratching.[46] PHN pain is typically severe with VAS ratings of 8. When present, background pain fluctuates from moderate to excruciating.

The affected areas are usually hypoesthetic or anesthetic, with pale or red/purple scars. These "anesthetic" scars often exhibit allodynia and hyperalgesia. No different from other neuropathic pain conditions, a heterogeneous mix of sensory signs and symptoms are observed in PHN.[41] Most patients with PHN develop allodynia and diminished responses to temperature and pinprick.

PHN Treatment

Several evidence-based treatment options are available for PHN. It appears that early treatment improves treatment effectiveness.[47,48] TCAs present an effective treatment option for PHN with an overall Number Needed to Treat (NNT) of 2.6. Amitriptyline is the most extensively studied Tricyclic Antidepressant (TCA); however, other available TCAs such as nortriptyline or desipramine may also be used. Gabapentin (NNT of 4.4) and pregabalin (NNT 3.3–4.93) have been proven to be efficacious and are relatively safe in elderly patients.[47,48] Opioids (NNT ~ 2.7) and tramadol (NNT of 4.8) are a treatment option; however, the risk of Opioid Abuse Disorder (OAD) should be considered.[47,48] In the presence of allodynia, lidocaine patches (NNT ~4) are useful, with significantly fewer side effects compared to systemic drugs.[49–51] High concentrations of topical capsaicin (8%) (NNT of 8.8) was shown[52] as a safe treatment option.[52] For trigeminal PHN, however, capsaicin patches are not recommended and extreme care should be taken when applying treatments around the eyes.[53] Post-herpetic itch (PHI) is extremely difficult to treat; local anesthetics provide some temporary relief, but it does not usually respond to antihistamines.

More invasive PHN treatment options include epidural and intrathecal steroids, sympathetic and sensory nerve blocks, spinal cord stimulation, and neurosurgical techniques with dorsal root entry zone (DREZ) lesion.[54,55]

Painful Post Traumatic Trigeminal Neuropathy (PTTN)

Neuropathy (sensory change) is a disease resulting from damage to or malfunctioning of the somatosensory nervous system. When accompanied by pain it is termed as painful neuropathy.

Neuropathies can be divided into: peripheral neuropathy, when pain originates in peripheral nerve; ganglionopathy, when the ganglion is involved; radiculopathy, when affecting the dorsal root; or central neuropathic pain, when this originates from the central nervous system. Often there are overlapping conditions. This section focuses on Painful Traumatic Trigeminal Neuropathy (PTTN): pain resulting from damage to the trigeminal nerve. PTTN has been previously termed in the literature as: phantom tooth pain, atypical odontalgia, and atypical facial pain.

Craniofacial or oral trauma are probably the most common PTTN etiologies;[56,57] however, minor dental interventions such as nerve blocks, root canal treatment, and third molar extractions may also result in PTTN.[58–62] Other causes include infection (i.e., AIDS), metabolic abnormalities (i.e., diabetes), malnutrition, vascular abnormalities (i.e., trigeminal neuralgia), infarction (i.e., central post stroke pain), neurotoxins, radiation, and autoimmune diseases. In most cases, occurrence of iatrogenic PTTN or other post-traumatic neuropathies does not reflect on the quality of the surgical intervention.[63]

PTTN Etiology and Pathogenesis

The pathophysiology of painful traumatic neuropathies involves a series of events in the nervous system, involving changes in functional, biochemical, and physical characteristics of neuronal and glial cells. These changes are time dependent and progress from the peripheral to the central nervous system.[64–71] Selected aspects of these events are discussed in the subsequent section.

Peripheral Sensitization Peripheral sensitization is usually initiated in response to a variety of stimuli or types of tissue damage. Inflammatory mediators that are released at the damaged area directly activate or indirectly sensitize nociceptors. Development of sensory changes such as hyperalgesia and/or allodynia are characteristic of peripheral sensitization.

It has been shown that perineural inflammation along the nerve trunk (not necessarily in the nociceptor area) can induce ectopic activity and spontaneous pain at the target organ supplied by the nerve.[72,73] Inflammation can affect nerve function either by secretion of mediators such as cytokines or by local pressure induced by edema.[74] The inflammatory process and the peripheral sensitization progress rapidly; however, the condition is reversible. Nevertheless, if inflammation persists, it may induce nerve damage.[75]

Nerve Injury and Ectopic Activity Trauma or severe inflammation may result in neuronal tissue injury leading to subsequent cell death. However, if the proximal stump survives,

healing may occur, which often involves disorganized sprouting of nerve fibers that form a neuroma. Neuroma formation may be dependent on the degree of nerve damage and usually occurs when the perineurium is damaged. Milder injuries, such as nerve constriction or compression, may induce focal demyelination and regions of neuroma formation, which are characterized by ectopic neural activity partially caused by upregulation of specific sodium and calcium channels and downregulation of potassium channels. Mechanical and chemical stimulation of the neuroma can induce ectopic activity, resulting in pain when the injured area (and the neuroma) is touched. Ectopic activity is also seen in the cell bodies of injured nerves in the dorsal root or trigeminal ganglia; this may in part explain spontaneous neuropathic pain. Experimentally, trigeminal nerve neuromas are less active than those in sciatic nerve, suggesting relative resistance of the trigeminal nerve to trauma-induced hyperactivity.

Phenotypic Changes Nerve injury results in altered expression of neuropeptides in trigeminal ganglion, suggesting functional modifications. For example, under normal circumstances, Aβ fibers transmit innocuous stimuli; however, in the presence of persistent inflammation or injury there is a phenotypic change and they begin to express substance P.[67] Aβ fibers thus acquire the ability to induce painful sensations in response to peripheral stimulation, partially explaining the phenomenon of allodynia.

Sensitivity to Catecholamines During periods of stress or anxiety, which are accompanied by increased sympathetic activity, patients may report increased pain in the injured area. This may be due to upregulation of α-adrenoreceptors in the dorsal root ganglion and the site of injury that induce sensitivity to circulating catecholamines. Additionally, sensory-sympathetic interactions can be amplified by basket-like sprouting of sympathetic fibers around large neuronal cell bodies within the dorsal root ganglion. This phenomenon has not been detected in the trigeminal ganglion and may explain the relative rarity of sympathetically maintained craniofacial pain.[13]

Central Sensitization Ongoing or bursts of activity from primary afferents transmitted to the dorsal horn neurons (DHN) may trigger changes in the central nervous system. Repeated input from primary nociceptive afferents increasingly depolarizes DHNs leading to augmented responses ("wind up"). Prolonged DHN depolarization results in activation of the NMDA receptor (NMDAr), a calcium channel normally blocked by a magnesium ion. Upon activation, the magnesium ion blocking the NMDAr is removed, allowing calcium ion influx to the DHN and initiating a variety of intracellular events. Activation of NMDAr is thought to contribute to central sensitization by enhancing neuronal activity. Repeated nociceptive afferent input also leads to activation of other calcium channels (L-, P-, and N-type) resulting in increases in intracellular calcium and DHN hypersensitivity, which manifests as hyperalgesia and/or allodynia.

Prolonged hypersensitivity may activate adjacent DHNs, probably by diffusion of neurotransmitters or by unmasking of silent inter-DHN connections. Activation of adjacent DHNs expands the receptive field area, leading to perception of pain in areas not normally innervated by the involved peripheral nerve. The increase in receptive field can be detected clinically as sensitivity in the uninjured areas in the vicinity of the injury, named secondary hyperalgesia. The phenomenon of central sensitization accounts for increased pain and spread of pain to adjacent structures in patients with severe facial pain. The early neuronal excitability responds well to treatment as it is activity dependent. However, prolonged stimulation and long-term changes originating in the DRG and DHNs involve modified gene expression and downregulation of repressor mechanisms that lead to further excitability. It is important to note that central sensitization characterized by hyperalgesia, temporal summation, and abnormal sensation may also develop following a minor injury such as third molar extraction or root canal treatment.[76,77]

Some months after nerve injury, neuronal death occurs (mainly C-fibers) and sprouting of Aß fibers from deeper lamina follows as injured C-fiber terminals withdraw from lamina I/II. The sprouting of Aß fibers results in increased pain induced by light touch.[78]

Glial and Satellite Glial Cells Spinal cord glial cells have been shown to play an important role in the normal development, connectivity, and plasticity of the central nervous system.[64] They also have a role in the initiation and maintenance of chronic pain and pain modulation. Glia cells express receptors and transporter proteins for many neurotransmitters and are able to release excitatory molecules, such as pro-inflammatory cytokines, glutamate, nitric oxide, and prostaglandins, in response to neuronal signals. This leads to the enhancement of DHN hyperexcitability and neurotransmitter release from primary afferents.[64,79] Glial cells may be an attractive therapeutic target because they participate in pathological pain and not in acute nociceptive responses.[80,81]

PTTN Epidemiology

Traumatic injuries to the trigeminal nerve largely result in either no residual deficit or in a nonpainful neuropathy; only

a small proportion develop a painful neuropathy. There is wide interindividual variability in the onset and features of PTTN following identical injuries.

Macro trauma Mild hypoesthesia of the infraorbital nerve is frequently observed following zygomatic complex fractures; however, neuropathic pain develops in only 3.3% of patients followed up for 6 months[56] compared to around 5–17% in other body regions.[82,83]

Dental Implants Neuropathy secondary to direct or indirect neuronal trauma may develop following implant placement. Between 0.6–36% of patients will experience neurosensory disturbances following implant placement[84–89] as a result of damage to adjacent nerves that may also lead to pain.[90–92] The large incidence range for neurosensory disturbances may imply that both transient and permanent changes were included. However, the exact incidence of postimplant PTTN is unclear. Direct damage may occur during site preparation and/or implant insertion, and indirect damage may result from bleeding and pressure buildup around the nerve or a perineural inflammatory response.

In some cases a major nerve trunk, usually the inferior alveolar nerve, may be impinged to a variable degree,[93,94] especially when the implant is over inserted. In these cases, significant sensory dysfunction is immediately present postoperatively and the neuropathy is believed to result from inflammation and direct physical damage caused by the preparation and/or the implant.[95]

A small group of patients develop pain in spite of normal healing and in the absence of apparent complications. Pain and "sensitivity" to mechanical (chewing, brushing) and often thermal stimuli develop in these patients following implant loading. In some cases, the pain resolves when the implant is unloaded. The underlying mechanism for this pain is unclear; however, it is believed to be neuropathic.[96]

Mandibular and Third Molar Extraction Between 0.3–1% of third molar extractions may be associated with altered sensation in the lingual or inferior alveolar nerve that persists for varying periods.[97,98] Lingual nerve damage is observed less frequently than inferior alveolar nerve injuries[99–101] but may reach 4% in extraction techniques involving nerve retraction.[102]

Nonpainful neuropathies that may develop following dental interventions have a reasonably good prognosis and most patients report improvement.[103]

Root Canal Treatment Multiple factors, including apical infection or inflammation[104,105] accidental injection or leakage of hypochlorite rinsing solution[106–108], and extrusion of filling materials[109,110] have been reported to cause chemical/physical injury that may contribute to nerve damage following endodontic therapy. Between 3–13% of cases report persistent pain following successful endodontics[58,111–114], and 5% of surgical endodontics cases will develop chronic neuropathic pain.[115] Multiple factors have been associated with persistent pain following endodontic treatment, including: long duration of preoperative pain, marked symptomatology from the tooth, previous chronic pain problems, and history of painful treatment in the orofacial region.[113,114] Patients with persistent pain following endodontic treatment may have a deficient endogenous inhibitory system.[77] The importance of preoperative pain parameters implies that some sensitization may have occurred, predisposing to chronic pain.

Local Anesthetic Injections Nerve injury may occur following local anesthetic injection secondary to physical trauma by the needle or by chemical insult from the anesthetic solution.[116–119] Injuries more commonly occur during blocks to the inferior alveolar and lingual nerves, with lingual nerve injuries being more permanent.[62] Lingual nerve injury is more likely during repeated injections and when the injection was reported as painful.[62] The signs associated with injury due to local anesthetic injection are similar to other PTTNs and include burning pain, paraesthesia, allodynia, or hyperalgesia. It has been suggested that the degree of injury may be dependent on the type and toxicity of anesthetic agent used.[120,121] Articaine 4%, when used as an inferior alveolar nerve block, was shown to be significantly associated with nerve injury and clinical symptoms.[122] Therefore, its use for nerve blocks should be limited.

PTTN Diagnosis

Trauma cases should be carefully assessed to detect fractures, other injuries, and extent. Depending on the case, plain radiography or cone beam computerized tomography (CBCT) may be used.

Sensory testing is recommended, preferably with quantitative dynamic assessment,[11,123] to evaluate the degree of injury.[124,125] When advanced quantitative sensory testing (QST) equipment is not available, dental instruments may be adapted to assess gross sensory changes associated with PTTN. For example, pin-prick sensation can be tested with a dental probe, thermal sensation with warm/cool instruments, and mechanosensation with cotton wool. The affected areas should be carefully mapped, marked, and photographed to become part of the patient's documentation, evaluation, and follow-up.

PTTN Clinical Features

PTTN is more prevalent in females and commonly occurs around 45–50 years of age.[61,126–128] The pain is in the injured

area and the affected nerve dermatome accompanied by evident sensory dysfunction.[126] The pain may spread across dermatomes, but rarely crosses the midline. However, in more extensive injuries, where multiple nerves are affected, bilateral pain may occur. The pain is usually burning or shooting, with a moderate to severe intensity (VAS 5-8)[59,60,126,127,129] continuous, and long lasting.[126] Paroxysmal spontaneous pain and pain triggered by touch or function has also been reported.[59] Unlike trigeminal neuralgia, triggering areas are usually not accompanied by a latency or refractory period.[126] Allodynia or a positive Tinel's sign occurs more frequently in PTTN than in trigeminal neuralgia.[59]

Painful neuropathies may be associated with positive (e.g., dysesthesia) and negative symptoms (e.g., numbness).[123,126,127] The sensory symptoms frequently associated with PTTN include thermal and mechanical allodynia.[130] Extensive changes in the central nervous system somatosensory processing may induce additional sensory changes.[11,131,132] The sensory changes may be described by the patients as swelling, a foreign body, numbness, hot or cold, local redness, or flushing, but these are not always demonstrable.[59,126]

Patients with PTTN may present with elevated levels of depression and pain catastrophizing and reduced quality of life. Quality of life and emotional problems, but not anxiety, can by predicted based on the intensity of the pain.[127,133]

PTTN Management

PTTN is characterized by a poor prognosis, improvement is observed in less than one-third of patients and only 10–20% will report a significant improvement.[103,127] Approximately half of the patients reported no improvement or worsened pain. Some degree of pain was experienced by most cases even at an average of 13 years after onset.[127] Prevention is obviously preferable; however, it is not always possible.

Approaches for Preventing PTTN It is unclear why some patients develop persistent postinjury (or postsurgical) pain and others do not. The factors contributing to the development of persistent pain may be grouped into three phases:[134] (1) the preoperative phase includes risk factors specific to each patient, such as psychosocial parameters, genetically controlled pain modulatory mechanisms, the presence of related preoperative pain (i.e., painful surgical site), and comorbidities such as other pain disorders, obesity, and sleep disorders;[135] (2) the intraoperative phase includes surgery dependent factors, such as technique, associated nerve and tissue injury, as well as the analgesic regimens; (3) the postoperative phase involves the patient's coping ability, postoperative pain intensity, healing with scar formation, as well as possible additional confounding factors such as chemotherapy or other unrelated treatments.[134,136]

Preventive analgesia (pre-emptive analgesia) is often recommended to avert the development of persistent postsurgical pain. Preventive intervention may involve various modalities and the recommended protocol varies with pre-, intra- and postoperative components. Currently there is not enough evidence supporting a routine implementation or a unified protocol,[137] yet a preventive strategy should be employed in selected cases. This may include selection of an alternative surgical approach that can minimize tissue damage and nerve involvement, preoperative anti-inflammatory and analgesic treatments, deep local or regional anesthesia, and adequate postoperative analgesics to ensure no perioperative pain. Gabapentin employed 2 hours preoperatively and continued for 1–5 days postoperatively may reduce the incidence of persistent postsurgical pain.[136] Preoperative anesthetic blocks have been suggested to reduce postoperative pain, but no protocol has been broadly accepted.[138,139] The use of local anesthetic blocks during surgery (under general anesthesia) to prevent the injury-associated afferent barrage and resultant central sensitization has been proposed; however, results are inconsistent. Local anesthetics have been shown to suppress postoperative pain and reduce analgesic consumption, but the effect on preventing chronic pain is unknown.[140]

A less efficient pain modulatory capacity has been shown to be indicative of patients' risk to develop postoperative chronic pain.[141–143] This could eventually translate to a chairside screening test to identify at patients at risk.

Factors contributing to lack of success in preventive strategies include inadequate management of the injury related sensory barrage and inadequate pain treatment duration.[139] Preventive programs for selected patients (at risk) should include preoperative and perioperative analgesics, deep local or regional anesthesia, and excellent postoperative analgesics.

Approaches for Established Painful Traumatic Trigeminal Neuropathies

Pharmacotherapy Anti-inflammatory therapy is indicated for the treatment of postoperative clinically symptomatic temporary perineural inflammation (neuritis), as inflammation and neuritis has been shown to have a significant role in the pathophysiology of NP. Standard NSAIDs (for example, naproxen 500 mg b.i.d., ibuprofen 400 mg t.i.d.) are recommended to treat mild cases. The use of steroids such as prednisone, 40–60 mg initially then tapered over 7–10 days, or dexamethasone, 12–16 mg initially then similarly tapered, may be warranted in severe cases with sensory alterations or significant pain. Animal studies show that early dexamethasone may reduce neuropathic pain[144] but there is no support for this concept from rigorous clinical studies. Treatment with steroids should be as short as possible and tapered to

reduce side effects from consistently high dosages. If treatment is successful, patients may be transferred to a NSAID with an antacid treatment for a further 7–10 days.

PTTNs are extremely difficult to manage.[145] Estimation of the Number Needed to Treat (NNT) for neuropathic pain induced by peripheral nerve injury is challenging due to the insufficient number of controlled trails. However, traumatic neuropathies are the most recalcitrant to treatment.[145,146] Antiepileptic drugs (AEDs) and tricyclic antidepressants (TCAs) remain the mainstays of NP treatment.[47,48,147]

The available pharmacotherapies (antidepressants, anticonvulsants, opioids) may provide improved quality of life, sleep, and mood, but usually require high doses for NP, resulting in significant side effects. In NP patients, a 30–50% reduction in pain is considered significant pain relief, and only 20–40% of patients attain this.[148–152]

Drugs with mixed serotonin/noradrenaline (e.g., amitriptyline and nortriptyline) or serotonin and noradrenaline reuptake inhibitors (e.g., venlaflaxine and duloxetine) have been shown to be superior to the selective serotonin reuptake inhibitors.[153,154] The NNTs for TCAs such as amitriptyline in painful polyneuropathies is relatively good and estimated to be 2.1.[147] The more novel antidepressant drugs, the serotonin and noradrenaline reuptake inhibitors (SNRIs) demonstrated less efficacious pain relief (NNT = 5) for NP; however, they have significantly fewer side effects and therefore may be considered as an alternatives for the treatment of painful polyneuropathy.[147]

As a group, anticonvulsant drugs (ACD) are inferior to the antidepressants in the management of painful polyneuropathies. However, ACDs are heterogeneous in their efficacy for painful neuropathies.[155,156] Carbamazepine or oxcarbazepine are efficacious in painful polyneuropathies (NNT = 3.7), but have more side effects than pregabalin (NNT = 4.5) or gabapentin (NNT = 6.4).[147] Based on the efficacy of pregabalin and gabapentin in other peripheral neuropathies, they are theoretically good options for managing PTTN.

Opioids are not considered an effective treatment for traumatic neuropathies (NNT = 5).[147] Combinations of drugs with different modes and sites of action may offer improved efficacy with reduced side effects. In diabetic polyneuropathy or postherpetic neuralgia, combinations of nortriptyline and gabapentin, or nortriptyline and morphine, have been shown to be more efficacious than monotherapy.[157,158] Similarly, patients with painful diabetic neuropathy who did not respond to gabapentin monotherapy showed significant pain improvement when treated with the combination of gabapentin and venlafaxine.[159] An oxycodone–gabapentin mix was shown to be more efficacious than gabapentin alone in diabetic neuropathy patients.[160] Lower doses of gabapentin and morphine may also be combined to achieve significant analgesia in patients with PHN and diabetic neuropathy .[161] Combining gabapentin and an opioid was shown to be superior to gabapentin alone in the treatment of neuropathic pain in adults, but this combination increases the risk of side effects.[162] On the other hand, a combination of duloxetine and pregabalin was reported to provide no significant advantage over high-dose monotherapy in the treatment of diabetic peripheral neuropathy.[163] To date, there is a lack of clear evidence supporting recommendation of any one specific drug combination for neuropathic pain.[162]

Based on the available evidence, TCAs/SNRIs or gabapentin/pregabalin are the first drugs indicated in painful peripheral neuropathy.[47,48,147] In patients initiated on amitriptyline that develop severe side effects, imipramine, desipramine, duloxetine, or venlafaxine should be considered. If these fail or are contraindicated, gabapentin or pregabalin offer the best chances for success. Similarly, in patients on gabapentin/pregabalin, treatment failure is an indication for a trial of TCAs or SNRIs. Combination therapy of SNRI or TCA with gabapentin or pregabalin should be considered if the above treatment options are partly successful.[147] Opioids or tramadol may be used only as third line monotherapy or add on therapy. It is important to keep in mind that opioid treatments pose a risk of addiction and abuse potential. Therefore, screening, preventive measures, and careful monitoring should be in place in all clinics prescribing opioids. Cannabinoids are increasingly being tested[147] and have NNTs of 3–5 in peripheral and central neuropathic pain.[164,165]

When applying a widely accepted pharmacotherapy protocol for neuropathic pain in a cohort of PTTN patients, unfortunately only 11% of patients achieved a ≥ 50% reduction in pain intensity, and patients with higher pain intensity scores were less likely to benefit from the therapy.[145] Comparable response rates have been reported in other painful neuropathies,[147] emphasizing the need for new drugs and treatment options for chronic neuropathic pain.

Topical treatments offer the benefit of minimal side effects, fewer drug–drug interactions, and improved patient tolerance; however, the affected areas are not always amenable to treatment.[166,167] Evidence-based topicals include lidocaine or capsaicin (low and high concentrations) patches and locally injected onabotulinum toxin A.[168] Individually prescribed topical formulations are also in use.[166]

Cognitive behavioral therapy (CBT) CBT does not have significant effects on pain intensity and quality of life measures in neuropathic pain patients.[169] Nonetheless, NP patients should be offered psychosocial therapy as anxiety and depression are frequently comorbid.

Surgical Options Surgery is recommended to improve sensation in injured patients with nonpainful neuropathies.[170–172] Roughly 50% of repaired cases will recover complete sensory function within 7 months[173] if treated within 1 year of injury.[171,174–177] Inferior alveolar nerve injuries have a marginally better prognosis with surgical treatment compared to lingual nerve injuries[178,179] and the presence of a neuroma is a negative prognostic factor.[173,177]

The role of surgery for painful trigeminal neuropathies is not clear. Often, patients with painful traumatic trigeminal neuropathy end up with more pain following peripheral surgical procedures (exploration, further apicoectomies). Therefore, patients with painful traumatic neuropathies should not undergo further surgery unless there are specific indications.[180] Surgical intervention for PTTN patients may be indicated for the release of scar tissue, decompression, and neuroma excision, all of which have been shown to have good success rates.[180]

Decompression of an injured nerve by shortening or removing the implant completely may promote healing and prevent neuropathy. Each situation needs to be weighed individually according to the time elapsed since insertion, type, and degree of the nerve injury. Early removal or replacement of the implants (< 24–48 hours after placement) has been suggested to reduce incidence of neuropathy and pain.[180,181] Microsurgical repairs may be considered for total resections of nerve bundles such as the inferior alveolar. Pharmacotherapy may be considered in management of early nerve injury and evidence of neuritis.

Osseointegrated implant removal may induce substantial collateral damage; therefore, implant removal must be weighed against the potential tissue damage and loss of function.

Central Surgery In refractory cases, central nervous system procedures may be considered.[182,183] Trigeminal dorsal root entry zone (DREZ) surgery may be performed.[183] However, the primary choice of surgery should be minimally invasive, such as computed tomography (CT)-guided percutaneous trigeminal tractotomy-nucleotomy (surgical division of the descending fibers of the trigeminal tract in the medulla) aimed to ablate pathways that carry sensation from the face.

Orofacial Complex Regional Pain Syndrome (CRPS)

Complex Regional Pain Syndrome (CRPS) is a category of chronic, painful neuropathic disorders resulting from injury.[184] Three types of CRPS have been defined: CRPS I (reflex sympathetic dystrophy); CRPS II (causalgia); and CRPS-NOS (not otherwise specified) to allow inclusion of patients not meeting all the criteria.[185] CRPS's clinical presentation includes spontaneous pain, allodynia, and hyperalgesia not limited to dermatomal regions.186

The specific signs that differentiate CRPS from non-CRPS neuropathic pain include regional changes in skin color, temperature, and motor function, sweating, edema, and thermal allodynia.[187] CRPS I may develop as a result of relatively minor local trauma with surgery, fractures, crush injuries, and sprains being the most common causes.[188] Injections, local infection, and burns resulting in minor or not identifiable nerve lesions with disproportionate pain have also been associated.[189] CRPS II occurs less frequently and results from substantial injury to a major nerve, most often following high velocity trauma or surgery. The major distinguishing characteristic of CRPS is the disproportionate severity of the syndrome relative to the injury and nondermatomal spread of pain over time.[184] Pain is commonly felt in the most distal part of the affected limb. CRPS I and CRPS II are often difficult to differentiate.[189]

It is not clear if CRPS occurs in the craniofacial region. The cases reported justify the diagnosis only on interventions aimed at interfering with sympathetic input,[190] although sympathetic involvement is not always essential for CRPS diagnosis.[191] With the exception of trophic and motor changes, CRPS criteria are similar to PTTN and other neuropathic pain conditions.

Classic Facial Neuralgias

The classic neuralgias that affect the craniofacial region are a unique group of neurologic disorders involving the cranial nerves and are characterized by: (1) brief episodes of shooting, often electric shock-like pain along the course of the affected nerve branch; (2) trigger zones on the skin or mucosa that precipitate painful attacks when touched; and (3) pain-free periods between attacks and refractory periods immediately after an attack, during which a new episode cannot be triggered. These clinical characteristics differ from other neuropathic pain disorders, which tend to be constant and have a burning quality without the presence of trigger zones.

Neuropathic pain involving the spinal nerves tends to be constant, whereas involvement of the cranial nerves may result in either constant pain or the classic brief episodes of shooting pain depending upon both the nature of the underlying disorder and the position of the lesion along the course of the nerve. For example, tumors involving the trigeminal nerve between the pontine angle in the posterior cranial fossa and the ganglion in the middle cranial fossa will usually result in the lancinating electric shock pain of classic TN, whereas more peripheral lesions will usually result in more constant pain. The classic craniofacial neuralgias include trigeminal neuralgia, glossopharyngeal neuralgia, occipital neuralgia, and geniculate neuralgia.

Trigeminal Neuralgia (TN)

TN, once also called tic douloureux, is the most common of the cranial neuralgias and chiefly affects individuals older than 50 years of age. The ICHD-3 subdivides TN into three subtypes that may only be diagnosed following imaging. Classical trigeminal neuralgia (CTN) occurs with "demonstration on MRI or during surgery of neurovascular compression (not simply contact), with morphological changes in the trigeminal nerve root." Compression is typically associated with nerve atrophy or displacement. Secondary trigeminal neuralgia is reserved for a typical TN phenotype associated with a local or systemic disease. Finally, idiopathic trigeminal neuralgia has been introduced for patients with typical TN not associated with nerve compression, local or systemic disease. Both classical and idiopathic trigeminal neuralgia are subdivided into purely paroxysmal and those with concomitant persistent pain.

TN Etiology and Pathogenesis

Approximately 10% of TN cases are symptomatic and have detectable underlying pathology, such as a tumor of the cerebellopontine angle, a demyelinating plaque of multiple sclerosis, or a vascular malformation. The most common tumor associated with TN is a meningioma of the posterior cranial fossa.

The most widely accepted theory is that a majority of cases of classic TN are caused by an atherosclerotic blood vessel (usually the superior cerebellar artery) pressing on and grooving the root of the trigeminal nerve. This pressure results in focal demyelinization and hyperexcitability of nerve fibers, which will then fire in response to light touch, resulting in brief episodes of intense pain.[192] Evidence for this theory includes the observation that neurosurgical decompression of the nerve root from the vessel eliminates the pain in a majority of cases.[193] Additional evidence for this theory was obtained from a study using tomographic magnetic resonance imaging, which showed that contact between a blood vessel and the trigeminal nerve root was significantly more frequent on the affected side.

Evidence against this theory explaining all cases of classic TN includes the observation by neurosurgeons that vascular compression is not always detected and manipulation of the area of the nerve root may eliminate the painful episodes even when an atherosclerotic vessel is not pressing on the nerve root. Neurovascular compression (NVC) is not identifiable in a significant number of CTN patients. For example, in a series of 219 patients with paroxysmal TN, 28.3% had no imaging evidence of NVC[194] and up to 17% of patients undergoing surgery for TN had no NVC.[195,196] Moreover, NVC is prevalent both on the symptomatic and asymptomatic side (89% versus 78%) in TN patients, but severe NVC is more prevalent on the symptomatic side (53% versus 13%).[197] Interestingly, pain recurrence after initially successful MVD is often not accompanied by renewed nerve compression.[198]

Furthermore, 17% of age-matched TN-free controls have imaging evidence of NVC.[199–203] Moreover, 14% of cadavers with no history of CTN demonstrate vascular contacts, although these had minimal grooving.[199,200] Classifying CTN and ITN separately allows further study of these groups. TN patients with no NVC are typically younger and three times more likely to be female,[204] supporting the clinical value of the new classification.

Observing neurovascular contact of itself, therefore, has low predictive value in establishing a diagnosis of CTN. The presence of anatomical changes associated with the neurovascular contact increases specificity and positive predictive value.[203] Although NVC clearly plays a role in individual patients, at a population level, the high prevalence of NVC and the rarity of CTN suggest that a finding of NVC in CTN may often be insignificant. Current evidence postulates that TN is a far more complex disease (or cluster of diseases) than previously appreciated.

The pathophysiology of TN seems complex. Around 2% of all TN cases may be familial, and family clusters of TN indicate that it may have a genetic origin.[205] Some of the suggested causes include: inherited anatomical changes affecting the base of the skull, which would promote compression of the trigeminal nerve by vascular structures; mutations in the gene encoding calcium channels resulting in hyperexcitability;[205] as well as mutations in the serotonin transporter gene (5-HTTLPR).[206] Therefore, certain individuals may be prone to develop pain following neurovascular compression while others may be resistant, as in traumatic neuropathies.

TN Clinical Features

The majority of patients with TN present with characteristic clinical features, which include episodes of intense shooting, stabbing pain that lasts for a few seconds and then completely disappears. The pain characteristically has an electric shock-like quality and is unilateral except in a small percentage of cases. The maxillary branch of the trigeminal nerve is the branch that is most commonly affected, followed by the mandibular branch, and, rarely, the ophthalmic branch. Involvement of more than one branch occurs in some cases.

Pain in TN is precipitated by a light touch on a "trigger zone" present on the skin or mucosa within the distribution of the involved nerve branch. Common sites for trigger zones include the nasolabial fold and the corner of the lip. Shaving, showering, eating, speaking, or even exposure to wind can trigger a painful episode, and patients often

protect the trigger zone with their hand or an article of clothing. Intraoral trigger zones can confuse the diagnosis by suggesting a dental disorder, and TN patients often first consult a dentist for evaluation. The stabbing pain can mimic the pain of a cracked tooth, but the two disorders can be distinguished by determining whether placing food in the mouth without chewing or whether gently touching the soft tissue around the trigger zone will precipitate pain. TN pain will be triggered by touching the soft tissue, whereas pressure on the tooth is required to cause pain from a cracked tooth. Just after an attack, there is a refractory period when touching the trigger zone will not precipitate pain. The number of attacks may vary from one or two per day to several per minute. Patients with severe TN may be severely disabled by attacks that are triggered by speaking or other mouth movements and in severe cases there can be significant weight loss due to inability to eat without severe pain.

In some patients, a dull continuous pain called pretrigeminal neuralgia precedes the typical shooting pain by weeks or months. In this stage, trigeminal neuralgia is more difficult to diagnose and is more often confused with dental pathology.

TN Diagnosis

The diagnosis of TN is based on the history of shooting, electric shock-like pain along a branch of the trigeminal nerve, the presence of trigger zones and refractory periods. A routine cranial nerve examination will be normal in patients with idiopathic TN, but sensory and/or motor changes may be evident in patients with underlying tumors or other CNS pathology. A clinical examination alone may be insufficient to distinguish symptomatic from classic TN; in some cases, electrophysiological testing of trigeminal reflexes is more accurate. Local anesthetic nerve blocks, which temporarily eliminate the trigger zone, and painful episodes are also good diagnostic tools.

Since approximately 10% of TN cases are caused by detectable underlying pathology, enhanced MRI of the brain is indicated to rule out tumors, multiple sclerosis, and vascular malformations.[207] Magnetic resonance angiography may also be needed to detect difficult to visualize vascular abnormalities.

TN Management

Initial therapy for TN should consist of trials of drugs that are effective in eliminating the painful attacks. Anticonvulsant drugs are most frequently used and are most effective. Carbamazepine is the most commonly prescribed drug and is an effective therapy for greater than 85% of newly diagnosed cases of TN. The drug is administered in slowly increasing doses until pain relief has been achieved. Skin reactions, including severe cases of erythema multiforme and toxic epidermal necrolysis, are serious side effects. Patients receiving carbamazepine must have periodic hematologic laboratory evaluations because serious life- threatening blood dyscrasias occur in rare cases. Monitoring of hepatic and renal function is also recommended. Patients who do not respond to carbamazepine alone may obtain relief by combining carbamazepine with baclofen or gabapentin. Oxcarbazepine is the 10-ketoanalogue of carbamazepine with a similar mode of action and is often better tolerated than carbamazepine. Routine serial testing for blood dyscrasias is not required, but hyponatremia may be a problem for elderly patients, especially those with cardiovascular disease such as an atrioventricular heart block.

Gabapentin, another anticonvulsant with fewer serious side effects than carbamazepine, may be effective in milder cases, but does not appear to be as reliable as carbamazepine or oxcarbazepine.

Other drugs that are effective for some patients include phenytoin, lamotrigine, baclofen, topiramate, and pimozide. Since TN may have temporary or permanent spontaneous remissions, drug therapy should be slowly withdrawn after a patient remains pain free for 3 months.

In cases where drug therapy is ineffective or when the patient is unable to tolerate the side effects of drugs after trials of several agents, surgical therapy is indicated. A number of surgical procedures that result in temporary or permanent remission of the painful attacks have been described, these include: procedures performed on the peripheral portion of the nerve, where it exits the jaw; at the gasserian ganglion; and at the brainstem, at the posterior cranial fossa.

Peripheral surgery includes cryosurgery on the trigeminal nerve branch that triggers the painful attacks. This procedure is most frequently performed at the mental nerve for cases involving the third division and at the infraorbital nerve for cases involving the second division. The potential effectiveness of this procedure can be evaluated prior to surgery by determining whether a long-acting local anesthetic eliminates the pain during the duration of anesthesia. This procedure is usually effective for 12 to 18 months, at which time it must be repeated, or another form of therapy must be instituted.

One procedure performed at the level of the gasserian ganglion is percutaneous radiofrequency thermocoagulation, although some clinicians continue to advocate glycerol block at the ganglion or compression of the ganglion by balloon microcompression. A severe complication of peripheral procedures is severe neuropathic pain including anesthesia dolorosa, which is numbness combined with severe intractable pain.

The most extensively studied and most successful surgical procedure is microvascular decompression of the nerve root at the brainstem where the artery is separated from the nerve root. Over 70% of patients experience long-term relief of symptoms.[193] It should be noted that 30% of the patients experienced a recurrence of symptoms and required a second procedure or alternative therapy. Complications are rare but include stroke, facial numbness, and facial weakness.

Gamma knife stereotactic radiosurgery is a minimally invasive technique for the treatment of TN.[208] The technique uses multiple beams of radiation, converging in three dimensions to focus precisely on a small volume of brain tissue. The method relies on precise MRI sequencing that helps localization of the beam and allows a higher dose of radiation to be given to targets inside the skull (for TN treatment: the trigeminal nerve where it enters the brainstem) with more sparing of normal tissue. This technique is not as effective as microvascular decompression, but is particularly helpful for elderly patients with a high risk of complications from surgery.

In summary, therapy for TN presently includes a variety of both medical and surgical approaches, each of which is effective for some patients. Drug therapy, including trials of several drugs or combinations of drugs, should be attempted before surgery is recommended. When surgery is necessary, the patient should be carefully counseled regarding the advantages and disadvantages of the available surgical procedures. Clinicians should also remember that since spontaneous remissions are a feature of TN, procedures resulting in temporary relief might be all that is necessary in some cases.

Glossopharyngeal Neuralgia (GN)

Glossopharyngeal neuralgia is a rare condition that is associated with paroxysmal pain that is similar to, although usually less intense than, the pain of TN. The location of the trigger zone and pain sensation follows the distribution of the glossopharyngeal nerve, namely, the pharynx, the base of the tongue, external ear canal, and infra-auricular retromandibular region.[209] Pain is triggered by stimulating the pharyngeal mucosa during talking or swallowing. The pain may be confused with geniculate neuralgia because of the common ear symptoms or with a temporomandibular disorder since pain may be associated with mandibular movements.

Glossopharyngeal neuralgia may occur with TN and, when this occurs, a search for a common central lesion is essential. Glossopharyngeal neuralgia also may be associated with vagus nerve involvement, which may cause syncope, asystole, bradycardia, hypotension, and cardiac arrest. Insertion of a pacemaker may be required to prevent syncopal episodes. The application of a topical anesthetic to the pharyngeal mucosa eliminates glossopharyngeal nerve pain, which can aid in distinguishing GPN from other cranial neuralgias.

The most common causes of glossopharyngeal neuralgia are intracranial or extracranial tumors and vascular abnormalities that compress the ninth cranial nerve. Treatment is similar to that for TN, with a good response to carbamazepine and oxcarbazepine. Refractory cases are treated surgically with microvascular decompression, percutaneous radiofrequency thermocoagulation, or gamma knife radiosurgery.[210,211]

Nervus Intermedius (Geniculate) Neuralgia

Nervus intermedius (geniculate) neuralgia is an uncommon paroxysmal neuralgia of CN VII, characterized by pain in the ear and less frequently the anterior tongue or soft palate. The location of pain matches the sensory distribution of this nerve (i.e., the external auditory canal, a small area on the soft palate, and the posterior auricular region). Pain may be provoked by the stimulation of trigger zones within the ipsilateral distribution of the nerve. The pain is not as sharp or intense as in TN, and there is often some degree of facial paralysis, indicating the simultaneous involvement of the motor root. Disorders of taste or lacrimation may also be present.[212]

Geniculate neuralgia results from vascular compression of the nerve root or herpes zoster of the geniculate ganglion and nervus intermedius of CN VII. This condition, referred to as Ramsay Hunt syndrome, is characterized by viral vesicles in the ear canal or on the tympanic membrane and pain. Since the symptoms result from inflammatory neural degeneration, a short course (2 to 3 weeks) of high-dose steroid therapy is beneficial. Use of an antiherpes drug such as acyclovir or valacyclovir significantly reduces the duration of the pain.

A recombinant herpes zoster vaccine has been developed and approved, which is effective in preventing herpes zoster and post herpetic neuralgia in 90% of individuals who have received the recommended two doses.[213]

Patients with geniculate neuralgia can be treated successfully with oxcarbazepine, carbamazepine, and/or gabapentin. Patients who do not respond to these medications may have a regional nerve blockade and, if this fails, undergo surgery for excision of the nervus intermedius and geniculate ganglion or microvascular decompression.[214]

Occipital Neuralgia (ON)

ON Etiology and Pathogenesis

Occipital neuralgia (ON) affects the distribution of the greater, lesser, or third occipital nerves and can stem from multiple causes, chiefly pressure on the affected nerve from

surrounding muscular and vascular structures, congenital deformities, neoplasms, myelitis, or degenerative joint disease.[215,216] Injuries to the affected nerve after surgery, whiplash injury, or multiple sclerosis may also cause ON.[216,217] The most common cause is nerve entrapment by surrounding muscles, which may be either secondary to or independent of joint changes.[215,218,219]

ON Epidemiology

The incidence and prevalence of occipital neuralgia has not been definitively determined. The greater occipital nerve is involved in 90% of cases, and 85% are unilateral.[215,220] Cases show no variation in temporal or seasonal frequency.[218]

Clinical Manifestations

Occipital neuralgia presents as "unilateral or bilateral paroxysmal, shooting or stabbing pain in the posterior part of the scalp, in the distribution(s) of the greater, lesser and/or third occipital nerves."[8] Like TN and GFN, each attack lasts seconds to minutes and consists of a severe sharp pain. The pain can include aching, allodynia, dysesthesia, or paresthesia, which may persist between attacks. The affected area can extend up the back of the head toward the vertex of the scalp and even to the ipsilateral frontal and orbital areas through connections to the trigeminal spinal nuclei.[220,221]

Clinical tests can help to confirm the presentation of ON, including Tinel's sign, in which patients feel tingling upon light pressure to the nerve, and the pillow sign, when patients feel pain upon neck extension while supine.[219]

ON Differential Diagnosis

Misdiagnosis of occipital neuralgia is common, owing in part to its similarity in presentation to multiple headache disorders. Tenderness and trigger points in the posterior neck muscles and joints causing both migraine headache and cervicalgia may be mistaken for the classic sign of tenderness in the affected nerve in ON.[222] Cervicogenic headache is also often confused with ON, but is due to pain referred from the underlying structures and occurs after injury to the affected area.[218,219] For this reason, palpation sensitivity of the posterior scalp in the area of either the greater or lesser occipital nerves is considered highly suggestive but not specific for diagnosis.[215] Patients with ON do not show worsening or triggering of symptoms with movement of the neck, distinguishing ON from other causes of neck pain.

ON Laboratory Findings

Imaging studies such as MRI or plain film are used to rule out an underlying cause of pain, including pathology affecting the area of the upper cervical spine or posterior neck muscles and central space occupying lesions.[216]

ON Management

Management of ON should begin with physical therapy, including applications of cold and heat, exercise, massage, and transcutaneous electrical nerve stimulation (TENS).[219,220] Blocks of the affected nerves are both diagnostic and therapeutic and may be administered with local anesthetic, corticosteroid, or onabotulinum toxin to decrease inflammation to the nerve.[217–220] For patients requiring additional treatment, systemic medications used in ON include nonsteroidal anti-inflammatory drugs, muscle relaxants, tricyclic antidepressants, and anticonvulsants.[220]

For persistent and unresponsive cases of ON, peripheral nerve and occipital nerve stimulation, pulsed radiofrequency, radiofrequency ablation, rhizotomy, neurolysis, and C2 dorsal root ganglionectomy can be considered.[218,219] Occipital nerve stimulation is particularly promising as a minimally invasive and reversible option which has been endorsed by the Congress of Neurological Surgeons. Radiofrequency ablation, which uses thermal insult to destroy A-delta and C fibers, may be effective in those patients with positive but insufficient responses to nerve blocks or those with ON affecting the third occipital nerve.[215,219] More destructive procedures carry increased risk of complications, including causalgia and neuroma formation.

Neck-Tongue Syndrome (NTS)

NTS Etiology and Pathogenesis

Neck-tongue syndrome (NTS) occurs when the C2 ventral ramus is compressed, entrapped, or stretched against the atlantoaxial joint as a result of underlying joint laxity. Afferent fibers from the lingual nerve are compressed in the same manner while transiting via the ventral ramus of C2 after anastomosing with hypoglossal nerve fibers. NTS can manifest secondary to minor or major trauma to the cervical joints.[223]

NTS Epidemiology

Approximately 50 cases of NTS have been reported to occur, primarily in childhood and adolescence with equal gender prevalence. It usually resolves with age.[223,224] NTS tends to cluster in families, likely due to susceptibility to joint laxity.[225, 226]

NTS Clinical Manifestations

NTS consists of severe sharp pain of the posterior neck or occiput together with numbness or involuntary movement of the ipsilateral tongue, both occurring after sudden movement of the neck.[8,227] Symptoms of NTS last between seconds to 2 minutes as in TGN, GPN, and ON.[226,227] Other headache symptoms, including pain shooting up the back of the head, can occur. Autonomic activation may also occur causing flushing and sensitivity to light and sound.[224,226,228]

The history is often positive for muscle guarding habits and the clinical examination is usually unremarkable, but may include tight cervical muscles and pain to palpation of the upper neck.

NTS Differential Diagnosis

The posterior neck pain in NTS may in its character and location resemble multiple other headache disorders, including cranial neuralgias and cervicogenic headaches. The main distinguishing factors of NTS are the simultaneous tongue symptoms.

NTS Laboratory Findings

NTS is usually self-limiting and does not require additional laboratory or imaging work up.[228]

NTS Management

Many patients with NTS will improve with time, and the symptoms are often rare and temporary enough to not require active treatment. Some patients may improve with exercises, postural correction, and habit awareness.[224] Spinal manipulation is not recommended as a treatment given the risk of adverse effects.[226] When necessary, patients can benefit from topical lidocaine application, local anesthetic and steroid injection to the posterior skull, and systemic medications including nonsteroidal anti-inflammatory drugs, steroids, tricyclic antidepressants, antiepileptics, and muscle relaxants.

Persistent Idiopathic Facial Pain (PIFP)

Persistent idiopathic facial pain (PIFP) is defined as "persistent facial and/or oral pain, with varying presentations but recurring daily for more than 2 hours per day over more than 3 months, in the absence of clinical neurological deficit."[222] This definition may include a large number of chronic facial pain disorders. PIFP has historically been termed atypical odontalgia (AO) or atypical facial pain (AFP). The diagnosis of AFP includes a heterogeneous group of patients since it was used when no other diagnosis was suitable.

Many cases diagnosed as PIFP could also be classified as chronic myofascial pain, traumatic neuropathy, pre- or atypical trigeminal neuralgia, facial migraine, or neurovascular orofacial pain.

PIFP Etiology and Pathophysiology

Studies of PIFP patients revealed increased neuronal excitability at the brainstem level,[229–231] disturbed inhibitory function of the prefrontal cortex,[232] and alterations in the dopamine systems associated with either/both pain transmission and its modulation.[233] Additionally, sensory changes consistent with a neuropathy or neuropathic pain have been shown employing QST in patients with PIFP.[128,230,234] The data seem to indicate that PIFP is a neuropathic pain syndrome similar to PTTN. PIFP and PTTN may represent extremes of a spectrum of clinical presentations. PIFP patients often have a history of mild trauma and subclinical sensory changes, while PTTN patients have history of a significant trauma and usually detectable sensory changes. Neurophysiologic and quantitative sensory examinations performed on PIFP patients by Forssell et al.[230] suggested that PIFP might be a heterogeneous entity representing one extreme of a continuum that ranges from definitive neuropathic pain syndromes to idiopathic pains with an unclear "neuropathic" involvement.[230]

PIFP Epidemiology

The estimated incidence of PIFP is 4.4 per 100,000 person years[235] and lifetime prevalence is around 0.03%,[236] with the majority of patients being females in their mid 40s.[237] PIFP may coexist with chronic orofacial pain syndromes such as chronic myogenic pain.[238]

PIFP Clinical Features

Minor surgical or other invasive dental or otolaryngologic procedures are often reported as the initiating event.[239,240,241]

Although there should be no clinically evident neurosensory deficits in PIFP[222] hypoesthesia has been reported in studies using quantitative sensory testing (QST).[128,230,234] This is confusing, since patients with a neuropathic type pain following surgery or other trauma with neurosensory changes should be diagnosed with painful traumatic trigeminal neuropathy (PTTN), as defined by the IHS.[126,222]

Pain in PIFP can be deep or superficial,[222] is poorly localized, radiates, and is unilateral in about 60% of the cases.[237] It is commonly described as aching, burning, throbbing or stabbing;[128,222,230,231,234,237,242] the pain severity is variable (rated 7 on an 11-point VAS) and it may be aggravated by emotional stress.[222,237] Most PIFP patients report persistent, long lasting (years) daily pain[237] that tends to spread in a nondermatomal pattern with time.[222] Typically, pain characteristics, location, and associated features change over time and pain free or remitting periods are very rare.[237] PIFP may coexist with other chronic orofacial pain or headache syndromes.[237]

Psychiatric and psychosocial disability have often been associated with PIFP,[243] although one study on 14 PIFP patients found no significant comorbid psychiatric disorders compared to controls.[231] PIFP patients reporting higher pain intensity tend to have increased scores for anxiety and depression,[244] suggesting that a psychiatric screening should be performed.[245] An interdisciplinary approach is needed for the diagnosis and management of PIFP.[246]

PIFP Management

The lack of a clear pathophysiological basis complicates the development of a treatment protocol. The approach to the management of PIFP patients should consider the effect of the pain disorder on the patients' personal lives.[247] Multidisciplinary approaches addressing comorbidities such as psychiatric disorders and the chronic course of the condition should be undertaken.[248] Considering the chronicity and resulting distress, behavioral interventions and medications known to have an effect in painful neuropathies, such as antidepressants and antiepileptic drugs, may be indicated. Patient education is also needed to clarify the diagnosis and to elucidate the risk of further invasive interventions aimed at pain relief in the absence of clear associated pathology.

Case series using tricyclic antidepressants,[249] an open study on duloxetine,[250] a randomized controlled trial on venlafaxine,[251] and open studies on anticonvulsants[252,253] and low level laser[254] have all shown beneficial effects but the level of evidence is low.

Occipital nerve blocks have not been efficient in PIFP patients.[255] Noninterventional novel therapies such as virtual reality,[256] hypnosis,[257] or complementary and alternative medicine[258] may have some benefit for PIFP patients. However, the evidence for psychosocial interventions is limited due to the lack of controlled studies.[259] Invasive procedures carry the risk for inducing a traumatic neuropathy and therefore may end up increasing pain.

It is important to note that available evidence for any of the treatments listed above is limited and randomized clinical trials are missing. Therefore a conservative, multidisciplinary approach based on experiences with comparable chronic orofacial pains or headaches is recommended.[248]

Atypical Odontalgia

Atypical Odontalgia (AO) is defined by the IASP as a severe throbbing pain in the tooth without major pathology and is considered a subentity of PIFP. AO has been referred to as phantom toothache, suggesting a neuropathic etiology.[260–262] It is also possible that various studies included some heterogeneous groups of patients with localized neuropathic or neurovascular syndromes. Repeated dental interventions aimed at pain relief in AO patients or undiagnosed orofacial pain cases may lead to nerve injury and PTTN. Chronic orofacial pain patients undergo extensive and often misguided surgical interventions[240,263] that are known to exacerbate pain in 55% of patients. About 5% of AO patients are misdiagnosed, which results in serious sequelae and delay of necessary treatment.[240]

Due to the ambiguity in the terminology it has been suggested that AO should not be used,[264] similarly to the way that AFP is no longer advocated. Patients with neuropathic pain following surgery or other trauma should be diagnosed as PTTN. However, in clinical reality, a number of patients with intraoral pain do not neatly fit any diagnostic category. These patients usually have persistent pain in the dentoalveolar region and have been grouped into a diagnosis of "primary persistent dentoalveolar pain" (PDAP).[265,266] Since AO seems to be an intraoral representation of PIFP, the term "persistent idiopathic dentoalveolar pain" seems very suitable.

Burning Mouth Syndrome (BMS)

There are many oral mucosal diseases that cause burning sensations as a result of observable local pathology. However, Burning Mouth Syndrome (BMS) refers specifically to burning pain involving the oral mucosa in the absence of either local pathology or underlying medical causes.[267] Over the years, the condition has also been known as stomatodynia, burning tongue, stomatopyresis, glossopyresis, glossodynia, and idiopathic glossodynia.

BMS Etiology and Pathogenesis

Before a diagnosis of BMS can be made, local and systemic causes of the symptoms must be ruled out.[268] These include oral mucosal lesions, candidiasis, and salivary gland disorders, as well as systemic causes such as anemia, diabetes, and deficiencies of iron, folate, and vitamin B12. In addition, antihypertensives in the angiotensin-converting enzyme (ACE) inhibitors class are known to cause oral burning as a side effect and, if suspected as the cause, the clinician prescribing these drugs should be consulted as to whether another class of antihypertensive drugs can be substituted.

Studies of BMS patients using laboratory investigations and imaging have shown an increased incidence of BMS in women after menopause. This has led to the suspicion of an association between BMS and hormonal changes,[269] but to date minimal evidence supports this theory.

Centrally, functional MRI of the brain of BMS patients demonstrates brain activation patterns similar to other neuropathic pain disorders as well as decreased dopamine levels. Locally, it has been hypothesized that dysfunction of the chorda tympani branch of the facial nerve may inhibit trigeminal nerve function causing reflex hyperactivity of the lingual nerve.[270,271] On incisional biopsy, patient with BMS are found to have local increases in ion channels associated with neural growth factors.[15,17,19] Salivary markers in affected patients also show altered immune mediator and mineral concentrations and increased markers of stress.[267,269]

BMS has also been associated with psychological disorders, particularly depression and anxiety. BMS patients may also suffer from gastrointestinal and chronic fatigue

syndromes, and other orofacial or generalized pain disorders.[272] The rates of psychiatric comorbidities observed in BMS, however, are approximately equal to those in other chronic pain disorders. Patients with BMS are also frequently found to exhibit altered sleep quality, although all of these may result from the correlation with anxiety and depression and not as a direct effect of BMS.[267] It is likely that some cases of BMS have a strong psychological component while in other cases factors including low-grade trauma and parafunctional habits (e.g., rubbing the tongue across the teeth or pressing it on the palate) play a larger role.[268] Sensory changes and altered pain modulation have been reported in BMS patients.[273,274]

Historical disagreement about the definition of this condition and the heterogeneity of patients included in studies have long led to confusion about patient characteristics, natural course of BMS, and effective management. For this reason, many have called for studies with standardized diagnostic classification and increased scientific rigor.

BMS Epidemiology

The estimated prevalence of BMS varies based on study design and diagnostic criteria between 3.7–15%.[272] Women experience symptoms of BMS 5 to 7 times more frequently than men, with the difference becoming most pronounced after menopause.[269,272] When questioned, 10–15% of postmenopausal women are found to have a history of oral burning sensations, and these symptoms are most prevalent 3 to 12 years after menopause.[275] Of patients with BMS, 30–60% also exhibit other neuropathic pains, decreased cold and heat sensitivity, and decreased pain thresholds.[267] Estimates may not capture the full burden of this condition, however, as patients commonly experience delays in diagnosis (mean 34 months) and misdiagnoses from multiple providers (mean 3.1 providers seen before receiving effective treatment).[269]

BMS Clinical Manifestations

The tongue is the most commonly affected structure in BMS, with pain in 71–78% of patients occurring in the anterior two thirds or tip of the tongue.[269] In half of the patients, the tongue is the only site affected. When more widespread, the dorsum and lateral borders of the tongue (72%), lips (24%), and anterior palate (25%) are frequently involved, although in some cases the burning pain may also affect the gingivae and pharynx.[269,272] Regardless of location, pain is usually bilateral and does not follow dermatomes.[272] There is no paroxysmal component of BMS. Pain may begin after dental treatment or another traumatic event in up to one third of patients.

Pain is most commonly described as burning or hot and intensity varies from mild to as severe as a toothache with average VAS 3.1–5.1/10.[269,272] Patients also describe the sensation as itching, tingling, tender, scalding, numb, raw, annoying, and uncomfortable.[269,271] The pain is long standing with variable intensity day to day, increasing toward the end of the day.[272,275]

BMS can be intermittent or constant, but eating, drinking cold drinks, or placing candy or chewing gum in the mouth characteristically relieves the symptoms, possibly due to activation of large neuronal fibers.[272] Common aggravating factors include personal stressors, fatigue, and specific foods (acidic, hot, spicy, and alcohol-containing).[268] More than two-thirds of patients complain of paresthesia, dysesthesia, or altered taste sensation[8,27] often described as metallic, bitter, or foul.[272] The subjective feeling of dry mouth is also common and although stimulated salivary flow is normal, unstimulated salivary flow may be decreased.

BMS is most common in patient with Type C personalities; those exhibiting fearful and neurotic tendencies.[267] Patients may also have symptoms that suggest depression, such as decreased appetite, insomnia or poor sleep quality, and a loss of interest in daily activities.[269] Women with BMS show more symptoms of obsessive-compulsive disorder, somatization, and paranoia than unaffected women, and men with BMS show more symptom distress than matched controls. Patients are also likely to exhibit multiple other nonspecific complaints, be taking other medications, and relate a history of severe menopause.[275]

BMS Differential Diagnosis

Other causes of oral burning must be eliminated by examination and laboratory studies. Patients with unilateral symptoms should have a thorough evaluation of the trigeminal and other cranial nerves to eliminate a neurologic source of pain. A careful clinical examination for oral lesions resulting from candidiasis, lichen planus, ill-fitting prostheses, allergy, or other mucosal diseases should be performed.[272,274] Patients complaining of a combination of xerostomia and burning should be evaluated for the possibility of a salivary gland disorder including Sjogren's syndrome, particularly if the mucosa appears dry and the patient has difficulty swallowing dry foods without sipping liquids.[268]

BMS Laboratory Findings

Laboratory studies should be reviewed or performed in order to rule out an underlying systemic cause of burning. In patients with no lesions or other systemic symptoms, clinicians should check complete blood count with a differential, metabolic panel including fasting blood glucose, hemoglobin A1C, iron, vitamin B12, and folic acid.[272,274,275] Other tests may be ordered on an individual basis according to examination findings.

BMS Management

Once the diagnosis of BMS has been made, the patient should be reassured that the burning is not caused by a serious or life-threatening disorder. Counseling the patient, acknowledging the condition, and connecting patients with other sufferers are helpful in management, and may be adequate for individuals with mild burning sensations. When necessary, consultation should be sought for any suspected underlying serious psychiatric disorder.[272,274,275]

BMS is often resistant to therapy and there are few evidence-based treatments, each of which has been evaluated only in small studies that lack long term follow up.[271] In addition, many BMS patients respond to placebo, complicating evaluation of treatment options.[275] Patients with parafunctional tongue habits often benefit from use of a protective soft dental splint.

Topical clonazepam is the most reliably effective drug therapy for BMS, although it is not effective for every patient.[276–278] A combination of topical and low doses of systemic clonazepam is also used.[279] It should be stressed to the patient that this drug is being used not to manage psychiatric illness but for its well-documented analgesic effect. Clinicians prescribing these drugs should be familiar with potential side effects including xerostomia, fatigue and lethargy, spasmophilia, euphoria, and the risk of dependence.[267,275] Systemic clonazepam carries the additional risks of memory and cognitive impairment.[272]

Many other topical and systemic medications have been proposed and studied in patients with BMS. These include pregabalin, histamine receptor agonists (lafutidine), other anxiolytics (chlordiazepoxide, diazepam), dopamine agonists (levodopa, pramipexol), and supplements including catuama (a mixture of guarana, catuaba, ginger, and muira puama).[268,269,272,274,280] A medication used topically is capsaicin, which depletes substance P to desensitize pain response.[267,271] Alpha lipoic acid (ALA), a mitochondrial antioxidant co-enzyme that increases neural growth factors, has also been studied.[281–284] Results to date are mixed but this treatment may be helpful, particularly in combination with other therapies.[271] Treatment with ALA can cause headache and gastrointestinal upset in some patients.[267,275]

Nonpharmacologic management strategies have also been proposed in BMS. The most commonly recommended is cognitive behavioral therapy (CBT), in which a trained counselor uses biofeedback, relaxation, exposure, and cognitive restructuring among other modalities to redefine the patient's pain experience. This is effective in finding coping strategies, addressing catastrophizing, and improving mood disorders.[267,272,285,286] Other defocusing strategies including psychotherapy, exercise regimens, yoga, tai-chi, and acupuncture may also be beneficial[269,271,287] and tongue protectors and other appliances can address any parafunctional habit.[269,272]

Central Causes of Facial Pain

Direct damage to the central nervous system (stroke or spinal cord trauma) or indirect damage induced by diseases such as epilepsy, Parkinson's disease, and multiple sclerosis may result in central pain (CP). These pains are usually associated with decreased sensation and are termed anaesthesia dolorosa and deafferentation pain. Painful peripheral traumatic neuropathies may involve central mechanisms; however, the initiating events are peripheral.

Central Post Stroke Pain (CPSP)

CPSP is characterized by constant or paroxysmal pain accompanied by sensory abnormalities such as decreased perception and frequently allodynia. Severity and prevalence of CPSP may be underestimated as many post-stroke patients are unable to self-report their pain.[288]

CPSP Epidemiology

CPSP occurs within 6–12 months in 2.7–11% of all stroke patients and 25% of brainstem infarct patients.[289–291] Women and younger patients seem to be at higher risk of CPSP following stroke.[290] CPSP is commonly located in the upper extremity (37.9%), the lower extremity (20.7%), and in both upper and lower extremities (10.3%). The pain is located more rarely in the head (16.0%) and in both head and lower extremity in (3.4%). The entire side of the body is affected in around 10%.[290,292]

CPSP Pathophysiology

Although the exact pathophysiology of CPSP is unclear, it is thought to result from imbalance in facilitatory and inhibitory pathways and ectopic activity in damaged neurons induced by the stroke. CPSP is often associated with lesions of the ventrocaudal thalamic nuclei and particularly within the ventroposterior inferior nucleus, suggesting that the pain is associated to thalamus pain pathways. Spinothalamic pathways and cortical processing have also been shown to be associated to CPSP.[293] However, not all patients with spinothalamic pathway damage following stroke develop pain, suggesting that this cannot be the sole pathophysiologic mechanism leading to CPSP.

CPSP Clinical Features of Head/Face

Brainstem lesions induced by lateral medullary infarct may induce pain in the face that is usually unilateral in the periorbital area.[294] The pain quality is most frequently described as burning or hot, aching, pricking, stinging, lacerating, and pressure like.[292] Patients with thalamic stroke frequently describe the quality of pain as lacerating. The pain intensity is moderate to severe that can be exacerbated by light touch, cold, and movement.[294]

According to IHS criteria, symptoms must occur within 6 months of a stroke to be classified as CPSP. The onset is usually within 1 month (range 3–6 months), although a gradual onset of CPSP within 6 years has been reported.[292] The pain is usually constant, around one quarter of CPSP patients reported persistent pain with superimposed attacks and 42% reported paroxysmal pain lasting seconds to minutes.[294]

Motor impairment and a variety of sensory symptoms may occur, depending on the location and extent of the lesion. Constant or evoked dysesthesia is the most common abnormal sensation;[289] however, other symptoms include unilateral pain and/or dysesthesia associated with loss of sensation to pin-prick, temperature, and touch.[292] Thermal sensory impairment has been reported in the majority of CPSP cases and sensory dysfunction that correlates with the presence of pain occurs in over half of cases.[294] About 60% of CPSP patients present with muscle spasticity.

CPSP Management

Antidepressants, such as amitriptyline, as well as anticonvulsants, such as lamotrigine, are effective in CPSP and should be considered first.[293,295,296] Gabapentin is a good second choice drug.[293] Intravenous treatment with lidocaine or propofol may provide short-term pain relief.[293] Poststroke patients may not respond well to tricyclic antidepressants, therefore anticonvulsants may be a better option.[297]

PAIN ASSESSMENT

Pain measurement is an essential element in any medical assessment, including diagnosis, monitoring of disease progress, and evaluation of treatment effectiveness. Unfortunately, there is no one common or easy method of pain measurement. Pain is difficult to measure; it is a personal and private experience that cannot be seen or felt by others. The methods used for pain assessment may include indirect, self-report, physiological, and behavioral methods.

Pain intensity and frequency are probably the most important features measured to assess a patient's wellbeing; however, pain quality, onset, duration, localization, and other additional factors that alleviate or aggravate the pain, occurrence of pain elsewhere in the body, and associated psychosocial problems should be assessed as well.

Drawing the painful area on a body map and a pain diary may provide necessary information. These methods should be standardized and used consistently with each patient.

Pain Scales

The visual analog scale (VAS) is the most frequently used method to assess pain intensity. The scale is usually a horizontal[298,299] or vertical 10 centimeter (cm) line[300] labeled at each end by descriptors such as "no pain" and "worse pain ever." The patient marks the line to indicate pain severity and level is quantified by measuring the distance in cm from zero (no pain) to the patient's marked rating. This method has been validated in a number of studies,[301] but was found to be insufficient in others.[302] A popular variation of the VAS that was designed for children or for patients that do not have the verbal skills to describe their symptoms is the Faces Pain Rating Scale, which is comprised of a series of faces with different expressions in a continuum from a happy face for "no pain" to a very sad face for intense pain.[303,304]

In the Numerical Rating Scale (NRS), patients are asked to rate their pain on a scale from 0 to 10 or 0 to 100, in which "0" is no pain and the other end of the scale represents the worst possible pain.[305] Verbal descriptive scales incorporate specific words organized to express the increasing and progressive intensity of pain. A category scale is a simple form of a verbal scale and in clinical trials is usually composed of four pain descriptions, such as none, mild, moderate, and severe. Simple category scales can be used for rough comparisons or in addition to other pain scales and the number of categories can be increased to achieve greater resolution. Hybrid scales combine verbal scales with graphic rating or with numerical scales; the descriptors are placed in appropriate locations on the analogue scale.[306,307]

There is no simple guide to the choice of pain scale; however, numerical, visual, and verbal scales have been validated in numerous studies and the choice must be specifically established considering the individual patient or research project in question.

Most visual analog, numerical, or verbal pain scales rate pain as a unidimensional experience. More sophisticated questionnaires have been developed that address the multidimensional experience that pain induces.

Pain Questionnaires

The McGill Pain Questionnaire (MPQ)[308] is the most frequently used questionnaire for the multidimensional assessment of pain. The MPQ assesses three separate components of the pain experience: the sensory intensity, the emotional impact, and the cognitive evaluation of pain. Patients are presented with 78 adjectives in 20 groups, or dimensions, and are instructed to select one from each of the groups that most closely matches their own pain experience. An overall score for each major dimension is obtained from the sum of either weighted scores or ranking the chosen words within the group.

The translation of the MPQ to many languages has shown that people from different ethnic and educational backgrounds use similar adjectives to describe the same pain

conditions.[309] The MPQ has been found to be sensitive to pain interventions, and therefore can evaluate treatment efficacy.[310–312] In the orofacial region, the MPQ has been validated in trigeminal neuralgia, atypical odontalgia, toothache, and Burning Mouth Syndrome.[313,314] A short form (MPQ-SF) is available that consists of 15 selected adjectives that patients score on a four-point scale and a VAS that is used for measurement of pain intensity.[315–318]

Other multidimensional questionnaires have also found common psychological patterns for patients in pain, regardless of etiology, location, treatment, and the medical or dental diagnosis.[319,320]

Quantitative Sensory Testing

The term Quantitative Sensory Testing (OST) embraces several methods used to quantify sensory nerve function. QST utilizes noninvasive assessment and quantification of sensory nerve function in patients with suspected neurological damage or disease. The common concepts in QST methods are that the assessment of normal and non-normal responses to various stimuli provides information about the functioning of the peripheral and central nervous system and that these responses can be quantified by the amount of physical stimuli required to evoke specific levels of sensory perception. The response to gross external stimuli has been part of the formal neurological evaluation since the late 19th century. The concept is still valid, and years of research and development of new tools have improved the benefit gained from such tests. External stimuli are usually mechanical and thermal.

QST is an accepted tool for the assessment of diabetic neuropathies[321] and other sensory abnormalities.[322] However, although it is an important tool, currently QST cannot be used alone to diagnose neuropathies.[321]

The establishment of normal QST ranges is complicated by numerous variables including probe or electrode size, stimulus frequency, site, rate of stimulus change, clinical environment, gender, age, and ethnicity. A significant attempt for QST standardization was made by The German Research Network on Neuropathic Pain.[323] Systematic sequences of thermal and mechanical QST were employed on patients suffering from various neuropathic pain conditions. The findings were categorized as gain or loss of sensation. Ninety two percent of the patients presented at least one sensory abnormality and a sensory profile was suggested for each neurological syndrome. However, combinations of gain and loss sensations were found to exist across the syndromes.

The use of QST in the trigeminal system or other orofacial areas requires further research before being used in routine clinical practice; however, the field is sufficiently developed to aid diagnosis and the evaluation of treatment.[123]

Dynamic Pain Psychophysical Testing

A growing body of evidence suggests that the use of a new generation of "dynamic" pain psychophysical testing can be used to evaluate pain modulation processes. The dynamic testing relies on the fact that pain perception is transmitted from the periphery to the CNS, and then modulated in the CNS before its arrival in the cortex. Similar external stimuli may be perceived differently among individuals, depending on their modulation processes. Two modulation components are routinely tested in the lab; Temporal Summation (TS), which is thought to be the psychophysical correlate of second/third order neuron wind-up, probably reflecting central sensitization, and Central Pain Modulation (CPM), which is thought to measure endogenous pain inhibition. TS is associated with excessive activation of N-methyl-D-aspartate (NMDA) receptors in response to extensive nociceptive input. The clinical manifestation may be allodynia and hyperalgesia.[324–326] TS is tested by application of identical repetitive stimuli, an increase in pain scores is documented along or in the end of the stimuli. CPM represents the endogenous analgesia system, where descending pathways induce modulatory effects on incoming painful stimuli.[327] CPM is tested by using two remote noxious stimuli with one, the "conditioning" pain inhibiting the other, the "test" pain. In recent years, many reports used both TS and CPM to demonstrate altered pain modulation in chronic pain patients. Enhanced TS was found in chronic pain patients such as fibromyalgia,[328–331] tension headache and musculoskeletal pain,[332,333] migraine,[334] chronic low back pain,[335] and Temporomandibular Disorders (TMD).[336–340] Similarly, less-efficient CPM response was found in many of the idiopathic pain syndromes such as TMD,[341] fibromyalgia,[331,342–344], tension headache,[345] BMS,[274] and Irritable Bowel Syndrome.[346] Among healthy subjects, reduced pain-modulatory capacity was demonstrated in older subjects[347] and among females compared to males.[348] A combination of reduced CPM and enhanced TS was found among patients with chronic postendodontic treatment pain.[77]

It has been suggested that the pain modulatory system can define susceptibility to the development of chronic pain disorders.[349–352] Patients who presented an altered pain modulation were found to be more prone to develop postoperative (thoracotomy) chronic pain.[141] Moreover, recent studies have shown that painful diabetic neuropathy patients with less efficient CPM benefit more from treatment with duloxetine,[353] which has the potential to enhance the descending pain inhibition by inhibiting reuptake of spinal noradrenalin (NA) and serotonin.[353–355]

	PTTN[1]	BMS[2]	PIFP[3]
Epidemiology	0.3–36% depending on the cause	0.7–15%	0.03% lifetime prevalence 4.4/100,000 person years incidence rate
Pathophysiology	Trauma, implants, mandibular third molar extraction, root canal therapy, local injection	Neuropathic pain state; hormonal and psychosocial factors implicated; altered salivary composition, epithelial changes in the tongue, reduced innervation	Neuropathic pain syndrome; trauma
Pain Quality	Burning, shooting, severe throbbing; continuous; unilateral	Burning or hot; spontaneous onset; chronic unremitting pattern	Aching, burning, throbbing, stubbing; deep, poorly localized, radiating, mostly unilateral
Pain Severity	Moderate to severe (VAS: 5–8)	Mild to moderate (VAS: 3–7)	Mild to severe (VAS: 7–8)
Diagnostic criteria[4]	A. Facial and/or oral pain in the distribution(s) of one or both trigeminal nerve(s) and fulfilling criterion C B. History of an identifiable traumatic event to the trigeminal nerve(s), with clinically evident positive (hyperalgesia, allodynia) and/or negative (hypoesthesia, hypoalgesia) signs of trigeminal neve dysfunction C. Evidence of causation demonstrated by both of the following 1. Pain is localized to the distribution(s) of the trigeminal nerve(s) affected by the traumatic event 2. Pain has developed < 6 months after the traumatic event D. Not better accounted for by another ICHD-3 diagnosis	A. Oral pain fulfilling criteria B and C B. Recurring daily for > 2 hrs. per day for > 3 months C. Pain has both of the following characteristics: 1. Burning quality 2. Felt superficially in the oral mucosa D. Oral mucosa is of normal appearance and clinical examination including sensory testing is normal E. Not better accounted for by another ICHD-3 diagnosis	F. Facial and/or oral pain fulfilling criteria B and C G. Recurring daily for > 2 hrs. per day for >3 months H. Pain has both of the following characteristics 1. Poorly localized, and not following the distribution of a peripheral nerve 2. Dull, aching or nagging quality I. Clinical neurological examination in normal J. A dental cause has been excluded by appropriate investigations K. Not better accounted for by another ICHD-3 diagnosis
